PREFACE

I AM greatly indebted to my friends and colleagues—Dr. A. Scott, Mr. H. V. Thompson, M.A., Mr. A. T. Green, F.Inst.P., Mr. A. Rigby, Mr. L. S. Theobald, B.Sc., Mr. F. H. Clews, M.Sc., and Mr. A. J. Dale, B.Sc., for help and suggestions in the proof-reading of Vols. VII, VIII, and IX; Mr. P. Roche and Miss Schoett, for help with the references; and Misses Till, Littler, and Stubbs, for help with the typing, indexing, etc.

J. W. M.

CONTENTS

CHAPTER LI

ARSENIC

- § 1. The History of Arsenic (1); § 2. The Occurrence of Arsenic (3); § 3. The Extraction of Arsenic (13); § 4. The Allotropic Forms of Arsenic (16); § 5. The Physical Properties of Arsenic (20); § 6. The Chemical Properties of Arsenic (32); § 7. The Physiological Action of Arsenic (42); § 8. The Atomic Weight and Valency of Arsenic (47); § 9. Hydrogen Arsenide, or Arsenic Hydride (48); § 10. The Arsenides (61); § 11. Arsenic Suboxide, and Trioxide (90); § 12. The Arsenites (116); § 13. Arsenic Tetroxide; Arsenosic Oxide (136); § 14. Arsenic Pentoxide; Arsenic Acid (137); § 15. The Ammonium and Alkali Arsenates (149); § 16. The Arsenates of the Copper-Gold Family (157); § 17. The Arsenates of the Calcium Family (166); § 18. The Arsenates of the Beryllium-Mercury Family (175); § 19. The Arsenates of the Aluminium Family (185); § 20. The Arsenates of the Titanium and Tin Families (188); § 21. The Arsenates of the Antimony-Vanadium Family (197); § 22. The Arsenates of the Sulphur-Chromium Family (203); § 23. The Arsenates of the Manganese and Iron Families (217); § 24. The Arsenates of the Platinum Family (234); § 25. The Fluorides of Arsenic (235); § 26. The Chlorides of Arsenic (237); § 27. The Bromides of Arsenic (247); § 28. The Iodides of Arsenic (250); § 29. The Halogen Compounds of the Arsenites and Arsenates (255); § 30. The Sulphides of Arsenic—The Disulphide (265); § 31. Arsenic Trisulphide (272); § 32. The Complex Salts of Arsenic Trisulphide—The Sulpharsenites (289); § 33. The Sulphoarsenides, Sulpharsenides, or Arsenosulphides (305); § 34. Arsenic Pentasulphide (313); § 35. The Complex Salts of Arsenic Pentasulphide—The Sulpharsenates (315); § 36. The Oxysulpharsenites and Oxysulpharsenates (325); § 37. Arsenic Sulphates (332); § 38. The Arsenic Sulphohalides, or Halogenosulphides (335); § 39. Arsenic Carbonates, Nitrates, and Phosphates (337).

CHAPTER LII

ANTIMONY

- § 1. The History of Antimony (339); § 2. The Occurrence of Antimony (342); § 3. The Extraction of Antimony (349); § 4. The Allotropic Forms of Antimony (357); § 5. The Physical Properties of Antimony (363); § 6. The Chemical Properties of Antimony (378); § 7. The Atomic Weight of Antimony (388); § 8. The Antimony Hydrides (390); § 9. The Antimonides (401); § 10. Antimonious Oxide, or Antimony Trioxide (420); § 11. The Antimonious Acids, and the Antimonites (428); § 12. Antimony Tetroxide, and the Hypoantimonates (434); § 13. Antimony Pentoxide and the Antimonic Acids (439); § 14. The Antimonates (446); § 15. Antimony Trifluoride (463); § 16. The Higher Antimony Fluorides (466); § 17. Antimony Trichloride (469); § 18. The Higher Antimony Chlorides (484); § 19. The Antimony Bromides (493); § 20. The Antimony Iodides (498); § 21. The Antimony Oxyhalides (503); § 22. The Mixed Antimony Halides (509); § 23. The Antimony

Sulphides (512); § 24. The Sulphoantimonites (532); § 25. The Higher Sulphides of Antimony (564); § 26. The Sulphoantimonates (569); § 27. Antimony Oxysulphides (576); § 28. The Antimony Sulphates (580); § 29. Antimony Sulphohalides or Halogenosulphides (583); § 30. Antimony Nitrates and Phosphates (585).

CHAPTER LIII

BISMUTH

§ 1. The History of Bismuth (587); § 2. The Occurrence of Bismuth (588); § 3. The Extraction of Bismuth (593); § 4. The Physical Properties of Bismuth (600); § 5. The Chemical Properties of Bismuth (624); § 6. The Atomic Weight and Valency of Bismuth (632); § 7. The Bismuthides (634); § 8. Bismuth Monoxide, and Trioxide (643); § 9. The Higher Oxides of Bismuth (653); § 10. The Bismuth Fluorides (659); § 11. The Bismuth Chlorides (660); § 12. The Bismuth Bromides (670); § 13. The Bismuth Iodides (674); § 14. The Oxyhalides of Bismuth (678); § 15. The Bismuth Sulphides (682); § 16. Complex Bismuth Sulphides; Sulphobismuthites (689); § 17. The Bismuth Sulphates, and Oxysulphides (698); § 18. The Bismuth Halogenosulphides, or Sulphohalides (702); § 19. The Bismuth Carbonates (703); § 20. The Bismuth Nitrates (705); § 21. The Bismuth Phosphates (711).

CHAPTER LIV

VANADIUM

§ 1. The History of Vanadium (714); § 2. The Occurrence of Vanadium (715); § 3. The Extraction of Vanadium (722); § 4. The Properties of Vanadium (728); § 5. The Atomic Weight and Valency of Vanadium (737); § 6. Vanadium Hemioxide, Dioxide, and Trioxide (739); § 7. Vanadium Tetroxide and the Hypovanadates (743); § 8. Vanadium Pentoxide (748); § 9. The Vanadates of Ammonium and the Alkalies (757); § 10. The Vanadates of the Copper Family (766); § 11. The Vanadates of the Alkaline Earths (768); § 12. The Vanadates of the Magnesium Family (772); § 13. The Vanadates of the Aluminium and Lead Families (775); § 14. The Vanadates of the Bismuth and Chromium Families (779); § 15. The Vanadates of the Manganese and Iron Families (790); § 16. The Hypovanadatovanadates (792); § 17. Pervanadic Acid and the Pervanadates (794); § 18. The Vanadium Fluorides and Oxyfluorides (796); § 19. The Vanadium Chlorides and Oxychlorides (803); § 20. The Vanadium Bromides (812); § 21. The Vanadium Iodides (813); § 22. The Vanadium Sulphides and Oxysulphides (814); § 23. The Vanadium Sulphates (818); § 24. The Vanadium Carbonates, Nitrates, and Phosphates (825).

CHAPTER LV

COLUMBIUM

§ 1. The History of Columbium and Tantalum (837); § 2. The Occurrence of Columbium and Tantalum (838); § 3. The Extraction of Columbium and Tantalum Oxides (840); § 4. Columbium (846); § 5. Columbium Hydrides (855); § 6. The Lower Oxides of Columbium (856); § 7. Columbium Pentoxide, and Columbic Acid (857); § 8. Columbates or Niobates (862); § 9. Percolumbic Oxide and the Percolumbates (869); § 10. Columbium Fluoride and Oxyfluorides (870); § 11. The Columbium Chlorides and Oxychlorides (875); § 12. The Columbium Bromides, Iodides, and Oxybromides (880); § 13. Columbium Sulphide, Oxysulphide, and Sulphates (880); § 14. Columbium Carbonate, Nitrate, and Phosphate (882).

CHAPTER LVI

TANTALUM

- § 1. The Preparation of Tantalum (883); § 2. The Physical Properties of Tantalum (884); § 3. The Chemical Properties of Tantalum (890); § 4. Tantalum Hydride (895); § 5. The Lower Tantalum Oxides (895); § 6. Tantalum Pentoxide and Tantallic Acid (896); § 7. The Tantalates (900); § 8. Pertantallic Acid and the Pertantalates (913); § 9. The Tantalum Fluorides, Fluotantalates, and Oxyfluotantalates (914); § 10. The Tantalum Chlorides and Oxychlorides (919); § 11. The Tantalum Bromides and Oxybromides (922); § 12. The Tantalum Iodides and Oxyiodides (923); § 13. The Tantalum Sulphides and Sulphates (924).

In the **cross references** the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus 5. 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances *A*, *B*, and *C*, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the

ABBREVIATIONS

triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle, ternary mixtures. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the

FIG. 1.

FIG. 2.

FIG. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER LI

ARSENIC

§ 1. The History of Arsenic

T. BERGMAN,¹ in his *De arsenico* (Upsala, 1777), said that it is probable that arsenic was first discovered by those who wrought in the roasting and fusing of ores, for it would betray itself by its white smoke, its garlic smell, and its pernicious effects in depraving metals, and destroying life. In the fourth century B.C., arsenic sulphide was designated *σανδαράκη*, *sandarach*, by Aristotle, in his *Μηχανικά Προβλήματα* (33. 2); *ἀρρηνικόν*, *arrhenicum*, by Theophrastus in his *Περὶ Λίθων*; and in the first century of our era, Dioscorides, in his *Περὶ Ὑγῆς Ἱατρικῆς* (5. 10), called the mineral sulphide *ἀρσενικόν*, *arsenicon*. In the first century of our era, Pliny, in his *Historia naturalis* (33. 22; and 34. 55 and 56), said :

Sandarach is found in gold and silver mines. The redder it is, the more powerful its odour, the better its quality. . . . *Arsenicum* is composed of the same matter as *sandarach*; the best in quality has the same colour as that of the best gold, and that which is pale in colour resembling *sandarach* is of inferior quality.

Pliny also confused white arsenic with ceruse; and the context of the Olympiodorus references to the preparation of alum shows that white arsenic was meant. Pliny also seems to have confused red-lead with realgar. The yellow *auripigmentum*, or orpiment of Pliny is the yellow arsenic sulphide; M. P. Vitruvius, in his *De architectura* (7. 7), added that *auripigmentum* is a mineral called by the Greeks *arsenicum*. The *sandarach* of these early writers was probably the mineral now known as *realgar*, AsS; and *arsenicum* and *auripigmentum*, the mineral *orpiment*, As₂S₃. The observations of Aristotle, and many early references to arsenic, were discussed by E. O. von Lippmann. J. H. Pott wrote on the orpiment, and J. G. Lehmann, on the *sandarach* of the ancients. The term *arsenic* is derived from the Greek *ἀρσενικός* = *ἀρρηνικός*, meaning valiant or bold, in allusion, said R. J. Haiy, to the great energy with which it acts on other metals. F. von Kobell said the Greek term was derived from the Arabian *arsa naki*; S. Fraenkel, however, said that this term does not occur in the Arabian language; rather was the Greek term derived from the Persian word for arsenic, *zarnich*, *zirnuk*, or *zirne*.

It is rather surprising that these early writers—Dioscorides, Pliny, A. C. Celsus,² and C. Galen—should mention several medicinal qualities of arsenical preparations, but did not mention the toxic properties of white arsenic—*i.e.* arsenic trioxide. They must have had an impure form of this oxide since Pliny said that in order to increase the energy of arsenicum, it was heated in a new earthen vessel until it changed its colour; and Dioscorides said that *sandarach* was mixed with carbon and calcined until it changed its colour.

The thirteenth-century Latin translation of Geber's *Summa perfectionis magisterii* shows that *arsenicum album* or white arsenic was obtained as a sublimate from arsenicum. He said that the product which has been sublimed cannot be inflamed like the impure raw arsenicum, because, when heated, it merely sublimes without inflammation. According to T. Bergman's *De arsenico* (Upsala, 1777), the eleventh-century Arabian writer Avicenna said that there are three forms of *arsenicum*—white,

yellow, and red—and that the white is obtained from the other forms by sublimation. He also mentioned the poisonous properties of white arsenic. In the *Breve breviarium de dono Dei* attributed to Roger Bacon, of the thirteenth century, it is stated that white arsenic is prepared by calcining orpiment with iron scales. The iron would have taken the sulphur, and the arsenic vap. set free would be oxidized to white arsenic. Both Geber, and Avicenna recognized that *arsenicum* has many of the properties of sulphur; and A. Libavius, in his *Commentationum metallicarum* (Francofurti, 1597), said:

Arsenicum is a rich, inflammable mineral juice which is akin to sulphur, yet more virulent because of the salt combined with it; it is composed of a sulphurous richness with a little mercury and spirit of salt.

Somewhat similar views were held by N. Lemery,³ J. Kunckel, and N. Sokoloff. J. J. Becher regarded *arsenicum* as a combination of *terra sulphuris*, common salt, and a metal; and C. Neumann said that it contains an acid of sulphur. According to M. Berthelot, metallic arsenic is first mentioned in a fragmental writing attributed to Zosimos of the third or fourth century; and the preparation of white arsenic is described by Olympiodorus, a writer of the fifth century. Geber, in his *De fornacibus*, supposed that arsenicum contains a metal; and Albertus Magnus, in his thirteenth-century work *De alchymia*, said that arsenicum becomes metallic when heated with twice its weight of soap. Basil Valentine called *arsenicum metallinum* a bastard metal; and in the seventeenth century N. Lemery obtained reguline arsenic—metallic arsenic—by heating white arsenic with potash and soap; and it was also made by J. Schröder, and J. F. Henkel. G. Brandt said that reguline arsenic must be regarded as a semimetal, and white arsenic, as the calx of reguline arsenic. This was supported by the work of J. Browall, and A. G. Monnet. In modern language, this means white arsenic is an oxide of the metal arsenic. The history of the different combinations of arsenic is indicated in connection with the individual compounds. The stoichiometrical relations of arsenic with other elements were worked out by J. J. Berzelius in 1817. In the Middle Ages, arsenic received various names—*Scherbenkobold*, *Näpchenkobold*, *Goblet-fiend*, *Bowl-sprite*, *Cobaltum*, etc. M. Muccioli discussed the history of arsenic in ancient China.

F. B. Fittica⁴ stated that arsenic is not an element, but rather a compound of phosphorus, nitrogen, and oxygen, PN_2O ; but C. Winkler, A. C. Christomanos, C. R. Gyzander, and E. Noelting and W. Feuerstein showed that F. B. Fittica erred grievously in his speculation

§ 2. The Occurrence of Arsenic

Arsenic is ubiquitous. Every particle of coal dust or ashes, every tin-tack and every metal cooking vessel, is slightly arsenical. Few manufactured food materials or food ingredients are entirely free from it. The glass of white bottles contains it and gives it up to some of the substances stored in them, whence it also enters into food. The Royal Commission on Arsenical Poisoning, recognizing this ubiquity, limited the permissible quantity to $\frac{1}{100}$ th grain per pound in solid and $\frac{1}{100}$ th grain per gallon in liquid foods.—ANON.

Arsenic occurs very widely diffused in nature, and traces of it are common in most organic matter. Traces of the element are common in natural waters. F. W. Clarke and H. S. Washington¹ estimate that the igneous rocks of the earth contain $n \times 10^{-6}$ per cent. of this element; and J. H. L. Vogt, $n \times 10^{-5}$ per cent. F. W. Clarke and G. Steiger found 0.00074 per cent. As_2O_5 to be present in a composite sample of 329 rocks from the United States. W. Vernadsky gave 0.04, 11 for the percentage amount, and 0.045 for the atomic proportion of arsenic in the earth's crust. H. A. Rowland,² and M. N. Saha reported no arsenic lines in the solar spectrum; but arsenic has been reported in a number of meteorites by A. Daubrée, C. Rumler, N. W. Fischer and A. Duflos, B. Silliman and F. S. Hunt, J. A. Antipoff, and L. H. Borgström.

Elemental arsenic occurs in veins in crystalline rocks and schists, and it commonly accompanies ores of antimony, silver, arsenic, zinc, and other metal sulphides. J. B. L. Romé de l'Isle³ agreed that the *Scherbenkobalt* of the German miners, mentioned by J. H. G. Justi, and the *Cobatum testaceum*, mentioned by R. A. Vogel, are forms of arsenic. L. A. Emmerling referred to the synonyms—*Fliegelkobelt*, *Fliegelstein*, *Fliegengift*, *Näpfchenkobelt*, *Löffelkobelt*, and *Schirrkobelt*—for the mineral arsenic. The crystals were described by A. Breithaupt. The arsenic occurring near Marienberg, Saxony, was at first supposed to be galena. J. C. Freiesleben regarded it as molybdenite, and A. Breithaupt, as arsenic glance; but C. M. Kersten showed that it contained scarcely a trace of sulphur, and A. Breithaupt thereupon called it bismuthiferous arsenic glance, and *hypotyphite*—from *ὑποτύφωμαι*, to glow or burn slowly—in allusion to its behaviour when heated. F. von Kobell supposed bismuth to be the chief impurity. A. Frenzel showed that arsenic is the chief constituent, and he regarded the mineral as *eine besondere Modification* of arsenic. The following analysis of native arsenic from Joachimstahl is by J. V. Janowsky; from Marienberg, by A. Frenzel; from Montreal, by N. Norton; from Ophir (California), by F. A. Genth; and from Saltash (Cornwall), by A. Russell and H. F. Harwood:

Origin.	As	Sb	Bi	Fe	Ni	S	SiO ₂
Joachimstahl .	90.91	1.56	—	2.07	4.64	—	0.55
Marienberg .	95.86	—	1.61	1.01	—	0.99	—
Montreal .	98.14	1.65	—	—	—	0.16	0.15
Ophir .	90.82	9.18	—	—	—	—	—
Cornwall .	94.80	5.15	—	0.15	—	0.11	0.10

C. Hintze found a Chilean mineral closely resembling that from Saxony, and he called it *arsenolamprite*—from *λαμπρός*, lustrous—J. W. Retgers regarded arsenolamprite as a distinct mineral species; and analyses—ranging from 95.86 to 98.43 per cent. As, up to 3.0 per cent. Bi, up to 1.01 per cent. of S, and up to 0.55 per cent. SiO₂—were published by C. Hintze, C. M. Kersten, and A. Frenzel.

The occurrence of elemental arsenic in Germany was described by A. Madelung,⁴ C. Hintze, G. Leonhard, L. A. Emmerling, F. Sandberger, O. Luedecke, J. C. L. Zincken, E. Reidemeister, A. Frenzel, J. F. John, M. Websky, H. Traube, V. R. von Zepharovich, A. E. Reuss, A. Eschka, and F. Babanek; in Austria-Hungary, by V. R. von Zepharovich, A. Frenzel, G. Benkő, G. Rose, C. F. Peters, E. Hatle, A. Höfer, J. V. Janowsky, and

E. Fugger; in Italy, by G. Jervis, and D. Bizzarri and G. Campani; in Spain, by A. Orío; in England, by H. Dewey, A. Russell and H. F. Harwood, and R. P. Greg and W. G. Lettsom; in Norway, by G. Leonhard, C. Bugge and S. Foslie, and A. Erdmann; in Russia, by P. N. Tschirwinsky; in Siberia, by J. D. Dana, and G. Leonhard; in Japan, by R. Scheibe, and A. Frenzel; in Australasia, by A. Liversidge, and J. D. Dana; in Chili and Peru, by I. Domeyko, and A. Raimondi; in Mexico, by C. F. de Landero, and A. del Castillo and M. Barcena; in Colorado, by C. Hersey; in New Hampshire, by G. Leonhard; in Maine, by J. D. Dana; in Arizona, by C. H. Warren; and in Canada, by G. C. Hoffmann, W. Gatt, M. E. Hurst, and N. N. Evans.

The world's production of arsenic—including the oxide and sulphide—in 1896 was 3674 metric tons for the United Kingdom; 2632 metric tons for Germany; 320 for Italy; 6 for Japan; and 271 for Spain, in 1907, 1913, and 1921. In 1926 there were 48 metric tons of white arsenic produced in Southern Rhodesia; 38, in the Union of South Africa; 1220, in Australia; 1000, in Greece; and 6354, in Mexico. The results, in metric tons, so far as they are available, are:

	Canada.	Germany.	Italy.	Japan.	Portugal.	Spain.	United Kingdom.	United States.	France (ore).
1907 .	317	2904	73	7	1538	2400	1523	916	7,900

1926 .	1779	—	136	—	—	—	3207	10,540	49,100

The chief minerals containing arsenic are the two sulphides, numerous arsenides, sulpharsenides, and arsenates of the heavy metals. Arsenopyrite or mispickel is perhaps the commonest mineral containing this element. The trioxide also occurs as the minerals *arsenolite*, and *claudetite*. The arsenical minerals include:

Arsenides.—*Algodonite*, Cu_3As ; *arsenargenite*, or *humtilité*, Ag_3As ; *arsenical copper*, or *domeykite*, Cu_2As ; *chloanthite*, or *white nickel ore*, NiAs_2 , or, $(\text{Ni}, \text{Co}, \text{Fe})\text{As}_2$; *humtilité* (see arsenargenite); *leucopyrite*, Fe_3As_4 ; *löllingite*, FeAs_2 ; *niccolite*, *nickeline*, or *red nickel ore*, NiAs ; *nickeline* (see niccolite); *rammelsbergite*, $(\text{Ni}, \text{Co}, \text{Fe})\text{As}_2$; *red nickel ore* (see niccolite); *safflorite*, $(\text{Co}, \text{Fe}, \text{Ni})\text{As}_2$; *skutterudite*, CoAs_2 ; *smaltite*, CoAs_2 ; *speiss cobalt*, $(\text{Co}, \text{Fe}, \text{Ni})\text{As}_2$; *white nickel ore* (see chloanthite); *whitneyite*, Cu_3As . **Mixed arsenides and antimonides.**—*Arite*, $\text{Ni}(\text{As}, \text{Sb})$, and *sperryllite*, $(\text{Pt}, \text{Rh})(\text{As}, \text{Sb})_2$. **Sulphides.**—*Orpiment*, As_2S_3 ; and *realgar*, AsS . **Mixed arsenides and sulphides.**—*Alloclasite* $(\text{Co}, \text{Fe})\text{S}(\text{As}, \text{Bi})$; *annivite* (see fahlerz); *arsenical nickel*, $(\text{Ni}, \text{Fe})\text{AsS}$; *arsenopyrites* (see mispickel); *baumhauerite*, $\text{Pb}_4\text{As}_8\text{S}_{13}$; *binnite*, $\text{Cu}_6\text{As}_4\text{S}_9$; *clarite* (see enargite); *cobalt glance*, $(\text{Co}, \text{Fe})\text{AsS}$; *cobaltite*, CoAsS ; *corynite*, $(\text{Ni}, \text{Fe})(\text{As}, \text{Sb})\text{S}$; *danaite*, or *glaucondote*, $(\text{Fe}, \text{Co})(\text{AsS})$; *dufrenoyosite*, $\text{Pb}_2\text{As}_2\text{S}_5$; *enargite*, *clarite*, and *huzonite*, Cu_3AsS_4 ; *epigenite*, or *regnolite*, $\text{Cu}_5\text{Fe}_3\text{As}_2\text{S}_{12}$; *fahlerz*, *tetraedrite*, *annivite*, *sandbergerite*, and *julianite*, $(\text{As}, \text{Sb})_2\text{S}_7(\text{Cu}_2, \text{Ag}_2, \text{Fe}, \text{Zn})_4$; *gersdorffite*, NiAs ; *glaucondote* (see danaite); *guitermanite*, $\text{Pb}_2\text{As}_2\text{S}_7$; *hermesite* (see mercury fahlerz); *hutchinsonite*, $(\text{Ti}, \text{Ag})\text{Pb}(\text{AsS})_4$; *jordanite*, $\text{Pb}_4\text{As}_2\text{S}_7$; *julianite* (see fahlerz); *lengenbachite*, $\text{Pb}_4(\text{Ag}, \text{Cu})_2\text{As}_4\text{S}_{13}$; *light red silver ore* (see proustite); *liveingite*, $\text{Pb}_2\text{As}_2\text{S}_{17}$; *lorandite*, TiAsS_2 ; *mercury fahlerz*, *schwarzite*, or *hermesite*, $(\text{Sb}, \text{As})_2\text{S}_7(\text{Cu}_2, \text{Hg}_2, \text{Fe}, \text{Zn})_4$; *hermesite* (see mercury fahlerz); *mispickel*, or *arsenopyrites*, FeAsS ; *pearceite*, $(\text{Ag}, \text{Cu})_{16}(\text{Sb}, \text{As})_2\text{S}_{11}$; *polybasite*, $(\text{Sb}, \text{As})_2\text{S}_{12}(\text{Ag}, \text{Cu})_{18}$; *proustite*, or *light red silver ore*, Ag_3AsS_3 ; *rathite*, $\text{Pb}_3\text{As}_4\text{S}_9$; *regnolite* (see epigenite); *sandbergerite* (see fahlerz); *sartorite*, $\text{Pb}(\text{AsS})_2$; *scleroclase*, PbAs_2S_4 ; *schwatzite* (see mercury fahlerz); *seligmannite*, PbCuAsS_2 ; *tennantite*, $\text{Cu}_3\text{As}_2\text{S}_7$; *tetraedrite* (see fahlerz); *wolfachite*, $(\text{Ni}, \text{Fe})(\text{As}, \text{S}, \text{Sb})_2$; *xanthoconite*, Ag_3AsS_4 .

Arsenites and arsenates.—*Adamite*, $\text{Zn}(\text{OH})\text{AsO}_4$; *allactite*, $\text{Mn}_2\text{Mn}(\text{OH})_{24}(\text{AsO}_4)_2$; *anabergite* (see nickel bloom); *ardennite*, $10\text{SiO}_2(\text{As}, \text{V}, \text{P})_2\text{O}_6 \cdot 5(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 10(\text{Mn}, \text{Mg}, \text{Ca}, \text{Cu})\text{O} \cdot 6\text{H}_2\text{O}$; *armangite*, $\text{Mn}(\text{AsO}_3)_2$; *arseniopleite*, $(\text{MnFe})_2(\text{Mn}, \text{Ca}, \text{Pb}, \text{Mg})_3(\text{MnOH})_6(\text{AsO}_4)_6$; *arseniosiderite*, $\text{Fe}_2\text{Ca}_2(\text{OH})_2(\text{AsO}_4)_3$; *atelestite*, $(\text{BiO})_2\text{Bi}(\text{OH})_2\text{AsO}_4$; *bayldonite*, $(\text{Pb}, \text{Cu})_2(\text{OH})\text{AsO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$; *berzelite*, $(\text{Ca}, \text{Mg}, \text{Mn}, \text{Na}_2)_3(\text{AsO}_4)_2$; *beudantite*, $(\text{Cu}, \text{Pb})_2\text{Fe}_2\text{O}_5(\text{SO}_3)(\text{P}, \text{As})_2\text{O}_5 \cdot \text{H}_2\text{O}$; *brandtite*, $\text{Mn}, \text{Ca}_2(\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$; *cabrerite*, $(\text{Ni}, \text{Mg}, \text{Co})_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$; *campylite*, $\text{Pb}_2\text{Cl}(\text{As}, \text{P})\text{O}_{13}$; *carmine spar* (see carminite); *carminite*, or *carmine spar*, $\text{Fe}_{10}\text{Pb}_3(\text{AsO}_4)_{12}$; *carynite*, $(\text{Mn}, \text{Ca}, \text{Pb}, \text{Mg})_3(\text{AsO}_4)_3$; *chalcophyllite* (see copper mica); *enevixite* (see henwoodite); *chlorotile*, $(\text{CuOH})_3\text{Cu}(\text{OH})_2\text{AsO}_4$; *chondrarsenite*, $(\text{Mn}, \text{Ca}, \text{Mg})(\text{MnOH})_4(\text{AsO}_4)_2 \cdot \frac{1}{2}\text{H}_2\text{O}$; *clinoclasite*, $(\text{CuOH})_3\text{AsO}_4$; *cobalt bloom*, or *erythrite*, $\text{Co}_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$; *conicalcrite*, $(\text{Cu}, \text{Ca})(\text{CuOH})(\text{As}, \text{P}, \text{V})\text{O}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$; *copper mica*, or *chalcophyllite*, $(\text{CuOH})_5\text{AsO}_4 \cdot 3\frac{1}{2}\text{H}_2\text{O}$; *cornwallite*, $\text{Cu}(\text{CuOH})_4(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$; *cube ore*, or *pharmacosiderite*, $\text{Fe}(\text{FeOH})_3(\text{AsO}_4)_3 \cdot 6\text{H}_2\text{O}$; *diadelphite* (see hæmatolite); *discentite*, $(\text{HOMn})_2\text{Mn}_3\text{SiO}_5(\text{AsO}_3)_2$; *dixenite*, $\text{Mn}_3(\text{AsO}_3)_2 \cdot \text{MnSiO}_3 \cdot \text{Mn}(\text{OH})_2$; *duftite*, $\text{Pb}_5(\text{PbOH})(\text{CuOH})(\text{AsO}_4)_6$; *durangite*, $\text{Na}(\text{Al}, \text{F})\text{AsO}_4$; *ecdemite*, $\text{Pb}_2\text{As}_2\text{O}_{15}\text{Cl}_8$; *endlichite*, $\text{Pb}_2\text{Cl}(\text{As}, \text{V})\text{O}_{13}$; *erinite*, $\text{Cu}(\text{CuOH})_4(\text{AsO}_4)_2$; *erythrite* (see cobalt bloom); *euchroite*, $\text{Cu}(\text{CuOH})\text{AsO}_4 \cdot 3\text{H}_2\text{O}$; *fermorite*,

(Cu,Sr)₃(F,OH)(P,AsO₄)₃; *finnemanite*, Pb₃(AsO₃)₂.PbCl; *flinkite*, Mn{Mn(OH)₂}₂AsO₄; *forbesite*, (Ni,Co)H.AsO₄.3½H₂O; *georgiadesite*, Pb₅Cl₄(AsO₄)₂; *haemafribrite*, (MnOH)₃AsO₄.H₂O; *haematolite*, or *diadelphite*, (Mn,Al){Mn(OH)₂}₄AsO₄; *haidingerite*, CaHAsO₄.H₂O; *hedyphane*, (Pb,Ca,Ba)₂Cl(AsO₄)₃; *henwoodite*, or *chenevixite*, (FeO)₂Cu₃(AsO₄)₂.3H₂O; *higginsite*, Ca(CuOH)AsO₄; *haernesite*, Mg₃(AsO₄)₂.8H₂O; *keottigite*, (Zn,Co,Ni)₃(AsO₄)₂.8H₂O; *lavendulite*, Cu₃(AsO₄)₂.2H₂O; *leucochalcite*, Cu₂(OH)AsO₄.H₂O; *lindackerite*, Ni₃Cu₆(OH)₄(AsO₄)₄(SO₄)₅.5H₂O; *liroconite*, Al₄Cu₆(OH)₁₅(AsO₄)₅.20H₂O; *liskeardite*, (Al,Fe)₂(OH)₆AsO₄.5H₂O; *manganostibite*, Mn₂(Mn₂O₇)(Sb,As)O₄; *mazapilite*, Fe₄(OH)₆-Ca₂(AsO₄)₄.3H₂O; *mimetesite*, Pb₂Cl(AsO₄)₃; *mixite*, BiCu₁₀(OH)₈(AsO₄)₅.7H₂O; *nickel bloom*, or *annabergite*, Ni₃(AsO₄)₂.8H₂O; *olivenite*, Cu(CuOH)AsO₄; *pharmacolite*, CaHAsO₄.2H₂O; *pharmacosiderite* (see cube ore); *picroparmacolite*, (Ca,Mg)₃(AsO₄)₂.8H₂O; *piticitite*, Fe₂₀(OH)₂₄(As,P)O₄₁₀(SO₄)₃.9H₂O; *polyarsenite* (see sarkinite); *rhagite*, Bi(BiO)₉(AsO₄)₄.8H₂O; *roesslerite*, MgHAsO₄.½H₂O; *roselite*, (Ca,Co,Mg)₃(AsO₄)₂.2H₂O; *sarkinite*, or *polyarsenite*, Mn(MnOH)AsO₄; *scorodite*, FeAsO₄.2H₂O; *svavite*, Cu₅(F,OH,Cl)(AsO₄)₃; *symplesite*, Fe₃(AsO₄)₂.8H₂O; *synadelphite*, (Mn,Al){Mn(OH)₂}₁₅(AsO₄)₂; *tilasite*, Ca(MgF)AsO₄; *trichalcite*, Cu₃(AsO₄)₂.5H₂O; *trigonite*, MnHAsO₃.Pb₃(AsO₃)₂; *trippkeite*, nCu.O.As₂O₃; *trogerite*, (UO₂)₃(AsO₄)₂.12H₂O; *tyrolite*, Cu(CuOH)₄(AsO₄)₂.3½H₂O; *uranospinite*, Ca(UO₂)₂(AsO₄)₂.8H₂O; *veszelyite*, {(Cu,Zn)OH}₂{Cu(OH)₂}(As,P)O₄₂.6H₂O; *walpurkite*, Bi₁₀(UO₂)₃(AsO₄)₇.10H₂O; *wapplerite*, (Ca,Mg)HAsO₄.3½H₂O.

Small proportions of arsenic contaminate numerous minerals and earths. Most volcanic sulphur contains a small proportion of arsenic. T. L. Phipson⁵ found 11·16 per cent. of arsenic sulphide in sulphur from the solfatara of Naples; and F. Rinne, 29·22 per cent. of arsenic in the sulphur from Java to which he gave the name *sulphurite*. H. D. Gibbs and C. C. James found arsenic in a number of samples of sulphur. M. Vollhase and M. Berndt found that of 77 samples of potassium carbonate, 21 contained arsenic acid in amount varying from 0·241 to 0·841 per cent. As₂O₅. Arsenic also occurs in nearly all iron pyrites—*e.g.* A. Breithaupt and C. F. Plattner found up to 4·39 per cent. in the pyrites from Freiberg; H. A. Smith, 0·944 per cent. in Belgian pyrites, 1·65–1·71 per cent. in Norwegian pyrites, 1·65–1·75 per cent. in Spanish pyrites, and 1·87 per cent. in Westphalian pyrites. H. Reguard found arsenic in malinite. D. Campbell, R. A. Smith, A. Daubrée, W. M. Doherty, and H. Fischer and D. Rüst, reported arsenic in the pyrites of coal, and in coal; hence, the presence of arsenic trioxide in the flue-gases from such coal observed by H. Ramage, etc. F. A. Walchner, H. Becker, E. Ludwig, and J. Mauthner, F. L. Sonnenschein, and M. Popp observed traces of arsenic in ferruginous earths, clays, and soils, from various sources; A. J. Kunkel, A. Daubrée, and F. Sandberger, in various limestones and marls; D. Campbell, and A. J. Kunkel, in sands from different localities. A. Daubrée observed 0·001 per cent. of arsenic in the basalt of Kaiserstuhl. F. Garrigou, indeed, found arsenic to be present in all the rocks and earths which he examined; but A. Gautier considered this plausible generalization too sweeping. If arsenical ores and minerals be exposed to air and moisture for some time, soluble arsenic salts may be formed, and these find their way into brooks and spring waters. The wide distribution of arsenic in mineral deposits is one reason why traces of arsenic are so common in the waters of rivers which arise in hills containing mineral veins. According to W. H. Weed and L. V. Pirsson,⁶ and A. Hague, the waters of some springs in the Yellowstone National Park, U.S.A., contain sulphur and arsenic; and the deposits from the Norris Geyser basin contain sulphur, orpiment, realgar, and siliceous sinter. These same sulphides are common in old fissures through which thermal waters have arisen in former geological periods.

There has been an extraordinary number of reports of the presence of arsenic in mineral waters, and in deposits from mineral waters. Indeed, F. Garrigou found arsenic in all the natural waters he examined. The subject was discussed by L. J. Thénard, J. Glax, A. Gautier and P. Clausmann, M. Goy and W. Rudolph, etc. F. Taboury showed that arsenic had been previously mistaken for selenium in the mineral waters of La Roche-Posay. Arsenic was found in sea-water by G. Bertrand, and A. Daubrée. According to the latter, the evaporated residue contained 0·009 per cent. As. A. Gautier found water in a well, 30 metres from Brittany at a depth of 5 metres, with 0·010 mgrm. of arsenic per litre; and from the

neighbourhood of the Azores at a depth of 10 metres, 0.025 mgrm. per litre, at a depth of 1335 metres, 0.016 mgrm., and at a depth of 5943 metres (6–8 metres from the bottom), 0.080 mgrm. per litre. W. R. G. Atkins and E. G. Wilson found the amount of arsenic, principally as arsenite, in sea-water to be as great or greater than that of the phosphate, and that reports of phosphates in sea-water have included also arsenate. A. A. Bado observed arsenic in the subterranean waters of Bellville, Cordoba, Argentine.

H. Kayser and C. Runge⁷ said that arsenic lines can be nearly always detected in the spectrum of the carbon arc-light; W. Stein observed arsenic in the ashes of and in the fumes from wood-charcoal. It was also observed in the ashes of many plants by H. Marcelet, F. Jadin and A. Astruc, W. Stein, V. Legrip, A. Chatin, J. E. Herberger, J. Girardin, F. Garrigou, and A. Gautier and P. Clausmann. F. Jadin and A. Astruc found 0.006 mgrm. of arsenic in 100 grms. of mushrooms; 0.007 to 0.025, in dry pears and beans; 0.003 to 0.0023, in fresh vegetables; 0.011 to 0.025, in nuts; 0.005 to 0.012, in fruit. The highest proportions of arsenic were found in red haricots, 0.025; almonds, 0.025; lettuce, 0.023; and celery, 0.020. H. Marcelet observed no relation between the proportion of arsenic and manganese in sea-water plants. It has also been reported in wines by M. Fermenti, and A. Barthélemy. The maximum quantity of arsenic found by H. D. Gibbs and C. C. James in California wines, was one part of arsenic in 2,500,000 parts of wine; the most probable sources of the arsenic were considered to be the arsenical sprays used for the vines; and the sulphur used for sulphuring the wine. A. Gautier, and C. Husson found arsenic in wines coloured with aniline dyes. A. M. Peter found arsenic in tobacco which had been sprayed with Paris green. The arsenic found in beer is mainly derived from the glucose; and the glucose obtains its arsenic from the sulphuric acid used in its manufacture. The outbreak of arsenical poisoning in 1900, reported by T. N. Kelynack and W. Kirkby, and E. S. Reynolds, was traced to the beer in which arsenic was introduced through the glucose. J. Clouet found that caramel frequently contains large amounts of arsenic. A. P. Luff found certain malts contained arsenic derived from the coke and anthracite coal used in the drying operations. T. H. Barry said that most printing ink compositions contain arsenic. A. Gautier found arsenic in terrestrial and marine chlorophyllous algæ. The occurrence of up to 0.1 grain of arsenic per pound of apples is due to the spraying of the trees with arsenical preparations when the rainfall is not sufficient to wash off the deposit. A. Hartzell and F. Wilcoxon found that some sprayed apples contained a maximum of 0.704 mgrm. of As_2O_3 per kilogram; and that cider and jelly made from such apples contained only traces of arsenic. R. Spallino found arsenic in snuff and tobacco; and R. E. Remington found arsenic invariably present in various kinds of smoking and chewing tobacco—*e.g.* cigars, cigarettes, etc.—and from 6 to 30 parts of arsenic per million were found in smoking and plug tobacco—*i.e.* about 0.05–0.27 grain of arsenic trioxide per pound. Approximately half the arsenic in pipe tobacco is evolved in the smoke, and about half of that in plug tobacco is soluble in water. W. P. Headden reported that virgin soils contain from 2.5 to 5 parts of arsenic per million, and the underlying marl, 4–15 parts per million. F. Rerchert and R. A. Trelles also found arsenic in soils. According to E. F. von Gorup-Besanez, plants grown on earth soaked with arsenious acids take up only an infinitesimal quantity of arsenic; while E. Davy, and A. Andouard found that superphosphate fertilizers may contain arsenic, and plants to which the manure has been applied may take up arsenic in their tissues. W. A. Lampadius said that a trace of arsenic in soils has a beneficial influence on vegetation.

According to P. Brouardel and G. Pouchet,⁸ the children of arsenic eaters—*vide infra*—contain arsenic; and that element can be detected in the placenta, and in the mother's milk. According to P. Orfila and J. P. Couerbe, F. P. Danger and C. Flandin, A. Gautier, A. Chevallier, C. H. Pfaff, N. Barbot and co-workers, C. Steinberg, and V. A. Jacquelin, arsenic is a normal constituent of the human

body, but P. Orfila, F. L. Sonnenschein, E. Ziemke, and G. H. E. Schnedermann and W. Knop deny this. The literature has been summarized by J. A. Fordyce and co-workers, and by G. Bertrand. F. L. Sonnenschein said :

I procured from the churchyard at Berlin the remnants of the body of a person killed twenty-five years previously, and investigated several others in a similar way, without finding the least trace of arsenic. Similar experiments in great numbers were repeated in my laboratory, but in no case was arsenic recognized.

A. Gautier found a small proportion of arsenic normally present in the thyroid glands of all the different animals; 127 grms. of human thyroid gland gave 0.95 mgrm. of arsenic. The arsenic in the thyroid gland of a sheep was found to be present in the nucleins, not the peptones; and hence it was inferred that arsenic may possibly form arsenic nucleins like those of phosphorus. Arsenic was also found in the thymus and brain, and only traces in the skin. No arsenic was detected in the liver of the dog, sheep, calf, or pig; in the spleen of the dog or ox; in the kidney of the pig; in the flesh of the dog; in the blood of the pig; or in the testicle of man. Arsenic was not found in healthy blood except in the menstrual period when 0.28 mgrm. per kilogram of blood was present. According to W. H. Blömdal, and L. van Itallie and J. J. van Eck, the human liver does not normally contain arsenic, but G. Lechartier and F. Bellamy, and F. M. Raoult and H. Breton found arsenic. G. Bertrand, and M. Segale favoured the hypothesis that arsenic, along with carbon, nitrogen, sulphur, and phosphorus, is a normal constituent of protoplasm. A. J. Kunkel did not find arsenic to be present as a normal constituent in any animal organ including the thyroid gland. A. J. Kunkel, C. Hödlmoser, and K. Cerny denied that arsenic normally plays a physiological rôle in the human organism; and, added D. Mann :

It is possible that traces of arsenic may occasionally be found in some of the tissues without there being any obvious explanation of its presence; but this does not constitute arsenic a physiological component of the human body. Until more evidence is forthcoming, arsenic must, as hitherto, still be regarded as not being a normal constituent of the human body.

The subject was also discussed by G. F. Schaefer, W. H. Blömdal, E. Ziemke, and A. Keilholz. A. Gautier found no arsenic in the muscles and adipose tissue of terrestrial animals. E. Marfurt stated that arsenic occurs normally in all parts of the human body he examined; and the older the organism, the greater the proportion of arsenic present. If arsenic normally plays a part in the organism, this rôle is not confined to one special organ. D. Scolosuboff found that the arsenic concentrates principally in the nervous tissue. Thus, he found the following amounts of arsenic per 100 grms. of the tissue of a bull-dog, 0.00025 grm. in the muscles, 0.00271 grm. in the liver, 0.00885 grm. in the brain, and 0.00933 in the marrow. E. Ludwig, on the contrary, found in all cases of acute or chronic arsenical poisoning the liver is richer in arsenic than the other organs: thus, he found the following amounts of arsenic per 100 grms. of tissue: brain, 0.00004 grm., liver, 0.00338 grm. R. H. Chittenden found in a human body the following proportions of arsenic calculated in grains of As_2O_3 on the entire organs: stomach and cesophagus, 0.158; liver, 0.218; intestines, 0.314; kidneys, 0.020; heart, 0.112; lungs and spleen, 0.1719; brain, 0.075; trachea, larynx, and tongue, 0.081; and diaphragm, 0.010. He said that the entire body contained 3.1 grains As_2O_3 ; and that when the arsenic has been administered in a single dose, it is irregularly distributed in the muscular tissue, but when administered in long-continued, small doses, the distribution is regular. In a case of chronic arsenical poisoning, D. Mann found that arsenic is eliminated from the system *via* the kidneys as urine, the bowels, sweat, saliva, bronchial secretion, and, during lactation, in the milk. It also appears in the skin and its appendages—the nails and hair. He detected 0.013 per cent. of As_2O_3 in the exfoliated horny scales of the epiderm; 0.008 per cent. in the hair; and probably more in the nails.

He added that there thus appears to be a strong affinity between the keratin-tissues and arsenic. He found arsenic in the brain and spongy bone, but it was not prominently present in the brain substance or bone. This was confirmed by T. Stevenson. G. Bertrand said that arsenic occurs in fish from a depth of 1800 metres in the Atlantic Ocean. He also found it in all tissues and organs of animals—fishes, mussels, sponges, etc.—and in hen's eggs. A single egg contained 0.005 mgrm. of arsenic—mostly in the yolk, but A. Gautier did not find arsenic in the eggs of fishes and birds. The Ministry of Agriculture and Fisheries on oyster mortality in 1920 reported finding oysters in certain beds containing 3.7 parts of arsenic per million, and H. E. Cox found up to 4 parts of arsenic per million in fish sold in the London market. According to A. C. Chapman, marine crustaceæ and shellfish have been found to contain from 10 to 174 parts of arsenic (as As_2O_3) per million of the wet edible portions; native oysters contained from 5 to 10 parts, and Portuguese oysters from 33 to 70 parts per million. In fresh-water fish, shellfish and crustaceæ, the amounts of arsenic ranged from only about 0.4 to 1.5 parts per million. The arsenic in the marine animals is therefore derived from the sea-water. Potted and canned crustaceæ and shellfish contained from 0.5 to 85 parts of arsenic per million. The arsenic in the urine of two experimental subjects was raised from the normal figure of about $\frac{1}{300}$ th grain per gallon to half a grain in one case, and one-third of a grain in the other, after a meal of lobster. A. Gautier and P. Clausmann concluded that people take daily in their food 0.021 mgrm. of arsenic, *i.e.* 7.66 mgrms. per year. This subject was discussed by P. A. Meerburg.

Traces of arsenic occur in numerous commercial products—*e.g.* zinc, antimony, bismuth, nickel, etc. C. E. Schafh autl⁹ found it in commercial copper, tin, lead, and iron; A. Loir, in most varieties of brass; and J. J. H. Spirgatis, and F. A. Genth, in antique and other bronzes. Arsenic can be introduced into materials by the use of inadequately purified metal derived from arseniferous minerals. L. Grimbert, and T. Bosch found up to 127 mgrms. per litre in commercial hydrogen dioxide; C. L. Bloxam, and A. Gautier, in hydrogen sulphide; A. Scott, in hydrobromic acid; F. W. Richardson, C. Pedersen, T. E. Thorpe, A. S. Del epine, W. Thomson, etc., in beer—*vide infra*; A. Chevallier, in vinegar; A. Barth elemy, and C. Kippenberger, in wine—*vide infra*; E. Bonjean, in sodium phosphate; H. Fresenius, in precipitated calcium phosphate; E. W. Davy, and A. Andouard, in superphosphates; C. F. B arwald, F. P. Dulk, C. Wittstock, H. W. F. Wackenroder, J. von Liebig, E. Noelting and W. Feuerstein, and G. Denig es, in yellow phosphorus; T. Husemann, and C. Winkler, in red phosphorus; T. Husemann, in phosphoric acid; M. Piron, C. R. Fresenius, E. Donath, and A. Gautier, in sodium sulphate and carbonate; L. Garnier, in bleaching powder, calcium chloride, and potassium chlorate; E. Buchner, in ferric chloride; K. Scholvien, in chloroform; A. Gautier, A. Latour de Tr ee and E. Lefran ois, and N. J. B. G. Guibourt, in sodium chloride—but G. S. S erullas found none in the salt from S ezanne; J. Marshall and C. S. Potts, in caustic alkalies; J. Morland, T. Poleck and C. Th ummel, A. Gl enard, W. B. Herapath, and J. W. Gunning, in bismuth preparations; E. Seybel and H. Wikander, H. A. Smith, E. Filhol and M. Lacassin, A. Houzeau, H. W. F. Wackenroder, G. Hattensaur, G. C. Wittstein, A. Gautier, A. Dupasquier, etc., in hydrochloric acid; G. Lockemann, and A. Gautier, in nitric acid, and in potassium nitrate; O. Gottheil, and A. Gautier, in aq. ammonia and ammonium salts; R. S. Morrell and C. I. Smyth, in printing inks; and E. E. Hjelt, F. P. Dulk, F. Selmi, H. Hager, E. Seybel and H. Wikander, R. Kissling, A. Bussy and H. Buignet, N. Blondlot, F. M. Lyte, J. Loewe, A. Dupasquier, W. Tod, A. Gautier, N. Gr ager, H. A. Smith, L. Ducher, W. Thorn, L. W. McCay, E. Buchner, A. Wagner, etc., in sulphuric acid. The two important acids—hydrochloric and sulphuric acids—being commonly arseniferous, and used in so many industrial processes, are *v eritables distributeurs de ce m etallor ide*. The fact that the presence of arsenic “poisons” the catalyst in the contact process

for sulphuric acid renders it necessary to clean the gases free from this agent. Hence sulphuric acid prepared by the contact process is free from arsenic, and is consequently preferred for use in the manufacture of foodstuffs. M. Ritter and M. Clouet, and O. Schweissinger found it in glucose, but O. Krey found none in petroleum which had been treated with sulphuric acid; and W. Fresenius, J. Marshall and C. S. Pott, E. T. Allen and E. G. Zies, L. Riedal, etc., in glass. Some iron enamels contain a high proportion of arsenic and antimony. E. Ritsert, J. Galimard and E. Verdier, R. Engel and J. Bernhard, J. Lewkowitsch, B. H. Paul and A. J. Cownley, J. Bougault, L. Barthe, A. C. Langmuir, and G. E. Barton found arsenic in commercial glycerol. Many organic and inorganic colouring agents contain arsenic; in some—like king's yellow, As_2S_3 ; mineral blue, copper potassium arsenite; Scheele's green, $CuHASO_3$; and Schweinfurt's green, or *emerald green*, or *Paris green*, $Cu(AsO_2)_2 \cdot Cu(C_2H_3O_2)_2$ —it is an essential constituent; while in others—like some of the aniline dyes—it is an impurity. In consequence, as shown by F. Springmühl, and W. F. Gintl, articles—paper, and fabrics—coloured with these agents may appear arseniferous. Thus, a non-fatal case of poisoning has been reported through inhaling the fumes from burning candles coloured with arsenical pigments; and F. W. Draper mentioned that poisoning has been produced by the use of arsenical pigments for colouring artificial flowers, toys, confectionery, and fancy papers used for wrapping confectionery. F. W. Draper, G. J. Warner, A. W. Stokes, T. T. P. B. Warren, H. Grimshaw, H. Fleck, and J. Wolf found the arsenical colours of tapestries or wall-papers may contaminate the air of a room and produce arsenical poisoning; W. Harding reported a number of cases of poisoning produced by the use of green baize curtains; and H. Vohl found arsenic in note-paper. The arsenic contained in the air of rooms with arsenical wall-paper is present as dust: or as diethylarsine, $(C_2H_5)_2AsH$; or, according to P. Klason, as ethyl-cacodyl, $\{As(C_2H_5)_2\}O$, a gas produced by the action of common moulds on organic matter in the presence of small amounts of arsenic. The *penicillium glaucum*, and the *mucor ramosus* have either no action or but a slight one; the *mucor mucedo*, and the *aspergillus glaucus* react well; while the *penicillium brevicaulis* is so well endowed with this quality that B. Gosio proposed its use as a reagent for arsenic, the garlic odour being perceived when the fungus is made to grow in soln. containing organic matter and only traces of arsenic. This reaction was discussed by R. Abel and P. Buttenberg, O. Emmerling, P. Biginelli, and B. Galli-Valerio and C. Strzyzowsky. Arsenical wall-papers, etc., were discussed by G. Kirchgasser, M. Segale, W. Foster, H. Vohl, N. P. Hamberg, etc.

§ 3. The Extraction of Arsenic

Elemental arsenic is used in commerce only to a small extent. Formerly, at Altenberg, Silesia, arsenic was made by reducing arsenic trioxide by charcoal in clay crucibles covered by another crucible or a conical iron cap. The method was economical, but the product was grey and pulverulent, and contaminated with arsenic trioxide. Arsenic is also formed when arsine is decomposed by heat. N. Tarugi¹ obtained arsenic by reducing arsenic oxide, an arsenite or arsenate by hydrogen, carbon, calcium carbide, or potassium cyanide; and A. Bettendorff, by reducing a soln. of arsenic trioxide in hydrochloric acid by means of stannous chloride.

The main sources of arsenic are as a side-product in the treatment of ores from tin mines, tin-copper mines, and tin-copper-tungsten mines; the waste heaps of exhausted copper mines; the arsenical pyrites mined solely for the arsenic. The common method of preparing arsenic is to heat mispickel, native arsenic, or leucopyrite in the absence of air when the arsenic sublimes. With mispickel: $\text{FeAsS} = \text{FeS} + \text{As}$, about half the arsenic is recovered; and with leucopyrite: $4\text{FeAs}_2 = \text{Fe}_4\text{As} + 7\text{As}$, the residue contains more arsenic than is represented by this equation. In both cases, therefore, the residues can be roasted in a reverberatory furnace so as to recover more of the arsenic in the form of arsenic trioxide (*q.v.*). The distillation is performed in retorts consisting of fireclay tubes or pots, each fitted with a piece of sheet-iron rolled so that one end fits the mouth of the retort, and the other end is luted to a fireclay receiver. The retorts are arranged in rows and tiers. With mispickel ores, arsenic sulphide collects in the receiver at the beginning of the operation. This can be prevented by mixing the ore with alkali or lime. In from 8 to 12 hrs., the receivers are removed. Crystalline arsenic collects on the iron spiral in the mouth of the retort while the pulverulent arsenic collects in the cooler part of the receivers. The object is to collect as large a proportion of the crystalline form as possible. The pulverulent form is used for the preparation of arsenical compounds. The process at Freiberg was described by O. Kast and J. Bräuning;² that at Reichenstein, Silesia, by B. Kerl; that at Ribas, Spain, by E. Lampadius; that near Chicago, by C. H. Jones; and that in Cornwall, by V. Thomas, and H. Dewey. J. F. Cullen proposed to feed the oxide with an incandescent mass of coke and collect the arsenic from the flue gases. A suggestion was made by G. M. Westman to heat the mispickel in an electric furnace in an atm. of nitrogen whereby arsenic is volatilized, and iron sulphide is run from the furnace as a matte. The arsenic vapour and nitrogen are conveyed by fans into condensers where the arsenic is deposited; the nitrogen is sent back again to the furnace. The process is used at Newark, New Jersey. E. H. Robie described the process at Jardine, Mont., where the ore is roasted for arsenic trioxide

and the residue sent to the smelter for recovering gold since the concentrates contain 2 ozs. of gold per ton.

M. G. Bachimont³ suggested heating the arsenical ore with ferrous chloride in closed vessels whereby arsenic trichloride is volatilized and iron sulphide or oxide remains. The arsenic trichloride is received in a soln. of ferric chloride and arsenic precipitated from the soln. by metallic iron. J. Robinson proposed to extract the arsenic as sulphide from arsenical ores by means of a soln. of sodium polysulphide, and precipitating the arsenic from the liquor. A. Siemens extracted the arsenic as sulphide by means of soln. of the alkali, alkaline earth, or magnesium hydrosulphide: $As_2S_3 + 6NaHS = 3H_2S + As_2S_3 \cdot 3Na_2S$, and electrolyzed the liquor. Arsenic is deposited at the cathode, and the sulphide of the basic metal at the anode: $As_2S_3 \cdot 3Na_2S + 3H_2 = 2As + 6NaHS$. E. W. von Siemens and J. G. Halske tried a somewhat analogous process. The electrolytic precipitation of arsenic was discussed by A. Riche, and H. Moissan. The winning of arsenic from the arsenical residues obtained in the manufacture of aniline dyes, was discussed by C. A. Winkler,⁴ M. Tabourin and M. Lemaire, Randu et Cie., C. Martins, E. A. Parnell, A. Leonhardt, and R. Brimmeyr. R. Jahn roasted the ore and passed the purified fumes through a reducing flame.

Arsenic can be purified by mixing it with charcoal powder and subliming; the arsenic sulphide is most volatile and comes off before the arsenic. Any undecomposed pyrites, or earthy matrix remains as a residue. The sublimation is conducted in two crucibles mouth to mouth, and luted with fireclay. The under crucible is fitted into a hole in an iron plate to keep as much heat as possible away from the upper crucible. As A. Bette⁵ showed, some arsenic trioxide is nearly always found associated with the sublimed arsenic; and to avoid this, the arsenic can be sublimed in a current of hydrogen. J. W. Retgers prepared arsenic free from sulphur by fractional sublimation. H. Ludwig obtained arsenic free from oxide, by mixing it with a little iodine before sublimation; and R. Böttger, by digesting it with a soln. of potassium dichromate in dil. sulphuric acid, or with an aq. soln. of sodium hypochlorite, or with chlorine-water. According to N. A. Orloff, arsenic cannot be freed from antimony by sublimation. To obtain arsenic free from antimony, crystallized sodium arsenate is precipitated as magnesium arsenate, dissolved in hydrochloric acid, and fractionally precipitated with ammonia. The middle fraction is dried, mixed with sugar-charcoal, and sublimed.

V. Augur⁶ found that when a soln. of arsenic trichloride in absolute alcohol at -15° is added to a soln. of hypophosphorous acid in the same solvent and cooled to the same temp., an ochre-yellow precipitate is slowly formed, which becomes reddish-brown on drying in a vacuum. This powder, which contains 68.2 per cent. of arsenic, 0.97 per cent. of phosphorus, 2.5 per cent. of alcohol, and (by difference) 28.33 per cent. of water, is rapidly and completely dissolved by dil. alkali hydroxides. This property is retained from two days to as many months, according to the conditions of preparation, but in time the substance becomes insoluble in alkalis. The same change is effected rapidly by contact with water, more slowly by alcohol, and immediately by heating at 100° . When heated to redness in a current of carbon dioxide, it loses water, alcohol, and hydrogen phosphide. The soln. in alkali is brownish-red, quite limpid by transmitted light, but cloudy by reflection. It is unaltered by boiling, but is rapidly oxidized by the air, forming arsenite. Alcohol, or excess of alkali, precipitates brown flakes, which are soluble in water, dil. acids and all soluble salts give a similar precipitate insoluble in water or alkalis. The brown, alkaline soln. can be freed from alcohol by dialysis, but it is impossible to remove all the phosphorus or all the alkali. The liquid is considered to be a true **colloidal solution of arsenic**. E. Lecoq obtained the soln. less contaminated with impurities by electrolyzing an alkaline soln., using an anode of arsenic, or, better, by the electrolytic reduction of a soln. of 3 grms. of arsenious oxide in a litre of 0.3 per cent. sodium hydroxide. A current of 2-3 ampères and 100 volts should be employed, using a platinum cathode and

a mercury anode. The soln. is cooled during electrolysis and purified by dialysis. The addition of a trace of gum renders the colloid much more stable. A soln. prepared in this way appears deep brown, and contains about 0.07 per cent. of arsenic. He found the colloid less toxic to animals than arsenic trioxide. F. Heyden found that a stable colloidal soln. of arsenic may be obtained by reducing its compounds in an alkaline medium in the presence of a protective colloid. White arsenic dissolved in aq. sodium hydroxide containing some protein material, such as white-of-egg, lysalbic acid or gelatin, is reduced by alkaline pyrogallol. The soln. is dialyzed or the colloidal arsenic precipitated by acid, washed, and again dissolved in water. The colloidal arsenic may be precipitated from soln. by acetone, alcohol, or a mixture of the latter with ether. On evaporating the soln., it is obtained in black, lustrous lamellæ, which dissolve in water to a deep brown soln. A. Gutbier and N. Kräutle examined the protective action of extracts of various plant colloids on colloidal arsenic prepared by the reducing action of sodium hyposulphite on slightly acidified soln. of arsenic trioxide, and so found it possible to obtain by evaporation solid colloids containing about 3 per cent. of arsenic which are quite soluble in water. The protected soln. of colloidal arsenic are not appreciably influenced by the addition of hydrochloric acid, sulphuric acid, sodium chloride, and barium chloride, whereas sodium hydroxide and sodium carbonate change the colour from dark brown to light yellow—*vide infra*, brown arsenic. A. Chwala obtained colloidal arsenic compounds by using salts of the metallic acids as protective colloids—*e.g.* calcium plumbate, or sodium antimonate with or without the addition of protalbinic acid. L. Dede and T. Walther prepared colloidal soln. of arsenic by bubbling purified arsine through water exposed to light of short wave lengths. According to the dilution, these soln. are yellow to bluish-violet in colour. Only the most conc. soln. show any tendency towards flocculence; more dil. soln. gradually become colourless owing to the slow oxidation of arsenic to arsenic trioxide. They are very insensitive towards electrolytes. The particles are negatively charged. H. Plauson treated a colloidal soln. of arsenic by treating the element in the so-called colloidal mill using agar-agar as protective colloid. E. Fouard prepared colloidal arsenic by electrolyzing a soln. of a salt of the metal containing a pure organic colloid (albumin, starch, or gelatin) with a current of a few milliampères. At the cathode, the metal ions are neutralized by the repelled, negatively-charged colloid micelles. A colloidal organo-metallic complex is thus formed. The anode is separated by immersion in a collodion cell rendered semi-permeable by precipitated copper ferrocyanide. The cathode should be a bad conductor so as to reduce the frequency with which formation of the complex occurs on the cathode.

§ 4. The Allotropic Forms of Arsenic

In 1725, J. F. Henkel¹ first prepared the so-called metallic arsenic by sublimation; and in 1843, J. J. Berzelius, in his memoir *Om allotropi*, showed that arsenic can exist in two allotropic states. One of these, *metallic* or *crystalline arsenic*, or α -arsenic, is produced when arsenic vapour mixed with another heated gas is deposited on a part of the vessel which is not strongly heated. It is a dark grey, crystalline mass which oxidizes in air, especially at 40°, forming what he called "black, pulverulent suboxide." The other modification, *amorphous* or *vitreous arsenic*, or β -arsenic, is produced when arsenic is very strongly heated, or when the vapour is condensed on a part of the vessel which is near the temp. at which arsenic volatilizes, so that the element is deposited in an atm. of its own vap. This modification of arsenic forms a light grey vitreous mass which, according to J. J. Berzelius, is denser than the α -form, and remains unaltered in air even when finely powdered, and heated to 70° or 80°. There is nothing here to show that these supposed allotropic states are not, as H. Watts suggested, due to differences in mechanical structure rather than to differences in atomic structure. The different allotropes are produced by differences in the compactness of the constituent matter. J. W. Hittorf showed that J. J. Berzelius was not correct in stating that the grey, vitreous form is denser than the metallic form, for the sp. gr. of the vitreous form is 4.72 when that of the metallic form is 5.72. A. Bettendorf showed that vitreous or β -arsenic, is always formed when the vap. of arsenic is cooled at 210°–220°, and it is deposited beside crystalline or α -arsenic when the element is sublimed in a current of hydrogen. The β -form of arsenic has a sp. gr. 4.716–4.740, and at 360° it is transformed into crystalline α -arsenic of sp. gr. 5.72. It will be observed that these sp. gr. also are not in harmony with J. J. Berzelius' statement that vitreous β -arsenic is specifically heavier than ordinary crystalline α -arsenic. A. Bettendorf also noticed that when arsenic is sublimed in a current of hydrogen, (i) the crust of vitreous arsenic, deposited in the hottest part of the zone of condensation, is succeeded by (ii) the crust of ordinary, crystalline arsenic, and beyond that is deposited (iii) a yellow powder which rapidly becomes (iv) grey pulverulent arsenic which he regarded as another allotropic form, and called γ -arsenic. The yellow unstable—possibly allotropic—form was not examined because it was transformed so rapidly into the grey form. Microscopically, γ -arsenic resembles flowers of sulphur; its sp. gr. is 4.71; and it is readily attacked by nitric acid. The γ -variety became crystalline α -arsenic at 358°.

R. Engel showed that β -arsenic, γ -arsenic, and the brown precipitates obtained by the reduction of arsenic trioxide with stannous chloride, hypophosphorous acid, or copper, or by electrolysis, are probably the same allotropic form having a sp gr. 4.6–4.7, and the differences observed in their chemical behaviour are due to differences in the state of subdivision. He admitted only two allotropic forms—the crystalline of sp. gr. 5.7 and the vitreous of sp. gr. 4.6–4.7; the crystalline form sublimes in vacuo at 360°, and the vitreous at 260°. He compared vitreous arsenic with yellow phosphorus, and crystalline arsenic with red phosphorus. A. Geuther reported another modification of amorphous arsenic of sp. gr. 3.7 at 15° to be produced when a mixture of 3 parts of phosphorus trichloride, and 2 of arsenic trichloride is treated with water. R. Engel said that the low sp. gr. of this product is due to the presence of impurities—principally arsenic trioxide. M. Berthelot and R. Engel measured the heat of transformation of the vitreous and crystalline forms of arsenic, and found it to be of the order of that of the diamond and graphite.

The existence of a yellow modification of arsenic, in addition to the crystalline and the vitreous or amorphous form was indicated by the work of A. Bettendorff, J. P. Cooke, L. Elsner, R. W. E. MacLeod, T. Petersen, J. W. Retgers, H. Rose, and A. Schuller. There was some doubt about this as a specific allotropic form because it had only an ephemeral existence, and could not be isolated; and R. Engel maintained that it was not a definite allotropic form, and suggested that the yellow colour is due to the vap. of arsenic. A. Bettendorff then showed that when stannous chloride acts on a soln. of arsenic trioxide in hydrochloric acid, a brown precipitate is obtained containing 96-99 per cent. of arsenic, and traces of tin. He also noticed that a faint yellow coloration temporarily appears when arsenic is distilled with hydrochloric acid; arsenic is then present in the hydrochloric acid, but it was not proved that the transient yellow coloration was due to arsenic. R. G. Durrant observed that when stannous chloride acts on the hydrochloric acid soln. of arsenic trioxide, or magnesium ammonium arsenate, the appearance of the solid arsenic is always preceded by a pale buff tint, and from this, the brown precipitate is formed. The buff coloration is best observed with mixtures which yield a very slow deposit; and shaken with carbon disulphide, a small proportion of arsenic is dissolved. The reaction was studied by F. A. Flickiger, R. Lobello, C. O. Curtman and H. Bekurts, G. Lochmann, S. H. de Jong, A. Ferraro and A. Carobrio, H. Hager, J. Mayerhofer, P. Lohmann, and K. Zwicknagl. The Farbenindustrie A.G. passed the vapour of a solvent for yellow arsenic over strongly heated arsenic, and immediately condensed the vapour. G. E. Linck obtained the yellow variety by gently heating arsenic in a current of carbon dioxide and strongly cooling the tube, which must not be exposed to light; in these circumstances, a yellow powder is deposited, which is converted into the mirror form of arsenic by heat or exposure to light. This yellow powder is readily soluble in carbon disulphide, and by evaporating the solvent is deposited in microscopic, rhombic dodecahedra which smell strongly of garlic. These change spontaneously into mirror arsenic, and the transformation, which can be watched under the microscope, is complete in about 3 minutes. H. Erdmann and M. von Unruh also obtained the yellow form by distilling arsenic in an aluminium tube in a current of carbon dioxide. The aluminium tube passed directly into a side-tube of a U-tube with a bulb on the opposite limb. A rapid current of cooled carbon dioxide played on to the distilled substance just as it emerged from the hot tube. By this sudden cooling, the arsenic is deposited in the yellow modification, which was at once dissolved in carbon disulphide in the U-tube, surrounded by ice-water. The yellow modification of the arsenic can be obtained from the soln. either by evaporation of the carbon disulphide or by cooling to -70° , when most of it separates from soln. The solid, yellow arsenic is extremely sensitive to all forms of light. It can be preserved for some time by keeping it at a temperature below -60° and away from the light. Even at very low temp., it is quickly turned black by the action of light. They added that there is no tendency for the dissolved yellow arsenic to change into the metallic modification, but the soln. slowly deposits a reddish-brown modification on standing. This reddish-brown variety is not changed into the metallic form by the action of light. A. Stock and W. Siebert obtained yellow arsenic by subliming arsenic in vacuo, and cooling the vap. by liquid air in darkness. The yellow arsenic is immediately blackened in light. They also found that a soln. of yellow arsenic is most readily prepared by passing a current of about 12 amp. between a carbon anode and a cathode consisting of an alloy of equal parts of arsenic and antimony, both electrodes being immersed in carbon disulphide contained in a vessel surrounded and covered by water and ice, the arsenic under these conditions dissolving in the carbon disulphide in the form of the yellow modification, whilst the antimony is disintegrated but does not enter into soln. After a sufficient quantity has dissolved, the carbon disulphide is separated from the water and filtered, and may be concentrated by distillation. D. Vörländer and co-workers observed no

sign of the formation of a doubly refracting form of yellow arsenic above -190° analogous to doubly refracting yellow phosphorus.

P. N. Laschtschenko measured the heat evolved on cooling heated arsenic and obtained the results shown in Fig. 1. The break between 738° and 750° refers to the transition of yellow to metallic arsenic, a change attended by the evolution of about 7 cal. per gram. The break between 822° and 868° is due to the change

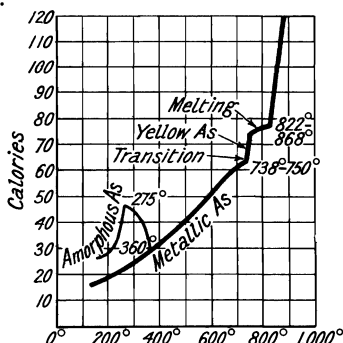

FIG. 1.—The Evolution of Heat by Cooling Arsenic.

of arsenic from the liquid to the solid state of aggregation. With amorphous arsenic, it is not certain whether the temp. 360° or 270° – 280° is the transition point. The sp. gr. of amorphous arsenic, heated to 360° and rapidly cooled to 15° , is the same as that of metallic arsenic; while that which has been heated to 275° is the same as that of grey arsenic. R. Engel gave 360° for the transition, and P. Jolibois, and R. Goubau gave 270° – 280° . P. N. Laschtschenko assumed that amorphous arsenic is a solid soln. of the yellow and metallic forms, just as ordinary red phosphorus is assumed to be a solid soln. of yellow and metallic phosphorus. This view is supported by the change in the sp. gr. of amorphous phosphorus with temp., and R. Engel's observations on the sublimation of arsenic. The sublimation temp. of amorphous arsenic is much lower than that of metallic arsenic. The sublimation of amorphous arsenic ceases at 360° , and transformation of amorphous into metallic arsenic can be effected by a prolonged sublimation at 310° , for the more volatile constituent of the solid soln. distils off, and metallic arsenic, non-volatile at that temp., remains; the irreversible, exothermal transformation is complete. H. Erdmann and co-workers gave 303° for the transition temp. because at this temp. the amorphous form becomes electrically conducting. P. N. Laschtschenko found that the temp. at which electrical conductivity appears depends on the conditions of the experiment. On heating the amorphous form in a sealed tube, he found that minute crystals of metallic arsenic appear at 270° – 280° ; while above this temp., the transformation proceeds by the distillation of the metastable amorphous form and its condensation in the metallic state.

According to H. Erdmann and M. von Unruh, the raising of the b.p. of carbon disulphide by dissolved yellow arsenic corresponds with the mol. formula As_4 ; and H. Erdmann and R. Reppert suggest that when yellow arsenic passes into metallic arsenic under the influence of violet or ultra-violet light, *grey arsenic* is produced as an intermediate stage, and they assumed that it has the mol. formula As_2 , while metallic arsenic is assumed to be monatomic. Grey arsenic, also called mirror-arsenic, is formed as a by-product in the preparation of the carbon disulphide soln. of yellow arsenic; when solid yellow arsenic is exposed to light at low temp., or when dissolved yellow arsenic is treated with alcohol, or cooled with carbon dioxide and ether, or with liquid air. The sp. gr. is 4.64 at 20° . While J. J. Berzelius, A. Bettendorff, A. Geuther, J. W. Hittorf, C. Ehlers, and T. Petersen believed that grey arsenic is amorphous, J. W. Retgers, G. E. Linck, H. Erdmann, and R. Reppert, and E. Frank hold that the grey form is crystalline or cryptocrystalline. Grey arsenic is stable towards atm. oxygen, and is oxidized by nitric acid more slowly than brown, or metallic arsenic. When a soln. of yellow arsenic is treated with oxygen, with arsenic tribromide, or with acetylene tetrabromide, or is allowed to remain in the dark, H. Erdmann and R. Reppert found that what they call *brown arsenic* is produced. Brown arsenic was obtained by A. Geuther, and R. Engel—*vide supra*; it was probably obtained by J. V. Janowsky in 1873 by the action of water on sodium arsenide; he regarded it as solid hydrogen arsenide; and O. Brunn. in 1889, by the action of air on arsine, and he regarded it as a soln. of arsine in arsenic; by A. Bettendorf, and R. G. Durrant, by the action of

stannous chloride on arsenic trichloride; by E. Frank, by the action of phosphorus trichloride, arsenic diiodide, hypophosphorous acid, and hydrazine hydrate on arsenic trichloride; and by O. Brunck, by reducing strongly acid soln. of arsenic trioxide with sodium hyposulphite—*vide supra*, colloidal arsenic. H. Jung found that the X-radiograms of precipitated brown arsenic; brown, translucent arsenic derived from cubic arsenic; and the arsenic mirror, all indicate that the arsenic is amorphous. H. Erdmann and R. Reppert said that brown arsenic has a sp. gr. of 3.67–3.69 at 20°. They assume that its mol. formula is As_8 . C. Ehlers examined the gaseous and solid impurities a high proportion of which is always present in brown arsenic. H. Erdmann and co-workers thus represent the mol. structure of these different allotropes of arsenic:

While H. Erdmann and co-workers attributed the differences in the four modifications of arsenic to differences in their mol. complexity, V. Kohlschütter and co-workers assumed that the different allotropic forms are due to differences in the quantity of matter distributed in a given space. Thus, the sp. vol. of yellow arsenic is 0.5, while that of metallic arsenic is 0.175. Hence, the conversion of yellow to metallic arsenic is a process of condensation. Grey arsenic is likewise assumed to be the same matter as metallic arsenic, but occupying a larger space; while brown arsenic is more diffuse than grey arsenic, and it is always obtained under the influence of a foreign substance which acts in a certain sense as a dispersing medium, the nature and conc. of which determines the state of distribution. This hypothesis is virtually the same as that of H. Watts previously indicated. H. Erdmann and co-workers gave 180° as the transition temp. of yellow to grey arsenic. P. N. Laschtschenko could find no evidence of such a transition point—Fig. 1—and there is no proof that the mol. wt. of grey, brown, and metallic arsenic are actually those which have been assigned to them. The results of these investigations indicate the existence of four allotropic forms of arsenic with the properties indicated in Table I. According to P. N. Laschtschenko, the probable **transition**

TABLE I.—COMPARISON OF THE FOUR ALLOTROPIC FORMS OF ARSENIC.

	Metallic.	Yellow.	Grey.	Brown.
Colour . . .	Steel-grey	Yellow	Grey to black	Pale reddish brown to dark brown
Translucency .	Opaque	Translucent	Translucent	Opaque
Crystalline form	Trigonal	Cubic	Cryptocrystalline	Amorphous
Sp. gr. . . .	5.72	(2.06)	4.64	3.67–4.13
Electrical . .	Conductor	Non-conductor	Non-conductor	Non-conductor

temperatures for metallic to yellow arsenic is between 738° and 750°; R. Engel gave 360° for the passage of amorphous to metallic arsenic; and P. Jolibois, and R. Goubau, gave 270°–280°. P. N. Laschtschenko found the irreversible transformation of brown or amorphous arsenic to grey arsenic occurs at 270°–280°; and of grey to metallic arsenic, at 360°. H. Erdmann and R. Reppert gave respectively 180°–200°, and 303°.

§ 5. The Physical Properties of Arsenic

Arsenic in its ordinary form is a silver-grey, or tin-white substance with a metallic lustre. The colours of the different allotropes have been previously indicated. F. P. Leroux said that the vap. of arsenic is lemon-yellow, but A. Schuller and later observers found it to be colourless. Arsenic occurs in nature usually massive, but is sometimes reticulated, reniform, stalactitic, or columnar. The natural **crystals** are usually acicular. G. Rose¹ found the crystals are trigonal with the axial ratio $a : c = 1 : 1.4025$; V. R. von Zepharovich gave $1 : 1.4013$. The **cleavage** on the (111)-face is perfect; that on the (110)-face, imperfect. M. L. Huggins studied the relation between the cleavage and the electronic structure. Twinned forms are common with sublimed crystals. O. Mügge showed that the (110)-plane is a gliding plane. The crystals were also examined by A. de Schulten, and C. W. Zenger. The **X-radiogram** of metallic arsenic was studied by A. J. Bradley, M. L. Huggins, and S. von Olshausen. The structure consists of two interpenetrating trigonal lattices—Fig. 4, 8. 52, 5. A comparison of the results of A. J. Bradley with those for antimony by R. W. James and N. Tunstall, and of bismuth by R. W. James, is shown in Table II. G. E. Linck and H. Jung esti-

TABLE II.—LATTICE CONSTANTS OF ARSENIC, ANTIMONY, AND BISMUTH.

Shorter at. distance	2.51 A.	2.87 A.	3.11 A.

mated the lattice constants of the trigonal crystals to be $a = 5.593$, and $\alpha = 84^\circ 38'$. The data were summarized by P. P. Ewald and C. Hermann. G. Rose believed that arsenic can be obtained in octahedral crystals belonging to the cubic system; L. Elsner, F. von Kobell, and M. L. Frankenheim came to the same conclusion; but J. P. Cooke suggested that the octahedral crystals are those of arsenic trioxide coloured with arsenic. This subject was discussed by C. F. Rammelsberg and

J. W. Retgers. The arsenolamprite of A. Breithaupt, and A. Frenzel, is probably, according to C. Hintze, a modification of arsenic belonging to the rhombic system—G. E. Linck said the monoclinic system. H. Jung showed that the X-radiogram of arsenolamprite agrees with that for metallic arsenic suggesting impure rhombohedral arsenic, or arsenic in which an allotropic form resembling black phosphorus is present. As previously indicated, the allotropic form called grey arsenic is cryptocrystalline. According to H. Erdmann and R. Reppert, grey arsenic is trigonal; J. W. Retgers, cubic; and G. E. Linck, monoclinic. Yellow arsenic is also crystalline and the crystals belong to the cubic system. The so-called brown arsenic, and arsenic mirrors, were shown by H. Jung to be amorphous.

G. E. Linck defined a *eutropic series* as one formed by the combination of successive elements of a sub-group by elements in the periodic system with the same radicle so that the compounds thus formed are characterized by similar crystalline form, and similar physical and chemical constants, which show a progressive change with the change in mol. wt. Red phosphorus is not eutropic with the trigonal forms of arsenic, antimony, and bismuth because the calculated ratios of the axes, at. vol., etc., do not fit the eutropic series of the other three elements. On the other hand, red phosphorus forms a eutropic series with mirror (grey) arsenic; and yellow phosphorus corresponds eutropically with yellow arsenic. The trigonal form of arsenic corresponds eutropically with crystalline antimony and bismuth, but no corresponding form of phosphorus is known. G. E. Linck illustrated this by Table III. E. Mitscherlich supposed metallic

TABLE III.—EUTROPIC SERIES WITH TRIGONAL ARSENIC, ANTIMONY, AND BISMUTH.

	At. wt.	Colour.	a : c	Lattice constants.		Sp. gr.	M.p.	Sublimation temp.	Oxidizability.

arsenic to be isomorphous with tellurium and antimony. The polymorphism of phosphorus, arsenic, antimony, and bismuth is illustrated by Table IV; the

TABLE IV.—POLYMORPHISM OF THE PHOSPHORUS-BISMUTH FAMILY.

eutropism is also illustrated by passing from left to right. The subject was also discussed by P. Möller, and R. Neumann. According to H. Erdmann and R. Reppert, although yellow phosphorus and yellow arsenic are so closely related crystallographically, they do not form mixed crystals. This is ascribed to the great difference of their solubilities in carbon disulphide. J. Nicklès discussed the isomorphism of this family of elements.

The **specific gravity** of native arsenic given by A. Breithaupt is 5.722–5.734; and by A. Russell and H. F. Harwood, 5.636. T. Bergman's value 8.31 was far too high for metallic arsenic. A. Bettendorf gave 5.726–5.728 at 14°; N. J. B. G. Guibourt, 5.700–5.959; A. L. Lavoisier, 5.76; C. J. B. Karsten, 5.6281; W. Herapath, 5.672–5.709; M. J. Brisson, and F. Stromeyer, 5.7633; V. Kohlschütter and co-workers, 5.73; T. Turner, 5.8843; L. Playfair and J. P. Joule, 5.230 at 3.9°; H. Ludwig, 5.395 at 12.5°; A. Wigand, 5.87; P. N. Laschtschenko, 5.7301 at 15°/15°; J. W. Mallet, for a sample which had been fused, 5.709 at 19°; and W. Spring, for a sample which had been compressed, 4.91. The sp. gr. of vitreous arsenic given by A. Bettendorf is 4.710–4.716 at 14°; A. Wigand, 4.78; V. Kohlschütter and co-workers, 4.60–4.72 at 18°; R. Engel, 4.6–4.7; and J. W. Hittorf, 4.69 at 17° for the material in pieces, and 4.72, when in powder. H. Erdmann and R. Reppert gave 4.64 at 20° for the sp. gr. of grey arsenic. E. Frank found the sp. gr. of grey arsenic sublimed in a current of carbon dioxide, 4.708 at 20°, and in a current of hydrogen, 4.7065 at 20°. The form prepared by treating arsenic trichloride with phosphorus trichloride was found by E. Frank to have a sp. gr. 4.17 at 16° and if heated to 200°, 4.42; if obtained with arsenic diiodide, 4.185 at 15°; if with hypophosphorous acid, 4.20 at 16°, and if heated to 200°, 4.54; and if with hydrazine hydrate, 4.54 at 18°. The product in these cases is probably a mixture of the brown and grey forms of arsenic. The brown arsenic prepared by A. Geuther had a sp. gr. 3.7 at 15°; H. Erdmann and R. Reppert gave 3.67–4.06 for the sp. gr. at 20°. V. Kohlschütter and co-workers, 3.7–4.7; and P. N. Laschtschenko, 3.693 at 15°/15°. This agrees with general experience that while a crystalline individual has a definite sp. gr., amorphous substances have a variable sp. gr. V. Kohlschütter and co-workers said that the purest brown arsenic they could obtain had a sp. gr. 4.52; and added that the sp. gr. of the grey and brown forms of arsenic, free from all impurities, are nearly the same so that the sp. gr. is not a sufficient criterion, to distinguish these modifications. I. I. Saslowsky gave 5.701 for the sp. gr. at room temp., and 13.2 for the at. vol. C. del Fresno studied this subject. R. M. Bozorth calculated the **atomic radius** of arsenic to be 1.36 Å. when that of oxygen is 0.65 Å.; W. L. Bragg gave 1.26 Å. for the at. radius; E. N. Gapon, 1.37 Å.; W. F. de Jong and H. W. V. Willems, 1.16 Å.; and M. L. Huggins, 2.32 Å. H. G. Grimm made observations on the ionic radius. P. N. Laschtschenko found the sp. gr. of amorphous arsenic at 15°/15°, and after heating in sealed quartz-glass tubes at different temp. and rapidly cooling:

Sp. gr.	15°	175°	235°	255°	275°	305°	365°	400°
	3.693	3.698	3.974	4.493	4.947	5.365	5.731	5.729

The corresponding curve is continuous, becoming horizontal at 360°; at 270°–280°, the sp. gr. becomes equal to that of grey arsenic, and at 360°, to that of metallic arsenic. H. Erdmann and R. Reppert found the sp. gr. of yellow arsenic at –50° to be 2.35; at –63°, 2.46; at –75°, 2.63; and at 18°, 2.026. J. J. van Laar calculated b of J. D. van der Waals' equation to be $b=0.00195$; for a , $\sqrt{a}=0.089$; and for the valency attraction, A , $\sqrt{A}=33$.

E. Mitscherlich, and A. Bineau found the **vapour density** to be anomalous. H. St. C. Deville and L. Troost gave 10.6 for the vap. density of arsenic at 563°, and 10.20 at 720°—the calculated value for As_4 is 10.38. J. Mensching and V. Meyer found the vap. density approximates more and more to the value for As_2 as the temp. is raised; and H. Biltz and V. Meyer obtained 5.543 at 1714°, and 5.451 at

1736°—the calculated value for As_2 is 5.20. H. Erdmann and M. von Unruh found that the effect of yellow arsenic on the b.p. of carbon disulphide is in agreement with the tetratomic mol. As_4 . S. Dushman studied the reactions $As_4 \rightleftharpoons 2As_2$; and $As_2 \rightleftharpoons 2As$. G. Preuner and J. Brockmüller's total press., P , at temp. between 300° and 1200° at constant vol., with the amounts of arsenic calculated in grams per c.c. are shown in Fig. 2. The corresponding partial press. for p_4 of As_4 ; p_2 of As_2 ; and of As are indicated in Table V. The average number of atoms, i , per mol. is as follows :

800°	$\left\{ \begin{array}{l} P \\ i \end{array} \right.$ 21 2.86 48 3.29 93 3.60 107 3.55 141 3.80 242 3.70 721 mm. 3.93

600	548.6	46.5	4.9	449.1	151.9	21.4	338.1	186.2	75.7
750	696.2	47.6	5.2	529.4	198.4	22.3	452.6	216.4	81.0

The calculated thermal values of the dissociation $As_4 = 2As_2$ are 24,050 cal. between 800° and 1100°; and for $As_2 = 2As$, 28,800 cal. at 800°, and 30,000 cal. between 900° and 1100°. The effect of temp. on the equilibrium constant, K_4 for $As_4 = 2As_2$ is $\log (K/760) = -(30,000 + 2T)/4.57T + 1.75 \log T - 2.4$; and K_2 for $As_2 = 2As$ is $\log (K_2/760) = -(24,050 + 2T)/14.57T + 1.75 \log T - 2$, where the chemical constant for the As_4 -mol. is -2.4 , and for the As_2 -mol., -2.0 . The dissociation constants are :

	800°	900°	1000°	1100°	1200°
K_4	3.50	10.0	24.0	52.7	10.3
K_2	0.52	1.8	5.4	13.9	31.5

Crystalline arsenic is brittle and somewhat hard ; the cast metal flattens slightly under the hammer, but is easily broken. J. R. Rydberg² gave 3.5 for the **hardness** of arsenic when that of the diamond is 10; and C. A. Edwards and A. M. Herbert gave 147.0 for Brinnell's hardness number. T. W. Richards found the average **compressibility** to be 4.5×10^{-6} between 100 and 500 megabars at 20°. According to C. I. Burton and W. Marshall, a press. of 300 atm. raises the temp. 0.261°, and when the press. is released the temp. falls 0.248°. The linear coeff. of **thermal expansion** was found by H. Fizeau to be 0.00000559 at 40°, and 0.00000602 at 50°. A. Bettendorf and A. Wüllner found the **specific heat** of metallic arsenic between

FIG. 2.—Dissociation Pressures of Arsenic Vapour at Different Temperatures.

21° and 66° to be 0.0830, and for amorphous arsenic 0.0758 between 21° and 65°; H. V. Regnault gave for metallic arsenic 0.0814. A. Wigand gave 0.0822 between 0° and 100° for metallic arsenic, and 0.0840 for grey arsenic. J. Dewar gave for the sp. ht. of metallic arsenic 0.0258 between -253° to -196°; T. W. Richards and F. G. Jackson, between -188° and 20°; and R. Ewald gave 0.0619 at -136°; 0.0736 at -39°; and 0.0772 at 28°. A. Bettendorf and A. Wüllner's value for the **atomic heat** is $C_p=6.22$ between 22° and 68°; A. Wigand, 6.17 between 0° and 100°; and R. Ewald, 5.79 between 1° and 55°. E. Jannettaz found the **heat conductivity** perpendicular to the (111)-face of a crystal of metallic arsenic to be $1\frac{1}{2}$ to 2 times as great as it is parallel to the chief axis. Arsenic volatilizes at a dull red-heat without fusion; J. K. Mitchell found that it does not volatilize at 294°, or even at the m.p. of zinc, but volatilization begins at dull red-heat visible in darkness—*circa* 530°. R. Engel observed no sublimation with metallic arsenic at 360°; but C. Zenghelis showed that even at ordinary temp. arsenic has an appreciable vap. press. for a piece of silver enclosed in the same vessel as arsenic acquires a film of arsenide in a few months. F. Krafft and A. Knocke showed that arsenic in a vacuum commences to volatilize at 96°, and sublimes rapidly at the constant temp. of 325°; under 760 mm. press., it sublimes constantly at 554°. E. G. M. Conechy concluded that metallic arsenic does not volatilize below 446°, but it does so below 457°, he therefore gave 449°–450° for the **sublimation temperature**. H. Erdmann estimated 360°–365°. W. P. A. Jonker gave 616° as the sublimation temp. at 760 mm. press.; O. Ruff and S. Mugdan, 633°; and G. Preuner and J. Brockmüller, 600° at 586 mm., 580° at 430 mm., and 569° at 334°. O. Ruff and B. Bergdahl gave 568° for the **boiling point** of arsenic; W. R. Mott, 616°. J. Johnston calculated 220° at 10^{-3} mm.; 260° at 10^{-2} mm.; 310° at 0.1 mm.; 360° at 1 mm.; 430° at 10 mm.; 490° at 50 mm.; 510° at 100 mm.; and 610° at 760 mm. The **vapour pressures** of arsenic, measured by G. Preuner and J. Brockmüller, and G. E. Gibson (in brackets), are:

	400°	469.4°	470°	499.9°	500°	526°	568.9°	633°
Vap. press.	6	(26.0)	28	(67.4)	61	130	(334.1)	760 mm.

The last value is by O. Ruff and co-workers, who also measured the vap. press. of arsenic. S. Horiba gave for the vap. press., p atm., curve of the solid,

FIG. 3.—Vapour Pressure Curves of Liquid and Solid Arsenic.

and for that of the liquid, $T \log p = -2450 + 3.80T$. The curves are shown in Fig. 3. He did not succeed in measuring the vap. press. of black arsenic. J. Johnston gave $\log p = -6670T^{-1} + 10.47$. W. Herz found that the constant c in the equation $\theta_1/\theta_2 = T_1/T_2 + c(\theta_1 - T_1)$ approximates -0.0005882, but has not a constant value—here θ_1 and θ_2 are the b.p. of two liquids at a definite press., and T_1 and T_2 the b.p. of the same liquid at another press. J. W. Retgers observed no signs of fusion in the partly sublimed crystals, but he noticed that corrosion figures were produced. F. Krafft observed that for many metals the interval between the commencement of vaporization and the b.p. in vacuo is nearly equal to the difference between the b.p. in vacuo and the b.p. at ordinary press.; and F. Krafft and A. Knocke observed the same rule applies also to the sublimation of arsenic, and thallium. In vacuo, arsenic commences to volatilize at 96°, and sublimes rapidly at 325°; and under atm. press., it sublimes rapidly at 554°. O. Ruff and B. Bergdahl gave 568° for the b.p. P. N. Laschtschenko found that amorphous arsenic begins to sublime between 270°–280°. N. W. Fischer tried to fuse it in a sealed glass tube, but the tube burst before fusion occurred; but A. N. Guntz and W. Broniewsky even stated

that arsenic has not a true m.p. but passes through a viscous state during the transformation from a crystalline solid to a liquid when arsenic is heated in evacuated quartz glass tubes. Above 500° , the fragments of arsenic soften, stick together, and slowly assume the shape of the containing vessel. The melted portion is distinguished from the solid arsenic by its brilliant steel-grey appearance, the solid being dull black. When all the arsenic is melted, a meniscus slowly appears. The same proportion of arsenic is melted by ten minutes' heating at 700° as by twelve hours' heating at 520° . Fusion is extremely slow at 500° , but at 1200° , it is practically instantaneous. At the latter temp., the interior of the quartz tube becomes roughened. The conclusion is drawn that at 500° arsenic forms a very viscous liquid of which the viscosity diminishes with rising temp. H. H. Landolt, and J. W. Mallet were more successful, for they were able to melt it in sealed tubes and they found the **melting point** lies between that of antimony and that of silver; and this agrees with W. P. A. Jonkèr's statement that arsenic does not show any signs of fusion when heated in a sealed tube at 800° . S. F. Schemtschuschny gave 624° for the m.p. of arsenic; W. Guertler and M. Pirani, and P. Jolibois, $850^{\circ} \pm 10^{\circ}$; R. Goubau, 817° ; W. R. Mott, 800° ; and P. N. Laschtschenko, 822° – 868° —*vide* Fig. 1. H. Rassow gave 818° ; S. Horiba, 818° to 822° ; and W. Heike obtained 830° , but his later work showed that 814.5° is nearer the mark. W. Guertler and M. Pirani gave 800° for the best representative value, but this is too low. H. Carlsohn said that the m.p. of arsenic compounds does not follow the additive rule. S. Horiba gave for the **triple point**, 36.5 atm. press. and 822° . L. Rolla estimated 929° for the m.p. of arsenic if it is melted under atm. press. The latent **heat of fusion** of arsenic is not known. S. Horiba calculated from the vap. press. curve, 22.4 cal. per mol. When sublimed in a sealed tube, arsenic melts when its b.p. does not coincide with the temp. of fusion; in other words, at this temp. we have to deal with a triple point in the system: solid, liquid, and gaseous arsenic. R. de Forcrand calculated the **heat of vaporization** to be 5128 cal.; J. Johnston, 30.5 cal. per mol.; and A. Henglein, gave 0.349 cal. for the mol. heat of evaporation. S. Horiba calculated 11.2 cal. per mol. for the liquid to gas transition, and 33.6 cal. per mol. for the **heat of sublimation** for the solid to gas transition. H. Rassow estimated that the **critical temperature** is over 1400° . P. N. Laschtschenko's observations on the thermal effect with cooling arsenic are summarized in Fig. 1; he gave 7 cal. per gram for the **heat of transformation** of metallic to yellow arsenic. The heat effect observed by S. F. Schemtschuschny was probably due to this transformation and not to the heat of fusion. According to T. Petersen, the heat of transformation of yellow into metallic arsenic is 33.4 Cals.; and for mirror arsenic into metallic arsenic, 10 Cals. M. Berthelot and R. Engel gave for the heat of the reaction: $2\text{As} + 5\text{Br}_{2\text{aq.}} + 5\text{H}_2\text{O} = \text{As}_2\text{O}_{5\text{aq.}} + 10\text{HBr} + 83.00$ Cals., with metallic arsenic, and 84.10 Cals. with mirror arsenic. T. Petersen found the **heat of oxidation** to be $(2\text{As}, 3\text{O}) = 1568.3$ Cals. with metallic arsenic, 1547.4 Cals. with mirror arsenic, and 1635.0 Cals. with yellow arsenic. H. Collins, and J. C. Thomlinson made some speculations on the heat of formation of some arsenic compounds.

J. H. Gladstone³ gave 0.2050 for the **refractory power** of arsenic vapour, and A. Haagen, 0.2696; J. H. Gladstone found the **refraction equivalents** to be 15.8; and A. Haagen, 20.22 for the H_{α} -line, and 18.84 for the A -line. C. Cuthbertson and E. P. Metcalfe gave 1.001550 for the **refractive index** of arsenic vap. for light of wave-length $\lambda = 5893$; and for $\lambda = 5460$, 1.001580. J. E. Calthrop studied the relation between the at. vol. and the index of refraction. F. Gryszkiewicz-Trochimovsky and S. F. Sikorsky found that the at. refractions of arsenic in combination with aliphatic radicles are 10.8, 10.9, and 11.3 for the H_{α} -, D -, and H_{β} -lines respectively. The at. refractions of the arylarsines increase with the number of aryl radicles combined with the arsenic atom.

J. Joubert⁴ found that arsenic exhibits **phosphorescence** if it be heated to 200° and some oxygen is present. According to L. Bloch, the phosphorescence of

arsenic at 200°, like that of sulphur and phosphorus, is accompanied by oxidation, by which arsenic trioxide is produced. As in the case of sulphur, no ionization occurs, and there is also no formation of ozone, which is produced by both sulphur and phosphorus. The product of oxidation of arsenic, either phosphorescently or with flame, always contains arsenic trioxide, just as some phosphoric oxide and sulphur trioxide are always produced in the parallel cases. The arsenic oxide, which may amount to $\frac{1}{3}$ th of the whole, seems to be formed directly from arsenic, since arsenious oxide cannot be oxidized under the conditions. It is assumed conversely that arsenic oxide is the sole original product, and this is mainly decomposed into arsenious oxide by a secondary change. The synthesis of arsenic trichloride without incandescence is unaccompanied by ionization.

H. Erdmann and R. Reppert found yellow arsenic to be unstable in **violet or ultra-violet light**, and in red-light it is slowly converted into metallic arsenic; **radium rays** have no effect on the speed of conversion. W. Thomson found that yellow arsenic is blackened almost instantly when exposed to a magnesium light. The rate of transformation in the dark is quickened by a rise of temp.; and at the temp. of liquid air, the yellow form remains unchanged for hours. A. L. Hughes found that arsenic exhibits a **photoelectric effect** giving off electrons when illuminated by the light from a mercury lamp. The longest wave-length effective in exciting the emission of photoelectrons from arsenic was $\lambda=2360$.

J. Piccard and E. Thomas⁵ discussed the colour of arsenic ions. According to R. Bunsen,⁶ arsenic and its compounds tinge the upper part of the colourless gas-flame pale blue. The **flame spectrum** was examined by V. Volpicelli, W. N. Hartley, W. N. Hartley and H. Ramage, C. de Watteville, etc. J. C. McLennan and co-workers said that the flame spectrum of arsenic consists of five lines 3266, 2860, 2780, 2350, and 2288 Å., and four bands with heads at 2634.5, 2570, 2503.5, and 2437.2 Å. G. Kirchhoff first examined the **spark spectrum** of arsenic, and observations have since been made by T. R. Robinson, W. A. Miller, J. Herpertz, E. O. Hulburt, W. Huggins, J. Plücker and J. W. Hittorf, R. Thalén, R. Capron, A. Ditte, G. Ciamician, R. J. Lang, O. W. Huntington, W. N. Hartley and co-workers, A. de Gramont, E. Demarçay, L. and E. Bloch, F. Exner and E. Haschek, A. Hagenbach and H. Konen, H. H. Pollock, J. M. Eder and E. Valenta, etc. The more prominent lines in the visible spectrum have the wave-length 6170 Å.; 6111 and 6022 in the orange-yellow; 5651 in the yellowish-green; 5559, 5499, and 5332 in the green. There are also numerous lines in the ultra-violet. A. de Gramont, and W. N. Hartley and H. W. Moss investigated *les raies ultimes* of the arsenic spectrum; E. O. Hulburt, and M. C. W. Buffam and H. J. C. Ireton, the under-water spark spectrum of the salts. The **arc spectrum** was examined by H. Kayser and C. Runge, and F. Exner and E. Haschek; the **ultra-violet spectrum**, by J. M. Eder, V. Schumann, R. J. Lang, L. and E. Bloch, W. A. Miller, and F. Exner and E. Haschek; and the **absorption spectrum** of the vapour by J. C. McLennan and A. B. McLay, J. N. Lockyer, A. Terenin, B. Rosen, A. E. Ruark and co-workers, and J. J. Dobbie and J. J. Fox. A. Terenin examined the spectrum of the light emitted by arsenic vapour at 1100°. According to J. Formanek, soln. of arsenic salts give no perceptible absorption spectrum, and there is no reaction with alkanna. The absorption arc spectrum of arsenic was found by J. C. McLennan and co-workers to have four, strong, univalent bands, the sharp edges of which were towards the red, and which occurred at wave-lengths 2634.5, 2570.0, 2503.5, and 2437.31 Å. The effect of *pressure* was examined by G. Ciamician, and W. J. Humphreys; and of *self-induction*, by A. de Gramont. The **series spectrum** was studied by J. C. McLennan and A. B. McLay, B. Rosen, G. Ciamician, T. van Lohuizen, and A. Fowler, but no series have yet been identified, though H. Kayser and C. Runge, and A. E. Ruark and co-workers observed lines with a constant difference in the spectra of arsenic, antimony, and bismuth. The **X-ray spectrum** was examined by E. Wagner, etc. The *K*-series was found by W. Duane and H. Fuh-Hu, H. R. Robinson and A. M. Cassie, A. Leide, Y. H. Woo,

R. Thoraeus, and M. Siegbahn to have the lines 1·17749 Å. for $\alpha_2\alpha'$; 1·17345 Å. for $\alpha_1\alpha$; 1·052 Å. for $\beta_1\beta$; and 1·038 Å. for $\beta_2\gamma$; and the *L*-series, by M. Siegbahn, H. Hirata, E. Friman, D. Coster and F. P. Mulder, M. Siegbahn and E. Friman, R. Thoraeus, A. Leide, L. H. Martin, and E. Hjalmar, to have the lines 9·6503 Å. for $\alpha_1\alpha$; 9·6173 Å. for $\alpha_2\alpha''$; and 9·3940 Å. for $\beta_1\beta$. D. Coster and F. P. Mulder also studied the *M*- and *N*-series; and A. L. Foley, the effect on the spectrum of exposing arsenic to X-rays or to ultra-violet light. J. E. P. Wagstaff gave $4\cdot36 \times 10^{12}$ for the **vibration frequency**, and W. Herz, $4\cdot53 \times 10^{12}$.

According to P. D. Foote and co-workers, the **ionization potential** of arsenic vapour is 11·54 volts; and the inelastic collision potential 4·69 volts, and the **resonance potential**, 4·7 volts. K. T. Compton gave 3·49 to 4·5 volts. The subject was discussed by G. Piccardi, and B. Rosen. C. G. Barkla and co-workers⁷ found that the *K*-series of **X-rays** of wave-length 1·172 Å., from the arsenic radiator, have the ratios of the mass absorption coeff., μ , divided by the density of the absorber for carbon, 2·49; magnesium, 19·3; iron, 134; nickel, 166; copper, 176; tin, 131·5; platinum, 105·7; and gold, 106·1; while W. H. Bragg and H. L. Porter found for aluminium, 23·6, and for zinc, 186. E. A. Owen found for the absorption coeff., μ , for gases at 0° and 760 mm., with the same rays, air, 0·00592; carbon dioxide, 0·00988; sulphur dioxide, 0·0548; and C. G. Barkla and V. Collier, for ethyl bromide, 0·028. T. E. Aurén gave 128 for the absorption coeff. when that of hydrogen is unity. The effect of X-rays in ejecting high-speed electrons from arsenic (oxide) was examined by R. Whiddington. A. L. Foley examined the effect of X-rays on arsenic, but with no definite results.

P. E. Shaw and C. S. Jex⁸ found the **triboelectricity** with glass is negative. According to H. Erdmann and R. Reppert, metallic arsenic is a conductor of electricity, but the yellow, grey, and brown forms of arsenic are non-conductors. A. Günther-Schulze, and K. F. Herzfeld studied the metallic conduction of arsenic. A. Matthiessen and M. von Bose found the **electrical conductivity** of metallic arsenic at 0° to be 0·00285 mho. E. Frank found the resistance of grey arsenic to be indefinitely large when cold, 40,000 ohms at 190°; 30,000 ohms at 200°; 15,000 ohms at 220°; 7000 ohms at 240°; and 4100 ohms at 255°. When kept for 20 minutes at 260°, the resistance was 3400 ohms; after 70 minutes, 1000 ohms; after 90 minutes, 250 ohms; and after 170 minutes, 11 ohms. The data were reviewed by A. Schulze. The **overvoltage** of hydrogen in a cell consisting of a platinum anode, arsenic cathode, and $N\text{-H}_2\text{SO}_4$ was found by V. B. Marquis to be 0·379–0·478 volt; and A. Thiel and W. Hammerschmidt gave 0·369 volt. G. Grube and H. Kelber found that with the arsenic cathode, hydrogen begins to come off in $2N\text{-H}_2\text{SO}_4$ at 0·284 volt; in $0\cdot1N\text{-H}_2\text{SO}_4$ at 0·358 volt; $N\text{-NaOH}$ at 1·016 volts; and in $0\cdot1N\text{-NaOH}$ at 0·948 volt—*vide infra*, arsine. A. Günther-Schulze studied the cathodic spluttering of arsenic. A. Matthiessen and M. von Bose gave for the **electrical resistance** at θ° between 12° and 100°, $R=R_0(1-0\cdot0038996\theta+0\cdot058879\theta^2)$. P. W. Bridgman found 0·0038 for the temp. coeff. of the electrical resistance; A. Matthiessen and M. von Bose gave 0·00076 between 0° and 95°. The coeff. is similar to that of a number of metals both with respect to magnitude and sign. Arsenic acquires neither the abnormal sign of the coeff. of its neighbours bismuth and antimony on the one side, nor the abnormally high coeff. of black phosphorus on the other. A. Matthiessen found the **thermoelectric power of arsenic** and lead to be –13·56 microvolts. N. C. Little gave the results indicated in Table VI for the **thermomagnetic effect** and the **galvanomagnetic effect** expressed in absolute electromagnetic units.

B. Neumann gave –0·550 volt for the absolute electrode potential of arsenic in $N\text{-AsCl}_3$. N. T. M. Wilsmore gave –0·293 volt for the **electrode potential** of arsenic in contact with a normal salt soln.—when the hydrogen electrode is zero. V. B. Marquis found the normal electrode potential of arsenic, calculated from the e.m.f. of the cell $\text{Hg, HgCl} | \text{LiCl in absolute alcohol} | 0\cdot176M\text{-AsCl}_3 \text{ in absolute alcohol} | \text{As} = 0\cdot153$ volt. This gave 0·040 volt for the arsenic-alcohol potential,

TABLE VI.—THERMOMAGNETIC AND GALVANOMAGNETIC EFFECTS IN ARSENIC, ANTIMONY, AND BISMUTH.

	Arsenic.	Antimony.	Bismuth.
Specific resistance	4.60×10^4	4.05×10^4	16×10^4
Thermal conductivity	3.68×10^6	1.67×10^6	$.81 \times 10^6$
Peltier heat against lead	3.80×10^5	0.78×10^5	-21.6×10^5
Thomson heat	3.33×10^3	2.34×10^3	0.94×10^3
Hall coefficient	4.52×10^{-2}	21.9×10^{-2}	-633×10^{-2}
Nernst coefficient	2.25×10^{-3}	17.6×10^{-3}	178×10^{-3}
Ettingshausen coefficient	1.75×10^{-7}	19.4×10^{-7}	350×10^{-7}
Righi-Leduci coefficient	4.15×10^{-7}	20.1×10^{-7}	-20.5×10^{-7}

0.111 volt for the arsenic-water potential, and 0.138 volt for the electrode potential. This places arsenic between hydrogen and copper in the **electrochemical series**. M. le Blanc found the electrochemical series to be : Pb, Sn, H, Sb, Bi, As, Cu, Ag, Hg ; and W. Ostwald, Pb, H, Sb, Bi, **As**, Cu, Hg, Ag, Pd. L. Kahlenberg and J. V. Steinle showed that the nature of the electrolyte determines the relative position of the metals in the electrochemical series—especially about the middle of the series. F. W. Bergstrom gave for the series in liquid ammonia : Pb, Bi, Sn, Sb, **As**, P, Te, Se, S, I. V. Bayerle found that the cathodic deposition of arsenic does not show reversible shifts on the polarization curves. B. Neumann gave -0.550 volt for the absolute electrode potential of arsenic against a normal chloride soln. ; J. von Zawidsky found -0.539 volt ; M. le Blanc and D. Reichenstein found the potentials of arsenic in soln. of potassium hydroxide, and sulphuric acid ; and N. A. Puschin, the potentials of alloys of arsenic with tin or lead. E. W. Washburn and E. K. Strachan gave 0.293 volt on the assumption that the potential of the normal iodine electrode is 0.256 volt, and R. Schumann, -0.2375 volt for a soln. of meta-arsenious acid : $\text{As} + 2\text{H}_2\text{O} = \text{HAsO}_2 + 3\text{H}$. L. Kahlenberg and J. V. Steinle found the electrode potential of various forms of arsenic in a soln. of arsenic trichloride, containing a gram eq. per litre, varied from 0.544 to 0.554 volt ; in arsenic triiodide, from 0.533 to 0.544 volt ; in arsenic tribromide, intermediate between that of the chloride and iodide—*viz.* 0.544 volt ; in *N*-NaCl sat. with arsenic trioxide, 0.360-0.365 volt ; in 0.5*N*-HCl sat. with copper arsenate, 0.367 volt ; with copper arsenite, 0.365 ; Paris green, 0.351 ; ammonium polysulphide, -0.065 volt ; 0.5 eq. arsenic pentasulphide in ammonium polysulphide, 0.052 volt ; and in soln. with 0.5, 0.25, and 0.125 mol. wt. of arsanilic acid per litre, respectively 0.152, 0.160, and 0.167 volt ; parahydroxyarsenic acid, respectively 0.090, 0.095, and 0.100 volt ; glycerine arsanilic acid, respectively 0.141, 0.146, and 0.152 ; secondary arsanilic acid, respectively 0.211, 0.223, and 0.234 volt ; and with acetoarsanilic acid, respectively 0.129, 0.141, and 0.152 volt. H. von Steinwehr gave 1.6×10^{-26} atm. for the **electrolytic solution pressure** $\text{As} \rightarrow \text{As}^{\dots}$. According to D. Reichenstein, arsenic dissolves from the anode in acidic and alkaline soln. ; and S. Berberich found that with a current of 40 milliampères, at room temp., a 100 per cent. yield of arsenious acid is formed in acidic or alkaline soln.—but in acidic soln., traces of arsenic acid are also formed. When the current is increased, a resistant film is formed on the anode, and this appears to increase the proportion of arsenic acid which is produced. C. Luckow found that arsenic can be **electro-deposited** as a dark brown or black mass resembling graphite, and at the cathode arsine is simultaneously evolved. A. Classen and M. A. von Reiss were unable to precipitate arsenic quantitatively by electrolysis from aq. soln., or in the presence of hydrochloric acid, ammonium oxalate, or alkali sulphides. Arsenic in every case was lost as arsine, or else a part remained in soln. undecomposed. G. Vortmann said that if the separated arsenic be collected by a mercury cathode, the loss as arsine is prevented. The electrodeposition of arsenic in the presence of other metals was examined by E. F. Smith and co-workers ; P. E. Jannasch and V. Wasowicz, L. K. Frankel,

O. Piloty, B. Neumann, N. Revay, H. J. S. Sand and J. E. Hackford, S. R. Trotman, A. Hollard and L. Bertiaux, A. Classen, S. C. Schmucker, L. W. McCay, etc. V. Bayerle found that the cathodic deposition of arsenic at the dropping mercury cathode is complex in both acidic and alkaline soln., and does not show reversible shifts on the polarization curve. V. Bayerle found that in the electrolysis of soln. of arsenic trioxide in hydrochloric acid a tenfold increase in the H-ion conc. raised the potential 0.120 volts, but changes in the deposition of arsenic by changing the conc. of the arsenic in the same acid are small. The main part of the current is concerned with the evolution of hydrogen, some arsine and arsenic may be formed. In the electrolysis of soln. of arsenic trioxide in alkali-lye, the reduction to arsenic at the cathode is probably a secondary effect produced by nascent hydrogen. The complexity of the cathode processes prevented conclusions being drawn as to the ionic behaviour of arsenious acid. T. Moore proposed to determine arsenic in soln. by converting it all into arsine electrolytically. This method was also used by T. E. Thorpe, and many others. E. T. Wherry found arsenic to be a poor **radio-detector**.

K. Honda⁹ found the **magnetic susceptibility** of diamagnetic arsenic to be -0.3×10^{-6} mass units at 18° - 200° ; and M. Owen gave -0.30×10^{-6} . B. H. Wilsdon examined the magnetic properties of arsenic. According to P. Pascal, in completely sat. derivatives, the diamagnetism of arsenic and of oxyarsenic groupings is considerably less than that of arsenic in higher states of oxidation, but these groupings have a constant magnetic individuality from one compound to the next, namely, $\text{As} = -209 \times 10^{-7}$; $\text{AsO} = -250 \times 10^{-7}$; $\text{AsO}_3 = -351 \times 10^{-7}$. These numbers form an arithmetical progression, which is taken as evidence that an atom of arsenic has the same degree of saturation in the arsines, oxyarsines, derivatives of arsenobenzene, organic arsenites, and minerals. The oxygen serves merely as a bond between the metalloids on the one hand and the metals, hydrogen, and organic radicals of the rest of the molecule on the other. If arsines are denoted as AsR_3 , the oxyarsines are $\text{AsR}_2(\text{OR})$, and arsenites $\text{As}(\text{OM})_3$. In derivatives of saturated arsenic, the diamagnetism of the following radicals forms an arithmetical progression also, but arsenic is excluded from it: $\text{As} = -430 \times 10^{-7}$; $\text{AsO} = -428 \times 10^{-7}$; $\text{AsO}_2 = -474 \times 10^{-7}$; and $\text{AsO}_3 = -518 \times 10^{-7}$. In the oxides of arsines, the cacodylates, the arsonates, and arsenates, therefore, the oxygen atom is distinctly similar to the oxygen of aldehydes and ketones, since it hardly represses the diamagnetism. The corresponding formulæ are then R_3AsO , $\text{R}_2\text{AsO}(\text{OH})$, $\text{RAsO}(\text{OH})_2$, and $\text{AsO}(\text{OH})_3$, which recall phosphonic and phosphoric acids. Arsenic in combination thus possesses two atomic susceptibilities according to the degree of saturation of the compounds.

§ 6. The Chemical Properties of Arsenic

In its chemical reactions, arsenic has the characteristics of an electronegative element, although in certain of its combinations it may act as an electropositive element—*e.g.* in arsenic sulphate, $\text{As}_2(\text{SO}_4)_3$. Arsenic replaces phosphorus, and antimony in the oxides, chlorides and sulphides at 200° or 300° . On the contrary, with the triphenyl compounds this order of replacement is reversed—triphenyl stibine, $\text{Sb}(\text{C}_6\text{H}_5)_3$, is decomposed by arsine, and triphenylarsine, $\text{As}(\text{C}_6\text{H}_5)_3$, is simply decomposed by phosphorus at 300° . Yellow arsenic like yellow phosphorus is a strong reducing agent. The garlic-like odour of the fumes from burning arsenic is supposed by P. N. Laschtschenko¹ to be characteristic of yellow arsenic because when a sealed tube, containing the vap. of arsenic above the transition temp., bursts, a strong odour of garlic was perceived.

W. T. Cooke² observed that the vap. density of arsenic in an atm. of **argon** and **helium** is quite normal, and there is no sign of chemical change. F. Fischer and F. Schrötter observed that no combination occurs when arsenic is sparked beneath liquid argon. W. Ramsay and J. N. Collie observed no reaction with **helium** at a red-heat. According to A. J. J. Vandevelde, and H. Reckleben and J. Scheiber, arsenic does not unite directly with **hydrogen**; the element can be sublimed in an atm. of that gas without change; and J. W. Retgers' statement that a solid hydride, AsH , is formed is wrong, for the product is an allotropic modification of arsenic. J. N. Lockyer observed no occlusion of hydrogen by arsenic. C. R. Fresenius and C. H. L. von Babo observed no arsine is formed by the passage of hydrogen over heated arsenic. If the gas appears to be arsenical, it is due to the mechanical transport of arsenic by the hydrogen, and this arsenic can be filtered from the hydrogen by cotton-wool. W. Ipatieff and co-workers found that when arsenic is heated with hydrogen and water under press., a little arsine and arsenious acid are formed. Hydrogen arsenides can be readily formed indirectly. Hydrogen has no action on a carbon disulphide soln. of yellow arsenic. F. H. Newman studied the adsorption of hydrogen by arsenic in discharge tubes. T. Panzer found that arsenic is not attacked in moist hydrogen.

T. Bergman found that dry **air** has no action on arsenic, and a similar observation was made by P. A. von Bonsdorff; and T. Panzer showed that arsenic is not attacked by air dried by phosphorus pentoxide. Amorphous arsenic does not appear to change on exposure to air; and crystalline arsenic retains its lustre in dry air, but in moist air it acquires a bronze colour and matte surface, and, in some cases, disintegrates into a black powder. The change takes place more quickly at 30° – 40° . R. Engel also found that vitreous arsenic does not change in moist air, but the crystalline form is rapidly oxidized. According to J. J. Berzelius, J. A. Buchner, and T. Thomson, some specimens seem to retain their lustre and solidity without increasing in weight. If arsenic has been long exposed to dry

air, it may be kept longer without tarnishing in moist air than is the case with fresh arsenic. The early observers thought that arsenic suboxide is formed when arsenic is exposed to moist air, but A. Geuther did not agree with this—arsenic trioxide was always produced. T. Panzer said that the oxidation of arsenic exposed to air proceeds more quickly in light than in darkness; an arsenic mirror suffered no perceptible change after a year's exposure in darkness, but an arsenic mirror was changed by a few days' exposure in light, forming arsenic trioxide. M. François and L. Seguin found that with fly-papers containing metallic arsenic, air and moisture oxidize the arsenic to arsenious acid—3 per cent. was so oxidized in 48 hrs. When arsenic is heated in air, it burns, emitting a reddish fume having an odour of garlic, and it forms arsenic trioxide; at a higher temp., the arsenic burns with a pale blue flame. This occurs, for example, when arsenic is held in the flame of a candle, and when removed from the flame, the arsenic smoulders away emitting a brown smoke. Arsenic which has been sublimed in hydrogen also smoulders in a similar way. J. K. Mitchell assumed that a suboxide is formed as an intermediate stage in the oxidation, because arsenic trioxide does not emit the garlic odour, and metallic arsenic does not volatilize at the temp at which the smouldering with the emission of brown fumes occurs. C. F. Schönbein suggested that the garlic-odour may be due to an allotropic form of arsenic trioxide. Arsenic burns vigorously in **oxygen**, and, according to H. B. Baker and H. B. Dixon, the thorough desiccation of the oxygen has no perceptible influence on this reaction. M. Thiele found that oxygen precipitates brown arsenic from a soln. of yellow arsenic in carbon disulphide. According to H. J. Emeléus, arsenic undergoes a slow luminous oxidation between 260° and 300°. This glow occurs in pure oxygen only on reducing the press. to a limiting value, which is analogous with the glow of phosphorus. The influence of temp. on the glow-pressure is largely influenced by the dimensions of the apparatus, occurring most readily when conditions favour diffusion and consequent removal of the oxidation product. In a gas-stream, arsenic glows at approximately the same temp. in air as in oxygen. The reduction of press. appears to produce the glow by accelerating the diffusion of the oxide. C. F. Schönbein found that **ozone** or ozonized turpentine or ether oxidizes arsenic to arsenic acid.

According to P. A. von Bonsdorff, at ordinary temp. and out of contact with air, arsenic undergoes no alteration when immersed in **water** freed from air by boiling; and J. W. Mellor observed that purified water and crystallized arsenic in a sealed glass tube suffered no detectable change during ten years. P. A. von Bonsdorff found that arsenic trioxide is quickly formed. H. M. Elsey found that there is a probable reaction: $4\text{As} + 3\text{H}_2\text{O} = \text{As}_2\text{O}_3 + 2\text{AsH}_3$. Water condenses on the surface of pulverulent arsenic exposed in air; and P. Orfila said that if arsenic covered with water be exposed to air at ordinary temp., it forms arsenic trioxide; the water absorbs oxygen from the air, transfers it to the arsenic, and dissolves the arsenic trioxide as it forms; if air be blown for ten minutes through the water holding powdered arsenic in suspension, the filtered liquid contains arsenic trioxide in soln.; P. F. G. Boullay, E. Hirschsohn, and H. Schwabe reported that when a mass of powdered arsenic—say 4 kgrms.—is exposed to air, it becomes heated, and may be inflamed; if the combustion be stopped by moistening with water, it may start again in the course of a few days. A. W. Büchner, however, said that this development of heat occurs only when the arsenic is moistened during its pulverization. W. T. Cooke found that in the absence of air, amorphous arsenic is but slightly attacked by boiling water; and when air was aspirated through the boiling water, only 0.0010 grm. of the element was dissolved by 50 c.c. of water, thus showing that the action is very little influenced by the presence of air. When crystallized arsenic is similarly treated, only 0.0025 grm. of arsenic is dissolved in about 1½ hrs. by 50 c.c. of water. If air be present, 0.0233 grm. was dissolved in the same time. If water were concerned in the oxidation of the arsenic, the formation of arsine might be anticipated: $2\text{As} + 3\text{H}_2\text{O} = \text{As}_2\text{O}_3 + 6\text{H}$; and $2\text{As} + 6\text{H} = 2\text{AsH}_3$; but this gas was never observed. T. Panzer also said that the oxidation

by moist air is due to the intervention of free oxygen, and not as a result of the decomposition of water. P. Orfila, however, did find that with boiling water some brown arsenic hydride, AsH_3 , is formed. H. V. Regnault observed that very little hydrogen is produced when a mixture of the vapours of arsenic and water is passed through a red-hot tube. The presence of alkali in the water favours the attack. W. T. Cooke showed that in the absence of air, dil. soln. of **sodium hydroxide** have a slightly greater action on amorphous arsenic than water; the action increases with the conc. of the alkali; and is not influenced by the presence of air; with crystalline arsenic, the action is very slight in the absence of air, but direct oxidation occurs in the presence of air. P. L. Chastaing said that a dil. soln. of sodium or potassium hydroxide attacks arsenic more rapidly in red light than it does in violet light. A. F. Gehlen, and E. Soubeiran found that when a mixture of alkali hydroxide and arsenic is heated, but not to redness, the alkali arsenide and arsenite is formed and hydrogen is evolved. According to C. F. Schönbein, **hydrogen dioxide** oxidizes arsenic to arsenic pentoxide; and L. J. Thénard noted a vigorous action with powdered arsenic.

According to H. Moissan,³ **fluorine** vigorously reacts with arsenic at ordinary temp. with incandescence forming a mixture of arsenic tri- and penta-fluorides; and J. Davy, and J. B. A. Dumas found that **chlorine** also reacts with arsenic with incandescence, forming the trichloride. Liquid chlorine was found by V. Thomas and P. Dupuis to react with incandescence near its b.p., forming a white cloud of arsenic trichloride. M. Thiele found that chlorine first precipitates brown arsenic from a soln. of yellow arsenic in carbon disulphide, and it then converts the brown arsenic into the trichloride. G. S. Sérullas obtained arsenic tribromide by the action of **bromine**; and A. Plisson observed that arsenic unites with **iodine** when the powdered mixture is warmed, forming the triiodide. G. E. Linck found that when arsenic is added to a carbon disulphide soln. of iodine or bromine, a reddish-brown powder separates out. H. Moissan found that arsenic reacts energetically with **iodine fluoride**. K. A. Hofmann and co-workers found the activity of **ammonium chloride** vapour on arsenic is greater than that of dry **hydrogen chloride** at 250°–350°. R. Napoli said that neither **hydrofluoric acid** nor **hydrochloric acid** attacks arsenic in the absence of air, but if air be present, the trihalide is formed; **hydrobromic acid**, and **hydriodic acid** act in consequence of their easy dissociation into the halogen, etc. M. Thiele observed no reaction between hydrochloric acid and yellow arsenic dissolved in carbon disulphide. W. S. Hendrixson, and F. A. Gooch and J. C. Blake observed that finely divided arsenic is oxidized by **chloric acid** or **bromic acid**, to form arsenic. Very dil. chloric acid has no action. A. F. de Fourcroy and L. N. Vauquelin observed that a mixture of arsenic and **potassium chlorate** detonates by percussion; and J. W. Slater found that a boiling soln. of the chlorate is reduced by arsenic, forming the alkali arsenate and chloride. K. A. Hofmann found that in the presence of a trace of osmium tetroxide, neutral or slightly acid soln. of potassium chlorate oxidize arsenic to arsenic acid.

J. J. Berzelius,⁴ and A. Gélis observed that arsenic unites directly with **sulphur** when a mixture of the two elements is heated. W. Guertler studied the affinity of arsenic for sulphur. M. Thiele found that **hydrogen sulphide** precipitates arsenic sulphide from a carbon disulphide soln. of yellow arsenic; O. Brunn, that hydrogen sulphide at 230° slowly converts arsenic into the trisulphide—*vide infra*, arsenic disulphide; and O. Ruff, that arsenic interacts with hydrogen sulphide in the presence of aluminium chloride, forming arsenic trisulphide and hydrogen chloride. H. Moissan and P. Lebeau found that **sulphur hexafluoride** can be distilled in the presence of arsenic without change. C. Heumann and P. Köchlin showed that arsenic reacts with **sulphur monochloride**, forming arsenic trichloride and sulphide or sulphur; and **sulphuryl chloride** reacts with powdered arsenic in the cold; and when heated, sulphur dioxide and arsenic trichloride are produced. H. Schiff said that dry **sulphur dioxide** reacts only with the vapour of arsenic, forming arsenic

sulphide, and trioxide; while C. Geitner observed that in a sealed tube at 200°, a mixture of arsenic and an aq. soln. of sulphur dioxide produces sulphuric acid and arsenic trioxide—some sulphur separates out, but no arsenic sulphide is formed. M. Thiele found that sulphur dioxide precipitates a little brown arsenic from a carbon disulphide soln. of yellow arsenic. G. Aimé found that **sulphur trioxide** oxidizes arsenic to the trioxide. R. H. Adie found that boiling conc. **sulphuric acid** dissolves arsenic with the evolution of sulphur dioxide and the formation of arsenic trioxide. The reaction begins at about 110°, and no hydrogen sulphide or arsine is formed. M. Thiele observed no reaction between sulphuric acid and yellow arsenic dissolved in carbon disulphide. M. G. Levi and co-workers observed the formation of arsenic acid by the action of a soln. of **alkali persulphate**. C. Heumann and P. Köchlin represented the reaction with **chlorosulphonic acid** by the equation: $2\text{As} + 6\text{HSO}_3\text{Cl} = 2\text{AsCl}_3 + 3\text{SO}_2 + 3\text{H}_2\text{SO}_4$. J. J. Berzelius⁵ found that molten **selenium** slowly dissolves arsenic, forming a selenide, and **hydrogen selenide** also readily reacts with arsenic. J. J. Berzelius⁶ also found that arsenic similarly reacts with **tellurium**, and with **hydrogen telluride**. E. B. Hutchins found that hot soln. of **telluric acid** attack arsenic.

Arsenic has no perceptible action on **nitrogen**; F. H. Newman⁷ studied the adsorption of nitrogen in discharge tubes; G. Gore, E. C. Franklin and C. A. Kraus, and C. Hugot found that arsenic is not attacked by liquid **ammonia**; C. A. Kraus observed complex ion formation with arsenic in ammonia soln. K. A. Hofmann and co-workers observed that ammonium chloride vapour at 250°–350° acts on arsenic much like an acid. J. J. Sudborough found that arsenic is attacked by **nitrosyl chloride** in the cold. Both **nitric acid**, and **aqua regia** oxidize arsenic with great vigour, forming arsenic trioxide and arsenic acid; if the nitric acid be dilute, added J. Personne, a part of the acid is reduced to ammonia. M. Thiele observed that yellow arsenic in carbon disulphide soln. is completely oxidized by nitric acid. According to P. Askenasy and co-workers, arsenic is not oxidized by nitric acid of a conc. up to 40 per cent., and no nitric oxide is formed by 50 per cent. HNO_3 in the cold, but with the boiling acid, there is a feeble reaction. In the absence of nitric acid, arsenic with an oxygen press. of 20 atm. and at 200° forms only arsenious acid. T. Curtius and A. Darapsky found that a 29 per cent. soln. of **hydrazoic acid** dissolves arsenic with the liberation of hydrogen, and, on evaporation, arsenic trioxide is deposited. C. C. Palit and N. R. Dhar observed but a slight action by 13 and 26 per cent. **nitric acid** at ordinary temp., and only a slight formation of nitrous acid. E. J. Maumené, and J. Personne said that some ammonia is formed when nitric acid acts on arsenic. F. W. Bergstrom found arsenic to be slightly attacked by **potassium amide**, and by **ammonium nitrate** soln. J. W. Slater found that a mixture of **potassium nitrate** and arsenic detonates vigorously when ignited; and a boiling soln. of **barium nitrate** dissolves arsenic slowly forming arsenate and arsenic trioxide. G. Landgrebe, and J. V. Janowsky found that arsenic phosphide, or phosphorus arsenide, is formed when a mixture of arsenic and **phosphorus** is heated to dull redness. O. Ruff observed that arsenic reacts with phosphorus in the presence of aluminium trichloride, forming a red substance which is decomposed by water giving a violet black substance with the composition PAs_4O_2 . According to H. Moissan, a mixture of **phosphorus trifluoride** and arsenic can be distilled without reaction. F. Krafft and R. Neumann found that **phosphorus trichloride** does not react with arsenic, but with 12 hrs.' heating at 200°, arsenic trichloride and phosphorus are quantitatively formed; with **phosphorus pentachloride**, B. Reinitzer and H. Goldschmidt observed the formation of arsenic and phosphorus trichlorides; while **phosphoryl chloride** dissolves arsenic, and with a prolonged heating at 250°, arsenic and phosphorus trichloride and pyrophosphoryl chloride are formed. F. Krafft and R. Neumann observed that with **phosphorus pentoxide**, arsenic trioxide and phosphorus are formed at 290°; and **phosphorus tetrithexasulphide** reacts in an analogous manner. M. Thiele observed no reaction between a carbon disulphide soln. of

yellow arsenic and **phosphoric acid**. T. Bergman, A. F. Gehlen, and A. Descamps observed that alloys of **antimony** and arsenic can be readily produced; and C. M. Marx, and A. Descamps obtained alloys with **bismuth**. A. Ditte observed that **vanadium pentoxide** is reduced by arsenic. F. E. Brown and J. E. Snyder observed no reaction between arsenic and **vanadium oxytrichloride**.

No direct chemical action between arsenic and **boron** has been observed; and similar remarks apply to **carbon**, and to **silicon**. E. Guenez⁸ observed that when arsenic is heated with **cyanogen iodide**, arsenic tricyanide is formed. V. Auger observed that when a mixture of arsenic and **carbon tetrachloride** is heated in a sealed tube at 160°, arsenic trichloride and carbon hexachloride are formed. G. E. Linck found yellow arsenic to be soluble in **carbon disulphide**, and H. Erdmann and M. von Unruh found that 100 c.c. of carbon disulphide dissolved

	-80°	-60°	-15°	0°	12°	18°-20°	46°
As . . .	0	0.8-1.0	2.0-2.5	3.8-4.0	5.5-6.0	7.5-8.0	11 grms.

H. Erdmann and R. Reppert found that yellow arsenic is precipitated when alcohol is added to soln. of yellow arsenic in carbon disulphide; and the observation was repeated by M. Thiele who also found that ether acts similarly, while with benzene, and chloroform, brown arsenic is precipitated; and with ligroin, yellow arsenic precipitates. F. W. Bergstrom observed that arsenic showed no sign of reaction with liquid ammonia soln. of cyanide of potassium or aluminium, over a long period of time. G. E. Linck also found yellow arsenic to be soluble to a less extent in **benzene, glycerol, and fatty oils**.

As A. Descamps showed, most of the **metals** unite with arsenic, forming alloys or definite arsenides—*vide infra*—and W. Spring believed that a high press. could bring about the combination of an intimate mixture of powdered arsenic and powdered copper, silver, zinc, cadmium, tin, or lead. Sodium arsenide is one of the primary products of the action of **sodium hydroxide** on arsenic, and the hydrolysis of this may be the source of arsine (*q.v.*). According to H. Erdmann and R. Reppert, yellow arsenic reduces a soln. of **copper sulphate**, and M. Thiele obtained a mixed precipitate of copper and copper arsenide from a soln. of a copper salt—sulphate, nitrate, or chloride; A. Descamps noted the reduction of copper salts by arsenic. C. Strzyzowsky said that Fehling's soln. is reduced by arsenic at 50°. M. Kohn represented the reaction in ammoniacal soln. by $6\text{CuSO}_4 + 2\text{As} + 6\text{NH}_4\text{OH} = 2(\text{NH}_4)_3\text{AsO}_3 + 3\text{Cu}_2\text{SO}_4 + 3\text{H}_2\text{SO}_4$; the cuprous salt is then reduced further: $3\text{Cu}_2\text{SO}_4 + 2\text{As} + 6\text{NH}_4\text{OH} = 2(\text{NH}_4)_3\text{AsO}_3 + 3\text{H}_2\text{SO}_4 + 6\text{Cu}$, and the copper reacts with the excess of arsenic, forming arsenide. Arsenic reacts with soln. of **silver nitrate**, and silver contaminated with a little arsenic is precipitated; likewise also with a soln. of **gold chloride**. A. Descamps also found that ordinary arsenic reduces auric chloride, forming gold arsenides. H. Erdmann and R. Reppert observed that **mercurous nitrate** is reduced by yellow arsenic to mercury contaminated with a little arsenic; and M. Thiele obtained an analogous result with the same salt and with **mercuric chloride**. M. J. B. Orfila also obtained mercury by the action of arsenic at ordinary temp. on soln. of mercurous nitrate and sulphate. J. W. Slater found that arsenic reduces **potassium permanganate** to manganese dioxide. R. Böttger found that arsenic reduces soln. of **ferric chloride or sulphate**. M. Thiele found that yellow arsenic reduces an aq. soln. of **platinum tetrachloride** to the metal; likewise also a soln. of **palladous chloride**, and **sodium rhodium chloride**. L. Kahlenberg and J. V. Steidle found that with an aq. soln. of silver nitrate arsenic reacts: $3\text{AgNO}_3 - 4\text{As} = 2\text{As}_2\text{O}_3 + 3\text{Ag} + 3\text{NO}$; but the reaction is not completed in several months; with **silver nitrite**: $6\text{AgNO}_2 + 2\text{As} = \text{As}_2\text{O}_3 + 6\text{Ag} + 3\text{NO}_2 + 3\text{NO}$; with **silver sulphate**: $3\text{Ag}_2\text{SO}_4 + 2\text{As} + 3\text{H}_2\text{O} = 6\text{Ag} + 3\text{H}_2\text{SO}_4 + \text{As}_2\text{O}_3$; **silver acetate**, $6\text{CH}_3\text{COOAg} + 2\text{As} + 3\text{H}_2\text{O} = 6\text{CH}_3\text{COOH} + 6\text{Ag} + \text{As}_2\text{O}_3$; similarly with **silver tartrate**; with **potassium silver cyanide**: $3\text{KAgCy}_2 + \text{As} = \text{K}_3\text{AsCy}_6 + 3\text{Ag}$; and with **silver fluoride**: $6\text{AgF} + 2\text{As} + 3\text{H}_2\text{O} = 6\text{HF} + 6\text{Ag} + \text{As}_2\text{O}_3$. In pyridine soln., silver nitrate reacts as in the case of aq. soln., but the

reaction is complete within a week; with silver chloride, $3\text{AgCl} + \text{As} = \text{AsCl}_3 + 3\text{Ag}$; and with silver sulphate, the black precipitate formed seems to be due to light. Arsenic does not replace the silver in soln. of silver palmitate or stearate in acetone and anhydrous ether. Aq. soln. of mercuric nitrate react with arsenic: $3\text{Hg}(\text{NO}_3)_2 + 8\text{As} = 4\text{As}_2\text{O}_3 + 6\text{NO} + 5\text{Hg}$; mercurous nitrate: $3\text{HgNO}_3 + 4\text{As} = 2\text{As}_2\text{O}_3 + 3\text{Hg} + 3\text{NO}$; mercurous sulphate: $3\text{Hg}_2\text{SO}_4 + 2\text{As} + 3\text{H}_2\text{O} = 3\text{H}_2\text{SO}_4 + \text{As}_2\text{O}_3 + 6\text{Hg}$; mercuric cyanide: $3\text{HgCy}_2 + 2\text{As} + 3\text{H}_2\text{O} = 6\text{HCy} + \text{As}_2\text{O}_3 + 3\text{Hg}$; mercuric acetate: $3(\text{CH}_3\text{COO})_2\text{Hg} + 2\text{As} + 3\text{H}_2\text{O} = 3\text{Hg} + \text{As}_2\text{O}_3 + 6\text{CH}_3\text{COOH}$; and mercuric chloride (or bromide): $3\text{HgCl}_2 + 2\text{As} + 3\text{H}_2\text{O} = 6\text{HCl} + \text{As}_2\text{O}_3 + 3\text{Hg}$. Pyridine soln. of mercuric stearate give a grey deposit of mercury; and with a soln. of mercuric palmitate in anhydrous ethyl alcohol, a white precipitate, probably of mercurous palmitate, is formed. An aq. soln. of cupric chloride reacts: $4\text{CuCl}_2 + 2\text{As} + 3\text{H}_2\text{O} = 2\text{Cu} + 2\text{CuCl} + 6\text{HCl} + \text{As}_2\text{O}_3$; cupric sulphate: $3\text{CuSO}_4 + 2\text{As} + 3\text{H}_2\text{O} = 3\text{H}_2\text{SO}_4 + 3\text{Cu} + \text{As}_2\text{O}_3$; copper nitrate, acetate, and tannate act like the salts of mercury; copper phosphate: $\text{Cu}_3(\text{PO}_4)_2 + 2\text{As} + 3\text{H}_2\text{O} = 2\text{H}_3\text{PO}_4 + \text{As}_2\text{O}_3 + 3\text{Cu}$; copper arsenite: $\text{Cu}_3(\text{AsO}_3)_2 + 2\text{As} = 3\text{Cu} + 2\text{As}_2\text{O}_3$; copper arsenate: $\text{Cu}_3(\text{AsO}_4)_2 + 2\text{As} = 3\text{Cu} + \text{As}_2\text{O}_3 + \text{As}_2\text{O}_5$; and an aq. soln. of copper glycine lost all its copper. Soln. of copper abietate and oleate in xylene or toluene gave precipitates of copper without arsenic passing into soln.; copper stearate and palmitate in chloroform or ether gave small deposits of copper. Molten copper oleate alone at $120^\circ\text{--}130^\circ$ gives a precipitate of copper, but in presence of arsenic the precipitate is greater, but no arsenic passes into soln. Aq. soln. of platinum tetrachloride react: $3\text{PtCl}_4 + 4\text{As} + 6\text{H}_2\text{O} = 3\text{Pt} + 2\text{As}_2\text{O}_3 + 12\text{HCl}$; gold chloride: $2\text{AuCl}_3 + 2\text{As} + 3\text{H}_2\text{O} = 2\text{Au} + \text{As}_2\text{O}_3 + 6\text{HCl}$; ferric chloride: $6\text{FeCl}_3 + 2\text{As} + 3\text{H}_2\text{O} = 6\text{FeCl}_2 + \text{As}_2\text{O}_3 + 6\text{HCl}$; cadmium sulphate: $3\text{CdSO}_4 + 8\text{As} = 3\text{CdS} + 4\text{As}_2\text{O}_3$. Arsenic gave white precipitates with aq. soln. of zinc chloride, aluminium sulphate, and lead nitrate; and no perceptible effect with soln. of manganese, cobalt, and nickel sulphates. H. Lessheim and co-workers discussed the co-ordination number of arsenic in its complex salts.

Some reactions of analytical interest.—Arsenic yields two series of salt, arsenious and arsenic salts derived respectively from arsenic trioxide and pentoxide. Neither of these salts gives a precipitate with hydrochloric acid. If **hydrogen sulphide** be passed into acidic soln. of arsenic trioxide, yellow flocculent arsenic trisulphide is precipitated: $2\text{AsCl}_3 + 3\text{H}_2\text{S} = 6\text{HCl} + \text{As}_2\text{S}_3$. The precipitate is insoluble in acids, even in boiling hydrochloric acid (1 : 1), but a protracted boiling with the conc. acid slowly forms volatile arsenic trichloride. This enables arsenic to be separated from other elements which do not form chlorides volatile under these conditions—*vide infra*. The sulphide is oxidized by conc. nitric acid to arsenic and sulphuric acids; it is also soluble in an ammoniacal soln. of hydrogen dioxide, and in a soln. of alkali hydroxide or sulphide, or in one of ammonium carbonate. The solubility is due to the formation of soluble alkali thioarsenites: $\text{As}_2\text{S}_3 + 6\text{KOH} = 3\text{H}_2\text{O} + \text{As}(\text{OK})_3 + \text{As}(\text{SK})_3$; or $\text{As}_2\text{S}_3 + 3(\text{NH}_4)_2\text{S} = 2\text{As}(\text{SNH}_4)_3$ —*vide infra*, the action of hydrogen sulphide on arsenic acid. The reaction may be reversed by treating the soln. with hydrochloric acid. Hydrogen sulphide gives no precipitate with normal arsenites because of the formation of the soluble thioarsenites: $\text{As}(\text{OK})_3 + 3\text{H}_2\text{S} \rightleftharpoons 3\text{H}_2\text{O} + \text{As}(\text{SK})_3$. If enough acid be present, the soluble thioarsenite is not formed. When hydrogen sulphide is passed into a cold, acidic soln. of arsenic pentoxide, the liquid remains clear for some time, and gradually becomes turbid owing to the separation of sulphur as the arsenic pentoxide is reduced to the trioxide and the formation of arsenic trisulphide: $2\text{H}_3\text{AsO}_4 + 5\text{H}_2\text{S} = 8\text{H}_2\text{O} + 2\text{S} + \text{As}_2\text{S}_3$; this reaction proceeds much more quickly if the soln. is warm. If a great excess of hydrochloric acid be present, it is possible that arsenic pentachloride is formed since the hydrogen sulphide precipitates from the cold soln. arsenic pentasulphide; with a warm soln. a mixture of the tri- and penta-sulphides is precipitated. If the acid soln. of arsenic acid be heated with a little sulphur dioxide or ammonium iodide before passing in the hydrogen sulphide, the arsenic acid is reduced to

arsenious acid, and this forming arsenic trichloride behaves as indicated above. Arsenic pentasulphide like the trisulphide is insoluble in hydrochloric acid, but is soluble in a soln. of alkali hydroxide or sulphide, or in one of ammonium carbonate. This is due to the formation of soluble sulphoarsenate: $\text{As}_2\text{S}_5 + 6\text{NaOH} = 3\text{H}_2\text{O} + \text{AsS}(\text{SNa})_3 + \text{AsS}(\text{ONa})_3$. Hydrochloric acid reverses these reactions. The pentasulphide is oxidized by nitric acid and by an ammoniacal soln. of hydrogen dioxide. J. F. Lassaigne⁹ said that one part of arsenic trioxide in 10,000 parts of water gives a yellow coloration with hydrogen sulphide; and if hydrochloric acid be present, the coloration is produced by one part in 80,000 parts of soln.; H. Reinsch gave 1 in 90,000 parts; R. Brandes and G. Ebeling, 1 in 160,000 parts; C. H. Pfaff, 1 in 24,000; T. G. Wormley, 1 in 13,200 parts; and F. Jackson, 1 in 1,024,000 parts. Some of these estimates must be rather poor shots. If **ammonium sulphide** be added to neutral, or alkaline soln. of arsenic trioxide, no precipitation of the sulphide occurs until an excess of acid has been added. Similar remarks apply to soln. of arsenic pentoxide. R. Schiff and N. Tarugi also noted that **ammonium thioacetate** gives a precipitate of arsenic trisulphide with acidified soln. of arsenic trioxide, or pentoxide. Arsenic trisulphide is precipitated by **sodium thiosulphate** completely from acidified soln. of arsenic trioxide; and arsenic pentasulphide from acidified soln. of arsenic pentoxide.

A soln. of **iodine** is decolorized by arsenious acid, the latter being oxidized to arsenic acid. The reaction is not quantitative in acid soln., but in alkaline soln. it proceeds: $\text{As}(\text{OH})_3 + \text{NaHCO}_3 + \text{I}_2 = \text{NaI} + \text{HI} + \text{CO}_2 + \text{AsO}(\text{OH})_3$. When **potassium iodide** is added to a hot soln. of arsenic trioxide in conc. hydrochloric or sulphuric acid, a red precipitate of arsenic triiodide is deposited. Neutral soln. of the arsenites with **silver nitrate** give a yellow precipitate of silver orthoarsenite soluble in nitric acid and aq. ammonia; arsenates under similar conditions give a chocolate-brown precipitate of silver arsenate. The precipitate from acidic soln. is the hydro-arsenite so that an alkali preferably ammonia should then be added to make the soln. neutral; or better, employ ammoniacal silver nitrate. A. Marcet discussed the use of silver nitrate in detecting minute quantities of arsenic. Aq. soln. of arsenic trioxide are not precipitated by soln. of **copper sulphate**, but if the soln. be alkaline, greenish-yellow cupric hydroarsenite is precipitated. The precipitate dissolves in alkali-lye, and when the soln. is boiled, red cuprous oxide is deposited. J. F. Lassaigne said that one part of arsenic trioxide in 160,500 parts of water gives a precipitate with ammoniacal soln. of copper sulphate; R. Brandes and G. Ebeling, 1 in 250,000; and P. Harting, 1 in 12,000. P. Harting found that **lime-water** gives a precipitate with up to one part of arsenic trioxide in 4000 parts of water; and J. F. Lassaigne said 1 in 5000. **Magnesia mixture**—a soln. of ammonium and magnesium chlorides in aq. ammonia—gives no precipitate with dil. soln. of arsenites, but with arsenates, a white crystalline precipitate of magnesium ammonium arsenate is produced: $\text{Na}_2\text{HAsO}_4 + \text{MgCl}_2 + \text{NH}_3 = 2\text{NaCl} + \text{NH}_4\text{O} \cdot \text{AsO} : \text{O}_2 : \text{Mg}$. The precipitate is insoluble in aq. ammonia, and when ignited it forms magnesium pyroarsenate, $\text{Mg}_2\text{As}_2\text{O}_7$. These reactions are utilized in the quantitative determination of arsenic. R. Brandes and G. Ebeling said that a green coloration is produced by **potassium chromate** when one part of arsenic trioxide is present in 1000 parts of water. An excess of **ammonium molybdate** with a boiling nitric acid soln. of an arsenate gives a yellow precipitate of ammonium arsenomolybdate: $\text{H}_3\text{AsO}_4 + 12(\text{NH}_4)_2\text{MoO}_4 + 21\text{HNO}_3 = 12\text{H}_2\text{O} + 21\text{NH}_4\text{NO}_3 + (\text{NH}_4)_3\text{AsO}_4 \cdot 12\text{MoO}_3$. When a few drops of an arsenite soln. are added to conc. hydrochloric acid, and then a little stannous chloride, the soln. becomes brown and then black owing to the separation of metallic arsenic: $2\text{AsCl}_3 + 3\text{SnCl}_2 = 3\text{SnCl}_4 + 2\text{As}$. The reaction proceeds more quickly on warming, and it does not occur in dil. soln.—*vide infra*, arsenic trichloride. A. Bettendorff's reagent is essentially **stannous chloride** which reduces soln. of arsenious acid (*q.v.*); E. Deussen, and E. Rupp and E. Muschiol recommended **calcium hypophosphate** as a precipitant.

According to A. Pinkus and F. Martin, arsenious and arsenic salts give no precipitate with **cupferron** (nitrosophenylhydroxylamine).

Compounds containing arsenic may be reduced in acid soln. by means of nascent hydrogen, forming arsine, AsH_3 . With sulphides, the reduction is slow: $\text{As}_2\text{S}_3 + 12\text{H} = 3\text{H}_2\text{S} + 2\text{AsH}_3$; but oxides are quickly reduced at ordinary temp.: $\text{As}_2\text{O}_3 + 12\text{H} = 3\text{H}_2\text{O} + 2\text{AsH}_3$. The hydrogen is produced by zinc and sulphuric acid, or electrolytically. The arsine which is given off enables as little as 0.007 mgrm. of arsenic to be detected with certainty. If the arsine along with hydrogen be passed through a heated glass it is decomposed into hydrogen and arsenic. The arsenic is deposited as a brownish-black mirror on the sides of the glass tube just beyond the place where it was heated. Details of the required manipulation are described in works devoted to analytical chemistry. This test—*Marsh's test*—was devised by J. Marsh about 1836. Numerous modifications have been suggested. By making a series of standard "mirrors" with known amounts of arsenic, and working under uniform conditions, the test can be made quantitative. Blank tests are made to be sure that all the reagents are free from arsenic, and antimony. Antimony also gives a mirror when antimonal compounds are treated in a similar way—*vide infra*, arsine, and stibine. The mirrors or crusts produced by the two elements are distinguished in the following manner:

(1) Arsenic is deposited a short distance from the flame, while the antimony is deposited close to the flame and on both sides of it. (2) The arsenic deposit is in two portions—glittering black, and brown; while the antimony stain is nearly homogeneous and usually tin-white. (3) When the arsenic stain is heated, it rapidly volatilizes as crystalline arsenic trioxide; while the antimony volatilizes slowly and does not give a crystalline sublimate. (4) If hydrogen sulphide be passed through the heated tube, yellow arsenic sulphide is formed, and if dry hydrogen chloride be now passed, the arsenic sulphide is not altered; antimony under similar conditions gives an orange or black sulphide, and hydrogen chloride forms volatile antimony chloride. (5) A soln. of bleaching powder dissolves the arsenic stain but not the antimony stain. (6) A soln. of stannous chloride slowly dissolves the antimony stain, but not the arsenic stain. (7) The arsenic stain dissolved in aqua regia, and treated with tartaric acid, ammonia, and magnesia mixture gives a precipitate of ammonium magnesium arsenate—not so with the antimony stain.

In the so-called *Gutzeit's test*, devised by H. Gutzeit, the arsine is passed through filter-paper impregnated with silver nitrate. A yellow or orange stain of $\text{AsAg}_3 \cdot 3\text{AgNO}_3$ is produced, if arsine eq. to over 0.005 mgrm. of arsenic trioxide be present. Antimony, selenium, and tellurium do not give the reaction—*vide* 3, 22, 21. In *Reinsch's test*, devised by H. Reinsch, a strip of polished copper foil is placed in the soln. of arsenious acid; the copper is coloured grey owing to the deposition of arsenic thereon, and the formation of copper arsenide. Conc. soln. give this result in the cold; dil. soln. with one part of arsenious acid in 100,000 parts of water give a grey film immediately on warming; a soln. with one part in 200,000 parts of water takes half an hour to form; and the limit is reached with about 1 in 250,000 to 300,000. If a large proportion of arsenic be present, the arsenical film may drop off. Arsenic acid requires warming to give the deposit. If antimony be present, it too is deposited. In the so-called *biological test* the *penicillium brevicaulis* is grown on sterilized bread at 37°. The garlic smell developed in about 24 hrs. enables 0.001 mgrm. of arsenic trioxide to be detected—*vide infra*. Arsenical compounds yield metallic arsenic when heated with potassium cyanide, or with a mixture of charcoal and potassium carbonate.

Some uses of arsenic.—The metal is used¹⁰ in making a number of alloys—*e.g.* speculum metal contains copper, tin, and a little arsenic; white copper is an alloy of copper with about 10 per cent. of arsenic; and lead-shot has 0.3–0.6 per cent. of arsenic. The arsenic renders the lead more fusible and harder; in the shot towers, the drops of lead assume the spherical form during their descent. Britannia metal often contains arsenic. Brass is sometimes "bronzed," "oxidized," or "black-nickelled" with a thin film of arsenic.¹¹ The use of arsenic oxide in the manufacture of glass is not so common as was formerly the case. Recipes

for some enamels for enamelled iron contain arsenic. Considerable quantities of arsenic are employed in the manufacture of Paris green and other insecticides for the preservation of fruit-trees in Canada, United States, Australasia, Algiers, etc.; of the vines in France; and of the indiarubber trees of the East Indies, and Malaya. It has been successfully used in the form of Paris green or white arsenic to kill the Colorado beetle so destructive to potatoes; and in the form of calcium arsenate, to control the boll weevil in infested cotton fields. A sat. aq. soln. of white arsenic is used as a wood-preserved, and as a preventative of "dry rot" and other similar afflictions. It is used for preventing the decay of vegetable matter in the holds of ships; in the wash used for walls in houses in India, etc., in order to prevent the attacks of insects. White arsenic is used in some forms of calico printing as a conveyor or fixer for certain aniline dyes; and it is used in making some glazes, and enamels. Arsenic is a constituent of the sheep-dips—*le bain de terse*; of arsenical soaps used in preserving the skins of animals; of various pyrotechnic recipes; of arsenical pastes used as rat-poisons; of fly-water, fly-powder, and fly-papers—*papier moure*—used for killing flies; of various quack nostrums for external use in cancer; various veterinary preparations contain arsenic—e.g. worm-balls, and tonic-balls; and it appears in a number of pharmaceutical preparations—thus, *liquor arsenicalis*, or *Fowler's solution*, is virtually a mixture of potassium arsenite and arsenious acid; and *liquor arsenici hydrochloricus* is a dil. soln. of arsenic trioxide in dil. hydrochloric acid. *Donovan's solution* of arsenic is about a one per cent. soln. of the iodides of mercury and arsenic used sometimes in skin diseases; *Clemen's solution* is a soln. of potassium bromide and arsenate; the *pitula asiatica* is a pill composed of arsenious acid, gentian, and black pepper. Several organic preparations are used medicinally: *dioxydiaminoarsenobenzol dihydrochloride*—with various trade-names, *salvarsan*, *606*, *arsenobillon*, or *kharsivan*, and *novarsenobenzol*, $C_6H_3(OH)(NH_2)As:(NH_2)(OH)C_6H_3$ —with the trade-name *neosalvarsan*, or *novarsenobillon*, $C_6H_3(OH)(NH_2)As:As(NH_2)(OH)C_6H_3.CH_2O.SONa$ —are used intravenously for syphilis; *sodium aminophenylarsenate*—also called *atoxyl*, $NH_2.C_6H_4.As(OH).ONa.nH_2O$, *soamine*, *arsamine*, etc.—and *sodium acetarsenate*—or *arsacetin*—used subcutaneously as a remedy for trypanosomiasis, malaria, relapsing fever, and epidemic cerebro-spinal meningitis. Arsenious oxide is used by dentists to destroy the nervous pulp of decaying and painful teeth.¹²

§ 7. The Physiological Action of Arsenic

So far as the published records go, arsenical preparations have been used for criminal purposes more than is the case with any other poison. The destruction of life by poison has been practised from very early times. It is probable that some of the accounts of the secret poisons of the ancients are highly exaggerated, like those recorded by F. Hoffmann.¹ The infamous Lucusta—mentioned by Tacitus (*Annales*, 4. 8; 12. 66; 13. 15), Suetonius (*Vitæ duodecim Cæsarum*, 6. 33), and Juvenal (*Satiræ*, 1. 71)—was apparently a recognized adept in the early part of the Christian era; she is said to have prepared the poison by which Agrippina removed Claudius, and by which Nero disposed of Britannicus, the son of Agrippina. J. B. Porta, in his *Magia naturalis* (Neapoli, 1589), introduces quite a lot of information about poisons. Assassination by poison appears to have been a tolerated if not a professed expedient among the Italian statesmen in the fifteenth and sixteenth centuries. During the latter half of the seventeenth century, the iniquitous La Spara and La Tofagna were notorious for their skill in the nefarious profession. In the art *negros efferre maritos*, they rivalled Lucusta herself. The attention of the Roman Government was first drawn to these proceedings partly by the unaccountable mortality amongst married men, and partly by the reports of the clergy, who, though bound by their vows not to betray individuals, could not help representing to the authorities the fearful number of accounts of domestic murders to which they were compelled to listen in the confessional. The two sorceresses compounded liquids in small glass phials bearing the image of a saint, and labelled with various names: *Acquetta di Napoli*, *Acqua Toffana*, the *Manna of St. Nicholas*, *Manna of Bari*, etc. It has been shown that the mysterious liquid was mainly a soln. of arsenious acid of varying concentration. The preparation was sold ostensibly for use as a cosmetic or for some other innocent purpose; actually over six hundred persons, including the popes Pius III, and Clement XIV, are said to have been poisoned through its instrumentality. The *acquetta di Perugia* is supposed to have been made by sprinkling pieces from the carcass of a pig, with white arsenic, and collecting the juice which ran from the meat. According to F. Hoffmann, and S. Hahnemann, arsenical poisons were used by the traditionally infamous Lucretia Borgia of Italy, and the Marchioness de Brinvilliers, and M. de St. Croix of Paris. According to one version, the two French poisoners learned the toxic art from Exili Gilles, but F. Funck-Brentano² supposed that they obtained their knowledge from C. Glaser, author of *Traité de chimie* (Paris, 1663).

Plants gradually wither when the root and stem are placed in a soln. of arsenious acid; and a small proportion of arsenic will be found in all parts of the plant. E. F. von Gorup-Besanez³ found that only infinitesimal amounts of arsenic are taken up by plants grown in arsenical soils—*vide supra*. The steeping of seed corn in arsenical preparations to prevent smut does not deleteriously affect the future growth of the plant. Arsenical fumes and smelter smoke from factories do not have a very marked injurious action on shrubs and trees in the vicinity. W. C. Ebaugh decided that the appearance of the leaves of lucerne and sugar-beet grown in smelter districts is entirely analogous to that produced when solid particles of fine dust are allowed to fall upon plants; and the effects observed in moist weather, when a whole field may be blighted, are due to the sulphur oxides. The complaints, however, show that not only are the trees and grass injured by the sulphur oxides in the fumes, but the grass is rendered poisonous for horses and stock. J. Haubner, J. Sussdorf, M. Freytag, and others have shown that in many cases the damage is due to the deposition of arsenious oxide on the vegetation. W. D. Harkins and R. E. Swain found excessive amounts of deposited not absorbed arsenic in the soils, snow, hay and grain, and the vegetation of the region about the Anaconda smelting works. The Inspector under the Alkali Acts of Great Britain reported in 1893:

The inspection of the arsenic works had been much called for by residents in the district where they are found, and the necessity for the adoption of remedial measures was shown by the frequent litigation brought about by the alleged destruction of cattle through eating grass said to be poisoned by the arsenic too freely distributed through the air from the chimneys up to which it had been carried by the draught. The arsenic driven off by the heat of the roasting furnace was caught and retained as far as possible, in long flues, culverts, and settling chambers, but although these were often of great extent, reaching in one place, a length of 2895 feet, or more than half a mile, and having a capacity of 60,795 cubic feet, yet arsenic was always liable to pass away. In one case, a test of the chimney gases showed the presence of as much as 7.40 grains of arsenic trioxide in a cubic foot of gases passing into the air, and small flakes of it were seen falling continually in a mild snow-shower;

and in 1906, he reported that the average escape of arsenic trioxide per cubic foot of chimney gases from furnaces provided with wash-towers was 0.080 grain in 1896, and 0.030 grain in 1906.

Infusoria, and the lower forms of animal life quickly perish in the presence of a dil. soln. of arsenious acid; although F. C. Calvert found that a 1:1000 soln. has no action on fungi and protoplasmic life. The effect of very dil. soln. on moulds has been indicated above. The toxic effect of arsenical preparations on insects is illustrated by the arsenical fly-papers. H. Eulenberg studied the effects on birds; H. Schulz, on rabbits and guinea-pigs; J. Lolliot, on dogs; and F. S. Hammett and co-workers, on rats. J. J. Theron and T. D. Hall discussed the toxicity of locusts poisoned by arsenic, when eaten by animals.

White arsenic has no action on the skin of man, but eczematous eruptions on the legs have been produced by wearing stockings coloured with aniline dyes prepared with arsenic. This recalls the reputed effects produced by the *poisoned shirts*, a favourite medium of the poisoners of the seventeenth century. The tail of the shirt was soaked in a conc. soln. of an arsenical preparation. When the dried garment was worn, it produced violent dermatitis with ulceration about the perineum and neighbouring parts. The Duke of Savoy is said to have succumbed to the effects of a poisoned shirt of this kind. C. M. Tidy⁴ mentioned fatal effects produced by the external applications of arsenical violet powder to infants; and A. Haberda, and C. E. Mangor, cases of death criminally produced by placing white arsenic in the vagina; and G. Feinstein, a case of acute poisoning from the use of arsenic in dentistry. In the so-called *Haff sickness*, more or less prevalent about the Haff lagoon, off the Baltic Sea, F. Glaser suggested that it is a form of arsenical poisoning from arsenical chloride fumes derived from the waste discharge, containing arsenic chloride, from the sulphite pulp plants on or near the Haff. This does not agree with the observations of the Königsberger Zellstoff-Fabriken und Chemische Werke, G. Lockemann, and S. Hilpert. A. Juckenack and A. Brüning said that arsenical gases could be produced by the action of algæ on arsenical trade wastes.

When used internally arsenic is considered to be a severe gastrointestinal irritant; but in minute doses the arsenic acts as a gastric stimulant causing a dilation of the gastric vessels, and an increased flow of gastric juice. Small doses stimulate the duodenum. Larger doses produce effects within 8 to 60 minutes. The sufferer experiences faintness, nausea, sickness, epigastric pains, and vomiting. The ejected matters are at first composed of the substances eaten, then they may appear brown and streaked with blood. Diarrhœa may accompany the vomiting, and the symptoms then bear a close resemblance to those of cholera. The extremities become cold, and the pulse is feeble. The face is at first pale, and then acquires a bluish tint; the temp. falls lower and lower, and there is finally a collapse. Death follows in from 5 to 20 hrs. after taking the poison. The dangerous doses of white arsenic are 0.13 gm. for an adult; 1.9 grms. for a horse; 0.64 gm. for a cow; and 0.32 to 0.64 gm. for a dog. E. W. Schwartze said that a fatal dose of dissolved arsenic trioxide administered by the mouth is 75 mgrms. per kilogram with rats; and the fatal dose with undissolved arsenic trioxide ground to an impalpable powder—0.0125–0.0025 mm. diam.—is about 100 mgrms. per kgrm.;

for rabbits, the fatal dose of dissolved arsenic trioxide is 15–20 mgrms. per kgrm. ; and for the undissolved arsenic trioxide powdered as just indicated, about 200 mgrms. per kgrm. ; and for chickens, respectively 66.7 mgrms. per kgrm., and 75 mgrms. per kgrm.

As observed by B. C. Brodie, whether the arsenic be taken internally or externally, the stomach is intensely inflamed, showing that arsenic is excreted by the blood into the stomach. The small intestine is also inflamed. The *gelation médico-legale de l'assassinat de la Duchesse de Praslin* was discussed by A. Tardieu.⁵ In chronic poisoning with small doses, arsenic is not classed as a cumulative poison. There is a loss of appetite, nausea, perhaps vomiting, slight abdominal pain, and mild diarrhoea. The eyelids become a little puffy, there is a watering of the eyes and nose—explained by the complaint of “always having a cold”—attended by an inflammation of the pharynx, air-passages, and lung-tissue ; salivation and sore gums ; and a slight headache. With the slow poisoning by repeated small doses, the illness may resemble in miniature that produced by large doses, or it may resemble very closely that state described by a general condition of ill health. There may be a slight yellowness or a brown pigmentation of the skin best marked about the neck. There may be a general increase of the epiderm scales, called keratosis. The relation between arsenic and the keratine tissue has been studied by H. G. Brooke and L. Roberts, S. Delépine, and A. Erlicki and J. Rybalkin. The exanthema sometimes produced is called *eczema arsenicale*. The nervous system is nearly always disturbed, but in a variety of ways. There may be fainting, and paralysis of the muscles of the limbs especially the extensors of the hands and feet ; ataxic gait, severe darting pains in the limbs, and rapid muscular atrophy. This subject was studied by G. Brouardel, W. H. Willcox, etc. There may be delirium, acute mania, and convulsions ; while, towards the end, a kind of hectic fever supervenes, ending in death by exhaustion. After death, there appears to have been widespread fatty degeneration of the heart, liver, kidneys, stomach, and muscles. The interference of arsenic with tissue oxidation determines the fatty degeneration. C. Binz and H. Schulz suggested that arsenic can take oxygen from and give up oxygen to the tissues. C. Binz stated that the white arsenic is excreted mostly as arsenic acid ; but this does not agree with the observations of T. Husemann, and J. D. Mann, who found the ingested arsenic is excreted as arsenious acid. T. Araki considers that both arsenic and phosphorus lessen oxidation because lactic acid appears in the urine when either of these poisons is taken ; that acid is the result of insufficient oxidation. Arsenic is excreted *viâ* the kidneys, then through the bile, and by the skin and hair. Arsenic appears in the urine 5 or 6 hrs. after it has been taken, and the elimination of one dose requires 5–8 days. According to D. Vitali, neither arsenic acid nor arsenious acid combines with albumin to form albuminates. By experiments on dogs, this author confirms the observation that arsenic anhydride is converted by the organism into arsenic trioxide, which then passes into the urine ; the arsenic acid is not found free in the urine, but rather in a state of combination ; and it probably displaces phosphoric acid in phosphoglyceric acid. This acid is a decomposition product of lecithin, and it thus seems as if the arsenic can really replace phosphorus.

It is well known to grooms, and horse-dealers that a little white arsenic given daily with the corn of a horse improves its coat, and renders it plump and fat, probably acting by increasing the assimilation of the food owing to the stimulation of the various cells and glands in the alimentary canal to superaction. When a horse has been so treated for a long time, and the practice is discontinued, the animal rapidly loses condition, presumably owing to the enfeebled secreting power of the cells and glands in the intestinal tract when the stimulus is withdrawn. According to J. Schallgruber,⁶ A. Tardieu, J. J. Tschudi, C. Maclagan, B. Knapp and co-workers, G. Joachimoglu, F. Kübler, J. F. W. Johnston, E. Schäfer, C. Heisch, E. Kopp, and H. E. Roscoe, white arsenic is widely distributed in some parts of lower Austria, in Styria, and in the hilly country extending towards Austria. The

white arsenic is locally known as *hidrach*—a corruption of *Huttenrauch*, smelter-house smoke—and is obtained from the flues attached to the smelting furnaces. The white arsenic is regularly eaten by some of the peasants. The doses taken are at first small, and they are progressively increased so that the arsenic-eaters can swallow with impunity 4 or 5 grains of arsenious oxide at a time. It is said that the object of the arsenic-eater is to be able to endure greater fatigue in mountain climbing by increasing the respiratory power. This recalls the medicinal use of arsenic in the cases of asthma and other chest diseases. It is also said that the arsenic-eater becomes plump and fat, and the skin greatly improved. The following is J. F. W. Johnston's romantic description of the effects :

By the use of *hidrach* the Styrian peasant-girl adds to the natural graces of her filling and rounding form, paints with brighter hues her blushing cheeks and tempting lips, and imparts a new and winning lustre to her sparkling eyes. Every one sees and admires the reality of her growing beauty ; the young men sound her praises, and become suppliants for her favour. She triumphs over the affections of all, and compels the chosen one to her feet. Thus, even cruel arsenic, so often the minister of crime and the parent of sorrow, bears a blessed jewel in its forehead, and, as a love-awakener, becomes at times the harbinger of happiness, the soother of ardent longings, and the bestower of contentment and peace.

It is also said that in some parts of India, particularly the Punjaub, arsenic-eating is practised as an aphrodisiac. According to C. Heisch's report, once the practice of arsenic-eating has begun, it can only be left off by very gradually diminishing the daily dose, as a sudden cessation causes sickness, burning pains in the stomach, and other symptoms of poisoning, very speedily followed by death. J. F. W. Johnston said that, as a rule, arsenic-eaters are long-lived, and are peculiarly exempt from infectious diseases, fevers, etc., but unless they gradually give up the practice invariably die suddenly. It is further stated :

In this part of the world, when a graveyard is full, it is shut up for about twelve years, when all the graves which are not private property by purchase are dug up, the bones are collected in the charnel-house, the ground is ploughed over, and burying begins again. On these occasions the bodies of arsenic-eaters are found almost unchanged, and recognizable by their friends. Many people suppose that the finding of their bodies is the origin of the story of the vampire.

The doctrine of habituation, outlined with some poetic licence by J. F. W. Johnston, was generally accepted for many years, although it now appears to be based on plausible evidence which, when critically examined, does not justify the conclusions. There have been sceptics—*e.g.* W. B. Kesteven, A. S. Taylor, and R. Christison—who called the reports a "mass of absurdity" and "a pure fable." W. B. Kesteven collected data from the arsenic-workers of Cornwall which showed that the so-called arsenic or *hidrach* of the Styrian peasants cannot be ordinary arsenic trioxide. Experiments on the subject have been made by G. Brouardel, L. de Busscher, M. Cloetta, A. R. Cushny, M. Danger and C. Flandin, M. Doyon and A. Morel, W. Hausmann, D. J. Healey and W. W. Dimock, A. Heffter, G. Joachimoglu, B. Knapp and E. and H. Buchner, F. Küfler, F. H. McCrudden, E. D. Mackenzie, K. Morishima, W. C. O'Kane and co-workers, D. McN. Parker, E. Schefer, T. Sollmann, J. J. von Tschudi, M. Willberg, R. A. Witthaus and T. C. Becker, etc. H. G. Wells said that the tacit assumption has frequently been made that all preparations of arsenic are equally toxic, and that they approach in toxicity very nearly to that of dissolved arsenic trioxide. The rate of soln. of arsenic trioxide depends on its grain-size, and so does its toxicity. Many vital factors have not been under the control of the experimenters. E. W. Schwartz showed that the toxicity of undissolved arsenic trioxide depends on its state of subdivision, and slight differences in the toxicity of dissolved arsenic trioxide occur with different species of animals. He concluded :

No unimpeachable evidence exists that either man or other higher animals can acquire a tolerance to this drug, owing chiefly to the erroneous assumption that all preparations of undissolved arsenic trioxide possess equal potency, and approach in degree the potency of

dissolved arsenious oxide. The consumption of large amounts of undissolved arsenious oxide can be as readily explained on the basis that a relatively insoluble and coarse preparation was used as by assuming that habituation had been produced. The toleration of large doses may therefore be due not to an attribute inherent in the consumer, but to an attribute inherent in the preparation used, namely, its relative insolubility due to the relatively small extent of exposed surface of the particles and the low specific rate of solution.

In cases of poisoning the stomach should be washed out; and the least irritating and depressing of emetics applied. Unlimited quantities of freshly precipitated ferric hydroxide or dialyzed iron should be taken; and if neither of these be available, magnesia, or castor oil and water, may be used. Give brandy or ether subcutaneously; and apply hot blankets to the feet and abdomen. The ferric hydroxide converts the arsenious acid into an insoluble form. This remedial measure was proposed by R. Bunsen and A. A. Berthold.⁷ It is not a true antidote, for it acts only where it comes in contact with the arsenious acid; and if the poison has been removed from the stomach by absorption with the tissues, the administration of the hydroxide is useless. Neither R. H. Brett, nor J. H. Orton obtained good results; but, according to D. MacLagan, this was owing to the incorrect application. T. and H. Smith found that hydroxide five months old has only one-fourth the power of the freshly prepared hydroxide in taking up arsenious acid—*vide infra*, chemical properties of arsenic trioxide. H. W. Fischer and co-workers tried the use of a negative hydrosol of ferric oxide, stabilized with glycerol, for intravenous injection in arsenical poisoning.

§ 8. The Atomic Weight and Valency of Arsenic

Prior to 1826, J. J. Berzelius¹ considered the at. wt. of arsenic to be 150.52 when that of oxygen is 16, and he represented the formula of arsenious and arsenic anhydrides to be respectively AsO_3 and AsO_5 , but when he found that the respective formulæ As_2O_3 and As_2O_5 better represented the facts, the at. wt. became nearer 75.26. P. T. Meissner, and O. B. Kühn took the equivalent of arsenic to be 37.5; and J. Dalton, 42. T. Thomson also made an estimate. The assumption that the at. wt. of arsenic is near 75 fits with Avogadro's law; with the sp. ht. rule; with the law of isomorphism; and the periodic rule.

Arsenic is trivalent in arsine, as is the case with nitrogen in ammonia, and of phosphorus in phosphine. In the arsenamide, too, of C. Hugot the arsenic is trivalent, $\text{As}(\text{NH}_2)_3$; and in the arsenic nitride, AsN , the arsenic has the same valency as nitrogen. Although W. R. Smith and J. E. Hora were unable to prepare arsenic pentachloride, AsCl_5 , yet O. Ruff and H. Graf prepared arsenic pentafluoride, AsF_5 , in which the arsenic is very probably quinquivalent. R. Bunsen, A. Cahours and A. Riche, H. H. Landolt, A. Michaelis, etc., have prepared many alkyl derivatives in which the arsenic is either ter- or quinquivalent. Thus, cacodyl with the empirical formula $\text{As}(\text{CH}_3)_2$ has a vap. density in agreement with the mol. formula $(\text{CH}_3)_2\text{As}.\text{As}(\text{CH}_3)_2$. Similarly with phenyl-cacodyl $\text{As}_2(\text{C}_6\text{H}_5)_4$, and A. von Baeyer's two series of chloro-alkyl derivatives—namely, $\text{As}(\text{CH}_3)_2\text{Cl}$, $\text{As}(\text{CH}_3)_2\text{Cl}$, and AsCl_3 ; and $\text{As}(\text{CH}_3)_3\text{Cl}_2$, $\text{As}(\text{CH}_3)_2\text{Cl}$, and $\text{As}(\text{CH}_3)\text{Cl}_4$ —illustrates the same thing. Substances like realgar, AsS , and arsenic selenide, AsSe , have mol. wts. in agreement with more complex molecules. Thus, above 1000° , the mol. of the sulphide is probably As_2S_2 , and below that temp. As_4S_4 . W. Schenk and G. Racky found no

evidence of bivalent arsenic, for the mol. wt. of the so-called arsenic diiodide corresponds with the formula As_2I_4 . W. H. Mills and R. Raper, and A. Rosenheim and W. Plato prepared optically active compounds of arsenic. M. Padoa discussed the valency of arsenic.

In 1811, J. J. Berzelius obtained the high value 80.2 (oxygen 16, silver 107.92) for the at. wt. of arsenic when calculated from the ratio $2As : 50$; the low value 69.7–70.1 from the synthesis of lead arsenite, $Pb_3(AsO_3)_2$; and in 1818, he obtained 75.01 from the action of sulphur on arsenic trioxide, $2As_2O_3 : 3SO_2$. T. Thomson obtained 76.35 for the ratio $2As : As_2O_5$. J. Pelouze calculated 74.95 from the ratio $AsCl_3 : 3Ag$, and J. B. A. Dumas, 74.90; while from the ratio $AsBr_3 : 3Ag$, W. Wallace obtained 74.22. F. Kessler obtained 75.13 from the ratio $3As_2O_3 : 2K_2Cr_2O_7$; and 75.26 from the ratio $3As_2O_3 : 2KClO_3$. J. G. Hibbs obtained 74.98 from the ratio $Na_4As_2O_7 : 4NaCl$; W. Ebaugh, 75.07 from $Ag_3AsO_4 : 3AgCl$; 74.97 from $Ag_3AsO_4 : 3Ag$; 75.09 from $Pb_3(AsO_4)_2 : 3PbCl_2$; and 75 from $Pb_3(AsO_4)_2 : 3PbBr_2$; and G. P. Baxter and F. B. Coffin, 74.95 from the ratios $Ag_3AsO_4 : 3AgCl$, and $Ag_3AsO_4 : 3AgBr$. F. W. Clarke gave 74.957 for the general average; B. Brauner, 75; and the International Table for 1925, 74.96.

The **atomic number** of arsenic is 33. F. W. Aston² found no **isotopes** other than for atoms of mass 75. G. Kirsch and H. Pettersson found that arsenic does not give off long-range particles corresponding with an **atomic disintegration** when bombarded by the α -particles from radium-C. N. Bohr³ represented the **electronic structure** of arsenic by (2)(4,4)(6,6,6)(4,1). The subject was also discussed by L. Brünighaus, J. H. W. Booth, M. L. Huggins, H. G. Grimm and A. Sommerfeld, C. D. Niven, S. Meyer, and H. Collins. M. Padoa discussed the valencies of the crystal lattices.

§ 9. Hydrogen Arsenide, or Arsenic Hydride

As a result of the observations of A. J. J. Vandavelde,¹ and H. Reckleben and J. Scheiber, it is not certain that arsenic and hydrogen can be made to unite directly—*vide supra*. Three hydrogen arsenides are known, AsH or As_2H_2 ; As_2H or

As₄H; and AsH₃. H. Davy first reported the formation of a solid hydrogen arsenide when water is electrolyzed by means of an arsenic cathode; G. Magnus was able to obtain only a very small quantity in this way; and E. Soubeiran, none at all. K. Olszewsky, however, obtained the solid arsenide by electrolyzing an aq. soln. of arsenic trioxide by means of platinum electrodes. Assuming that these products are the same as the brown arsenide obtained by J. V. Janowsky, E. J. Weeks and J. G. F. Druce, and H. Reckleben and J. Scheiber, the brown product is **hydrogen monoarsenide**, AsH, often written As₂H₂ in order to make the analysis correspond with the valency hypothesis H.As : As.H. E. Soubeiran gave H₂As; and E. Wiederhold, and J. Ogier, HAs₂. E. J. Weeks obtained the same brown hydride by the electrolysis of sodium hydroxide, using an arsenic cathode. The cathode was suspended in a porous pot, the electrolyte being a normal soln. of the alkali. A platinum anode was employed. A current of 100 milliamps. per sq. cm. was passed for about half an hour. Gaseous arsine was evolved, and a brown deposit appeared in the porous cell. J. L. Gay Lussac and L. J. Thénard, and H. Reckleben and J. Scheiber reported a solid arsenide to be formed when an alkali arsenide is decomposed by water: $2K_3As + 6H_2O = As_2H_2 + 6KOH + 2H_2$. J. V. Janowsky said that the product so prepared is only a mixture since it is not formed when a purified sodium arsenide is employed. H. Reckleben and J. Scheiber, and L. Moser and A. Brukl, obtained it by the action of water on sodium arsenide; and H. Thoms and L. Hess, by the action of water on calcium arsenide. E. Wiederhold obtained this arsenide when hydrochloric acid acts on an alloy of zinc and arsenic, although R. Engel seems to have supposed that the solid product is arsenic itself. N. Blondlot observed the formation of a brown solid when zinc acts on a hydrochloric acid soln. of arsenic trioxide in the presence of sulphuric, nitric, or nitrous acid. L. Moser and A. Brukl obtained this arsenide of a high degree of purity, but in small yield, by the atm. oxidation of an aq. soln. of arsine. J. Ogier obtained the brown solid by passing a silent electrical discharge through arsine; H. Reckleben and J. Scheiber obtained this arsenide together with some crystalline arsenic. J. W. Retgers said this arsenide is formed by heating that gas, or by holding a cold porcelain plate in the burning gas, but there is some doubt about this, for H. Reckleben and J. Scheiber obtained only arsenic by cooling the flame of arsine. J. L. Gay Lussac and L. J. Thénard obtained the solid by the incomplete decomposition of arsine by chlorine, but E. Wiederhold seems to have considered the product to be a mixture of arsenic and its hydride. O. Brunn obtained the solid by the action of air, nitric acid, or nitric oxide on arsine; E. Soubeiran, by the slow action of air or chlorine on arsine; T. Humpert, by the action of sulphuric acid on arsine; J. V. Janowsky, by the action of phosphorus pentachloride on arsine: $AsH_3 + PCl_5 = PCl_3 + 2HCl + AsH$ —no hydrogen appeared from this reaction. L. Moser and A. Brukl could not confirm this reaction in carbon tetrachloride soln. J. B. A. Dumas obtained the solid by the action of mercuric chloride on arsine; and E. J. Weeks and J. G. F. Druce by the action of stannous chloride on arsenic trichloride: $2AsCl_3 + 4SnCl_2 + 2HCl = As_2H_2 + 4SnCl_4$. The reaction occurs in aq. soln. or when alcohol, benzene, or chloroform are used as solvents. The yields are small. When an ethereal soln. of stannous chloride reacts with the hydrochloric soln. of arsenic trichloride, a 93 per cent. yield is obtained. The product cannot be dried in a steam-oven because it oxidizes so easily. It is therefore washed with alcohol, and ether, and dried in vacuo over sulphuric acid. H. Reckleben and J. Scheiber obtained the solid arsenide by the action of arsine on solid potassium hydroxide: $AsH_3 + 3KOH = K_3As + 3H_2O$; followed by $2K_3As + 6H_2O = As_2H_2 + 6KOH + 2H_2$. The solid hydride was also obtained from a mixture of oxygen, hydrogen, and arsine. Very little is known about this solid hydrogen arsenide—*vide supra*, brown arsenic. The brown pulverulent solid is said to be insoluble in water, alcohol, and ether. When the solid arsenide is heated in vacuo, it forms hydrogen and arsenic; and, according to G. Magnus, hydrogen free from arsenic is given off when the product has been previously dried by heating it in a current

of hydrogen at 100°. H. Reckleben and J. Scheiber said that J. W. Retgers' statements about the solubility of this arsenide—in methylene iodide, xylene, or conc. alkali-lye—really refer to yellow arsenic. They represented the reaction with ammoniacal silver nitrate: $\text{As}_2\text{H}_2 + 6\text{Ag}_2\text{O} = \text{As}_2\text{O}_5 + 12\text{Ag} + \text{H}_2\text{O}$. E. J. Weeks and J. G. F. Druce said that it is stable in air at ordinary temp. but is readily oxidized when warmed. A litre of water dissolves 0.35 gm. at 20°. Hot or cold conc. nitric acid, or hot dil. nitric acid oxidizes the arsenide to arsenic acid; similarly with aqua regia.

According to L. Moser and A. Brukl, **hydrogen diarsenide**, H_2As_4 , is formed during the oxidation of arsine with stannic chloride in the presence of hydrochloric acid. The red, amorphous, insoluble diarsenide is decomposed by heat into arsenic, arsine, and hydrogen. The compound is more stable than As_2H_2 , but gradually forms arsenic, especially if damp. It is unchanged by boiling water or hydrochloric acid, but forms arsenic with boiling concentrated (or fused) alkali. With nitric acid, bromine, or hydrogen dioxide, it gives arsenic acid.

In 1775, C. W. Scheele² discovered that a gaseous hydrogen arsenide is given off when a soln. of arsenic acid reacts with zinc. He said that the effervescence which first occurs soon ceases because each particle of zinc is surrounded by a regulus which protects the zinc from the acid. He collected some of the gas by tying a bladder to a phial containing the mixture of zinc and arsenic acid. He said that the air had the following properties:

It would not unite with water, nor did it precipitate lime-water; it was not absorbed when mixed with two-thirds of common air; and when a burning candle was brought to the mouth of the vessel, the air in the vessel inflamed with detonation; the flame took its direction towards the hand, which was thereby coloured brown. The matter that produced this colour proved to be arsenic, and it left a disagreeable smell behind. The internal surface of the vessel too was covered with a brown pellicle. Consequently, the air which holds the arsenic in soln. is of the inflammable kind.

J. Priestley passed steam over heated arsenic and obtained a gas whose "smell could not be distinguished from that of phosphorus." The gas was further examined by A. F. Gehlen, J. B. Trommsdorff, J. L. Proust, F. Stromeyer, and E. Soubeiran. *Le gas* proved to be what they called *hydrogène arsenié*, or *Arsenwasserstoff*, *arseniretted hydrogen gas*; also called **hydrogen tritarsenide**, AsH_3 , or **arsenic trihydride**, commonly called **arsine**.

Although arsenic does not unite directly with ordinary hydrogen, the case is different with hydrogen under press. and at an elevated temp., as shown by W. Ipatieff and co-workers, or when the hydrogen is *in statu nascendi*. F. Paneth and co-workers have shown that when rods of arsenic are used as in the preparation of activated hydrogen, arsine is produced. E. Soubeiran found that if arsenic powder be present when zinc is reacting with hydrochloric acid, some arsine is formed along with the hydrogen; and J. Thiele likewise obtained a similar result, and added that only traces of arsine are formed if iron be used in place of zinc, but if a little antimony chloride be present, more arsine is formed. If the arsenic be alloyed with the metal, more arsine is formed. Thus, H. Davy, and J. L. Gay Lussac and L. J. Thénard obtained arsine by the action of water or dil. acids on the alkali arsenides, and with suitable proportions of the alkali metal and arsenic—say K_3As —J. V. Janowsky, and A. P. Saunders obtained a gas very rich in arsine. G. S. Sérullas used an alloy of arsenic, antimony, and potassium obtained by igniting a mixture of antimony sulphide, arsenic trioxide, and cream of tartar, and P. Lebeau, and H. Thoms and L. Hess obtained arsine free from hydrogen by the action of water or dil. acids on calcium arsenide, Ca_3As_2 . E. Soubeiran, A. Vogel, and J. Ogier heated an alloy of zinc and arsenic with dil. sulphuric or hydrochloric acid, and obtained arsine almost free from hydrogen; J. V. Janowsky treated an alloy of arsenic with zinc, tin, or iron in a similar way; and H. Fonzes-Diaçon employed aluminium arsenide and water. H. M. Elsey noted that glasses contain-

ing arsenic give an odour of arsine when heated and stretched. The source of the odour is attributed to the reaction: $4\text{As} + 3\text{H}_2\text{O} = \text{As}_2\text{O}_3 + 2\text{AsH}_3$.

L. Gmelin said that when zinc is immersed in an aq. soln. of arsenic trioxide no gas is given off if no other acid be present. J. L. Proust found that arsine is produced if arsenic trioxide be present when zinc is dissolved in dil. hydrochloric or sulphuric acid. In the celebrated test for arsenic devised by J. Marsh, arsine is produced in this way. H. Beckurts said that sulphuric acid acts as well as hydrochloric acid; and N. Blondlot showed that if the sulphuric acid contains nitric or nitrous acid, some solid hydrogen arsenide is formed. D. Vitali said that the presence of mercuric chloride inhibits the production of arsine. L. A. Buchner, and A. Dupasquier added that if iron be employed in place of zinc no arsine is formed, and if tin be used, very little arsine is produced. J. Thiele, however, did obtain arsine by using iron free from sulphur, and he found that the reaction is promoted—without forming stibine—if a little antimony trichloride be present. J. C. Draper used magnesium in place of zinc. F. A. Abel and F. Field observed the formation of arsine when arsenical copper is boiled with hydrochloric acid; and A. Harding, when arsenical lead is boiled with hydrobromic acid. H. Anthes studied the production of arsine by the action of arsenical sulphuric acid on zinc, iron, and lead.

Metal salts, like the antimony trichloride just indicated, may stimulate the formation of arsine. J. Thiele seems to have found that hydrochloroplatinic acid, and platinized or silvered zinc diminish the sensitiveness of J. Marsh's test. C. Mai and H. Hurt found that copper sulphate, or hydrochloroplatinic acid accelerates the development of arsine; manganese sulphate has very little effect; ferrous sulphate hindered the production of arsine; while the addition of silver, mercury, cobalt, nickel, and other sulphates offers no advantage; Z. de Vamossy also recommended copper and platinum salts as promoters of the reaction, but, added A. Gautier, copper should not be used when a quantitative yield of arsine is desired; and D. Vitali said that mercury, by forming an alloy with arsenic, hinders the conversion of arsenic to arsine. According to E. Polenske, organic substances, and metallic salts which are reduced by zinc, interfere with the production of arsine; and conc. acids do not act so well as dil. acids. A. C. Chapman and H. D. Law found that the reducing efficiency of hydrogen obtained by the interaction of metals and acids depends on a number of chemical and physical factors. When pure zinc dissolves in sulphuric acid in the presence of arsenic trioxide, there remains in soln. a minute quantity C_{AsH_3} proportional to the product $C_{\text{As}}C_{\text{H}}$ which is influenced by the potential, E , of the active ions. With very dil. soln., $C_{\text{AsH}_3} = K[\text{As}_2\text{O}_3]P_{\text{H}}$, when $[\text{As}_2\text{O}_3]$ represents the amount of unreduced trioxide, and K , the equilibrium constant. The action of metal salts on the formation of arsine was also examined by G. Lockemann, and H. Reckleben and co-workers. D. Vitali said that a stick of zinc which has once been used for generating hydrogen in testing for arsenic in arsenical liquids, should not be used again because it may have retained some of the arsenic. On the other hand, N. Blondlot said that if stannous chloride be added to the flask containing the zinc and acid, the *whole* of the arsenic is given off as arsine; and A. C. Chapman and H. D. Law found that salts like palladium or platinum chloride, and nickel or cobalt sulphate cause much arsenic to be retained in the apparatus, and similarly with alloys of zinc with iron, nickel, cobalt, copper, silver, platinum, and sodium, but not with alloys of zinc with tin or cadmium; they also discovered that the presence of one or two grams of cadmium sulphate, lead acetate, or stannous chloride acts in a similar way and completely overcomes the "insensitiveness" due to the use of purified zinc and acid. G. Bischof, and C. L. Bloxam found that when arsenical liquids are electrolyzed, some arsenic is converted into arsine, at the anode, and C. L. Bloxam was able to detect the presence of 0.015 mgrm. of arsenic trioxide in this way. If arsenic acid is present it is first reduced to arsenious acid by sulphur dioxide or hydrogen sulphide. Observations on the electrolysis of the soln. were made by

K. Olszewsky, H. J. S. Sand and J. E. Hackford, S. R. Trotman, L. Ramberg, H. Blumenberg, C. Mai and H. Hurt, H. Frerichs and G. Rodenberg, C. H. Wolff, and F. M. L. Donny and M. Szuch. G. Grube and H. Kleber—*vide supra*, arsenic—found that the electrolytic formation and decomposition of arsine at the arsenic cathode is a reversible process. Arsine is the primary product of the electrolytic discharge of H-ions at the arsenic cathode, and hydrogen is formed by the decomposition of arsine. T. Moore attempted to determine the arsenic by electrolyzing the acidic soln., and catching the evolved arsine in a soln. of silver nitrate. T. E. Thorpe, W. Thomson, and others developed this mode of estimating arsenic in liquids of various kinds; and T. E. Thorpe studied the effects obtained with anodes of different metals. T. Fleitmann found that alkaline liquids containing arsenic give arsine and hydrogen when treated with zinc. H. Hager said that if antimony is present, the arsenic furnishes arsine, and the antimony is precipitated. According to J. W. Gatehouse, and O. C. Johnson, arsenical alkaline liquids yield arsine when treated with aluminium; or, according to E. W. Davy, with sodium amalgam. E. Reichardt also found that arsenates are slowly reduced to arsine by nascent hydrogen in alkaline soln.; C. Himmelmann, that arsenical liquids also furnish arsine when heated with aq. ammonia or ammonium chloride and zinc or iron. A. C. Vournasos prepared arsine by passing the vapour of arsenic at about 460° over sodium formate just below its decomposition temp.; or by heating a mixture of three parts of powdered arsenic and eight parts of dry sodium formate at 400° in a round-bottomed flask. A mixture of calcium oxide or sodium hydroxide with the sodium formate gives better results since it prevents the formation of sodium oxalate and of carbon monoxide if the temp. is too high. Arsenic trioxide or pentoxide, sodium arsenite, solid hydrogen arsenide, Schweinfurt's green, arsenic trisulphide, etc., all give the arsine when used in place of arsenic. According to F. Selmi, arsine is formed when certain fungi grow on arsenical liquids and compounds—*vide supra*; and, according to H. Fleck, E. Reichardt, and J. Wolf, when tapestries coloured with arsenical pigments are exposed to moist air. M. E. Pozzi-Escott observed that arsenic is scarcely affected by the hydrogenases—*e.g.* philothion—*vide hydrogen sulphide*.

C. W. Scheele said that zinc, tin, and iron dissolve in aq. arsenic acid liberating this gas particularly when the dissolution of the metal is assisted by the presence of hydrochloric or sulphuric acid. N. W. Fischer obtained only hydrogen with zinc and aq. arsenic acid unmixed with any other oxide; but L. Gmelin confirmed C. W. Scheele's observation with purified arsenic acid and zinc. There have been contradictory reports on the production of arsine by the reduction of arsenical sulphides of different metals. The discrepant results may be due to differences in the way the arsenic is associated with the other elements. Thus, it may be present as free arsenic, free arsenic sulphide, or the arsenic and the metal may be together combined with the sulphur. C. L. Bloxam, A. Gautier, and J. Myers observed the presence of arsine in hydrogen sulphide prepared by the action of dil. sulphuric acid on arsenical iron sulphide; and J. Myers said that freshly precipitated arsenic trisulphide is reduced to arsine by zinc and sulphuric acid. Hence, too, arsenical sulphuric acid and zinc or iron sulphide furnish some arsine. R. Otto reported that fused and powdered arsenic trisulphide is not attacked by hydrogen *in statu nascendi*. W. Skey obtained some arsine by treating arsenical pyrites with a mixture of zinc and sulphuric acid: C. R. Fresenius and C. H. L. von Babo observed that no arsine is formed when a mixture of arsenic sulphide and sodium carbonate is heated in a current of hydrogen. If a ring of arsenic is obtained when the gas is passed through a red-hot tube, it is produced by the mechanical transport of finely divided arsenic by the gas, for if the gas is filtered by moist and dry cotton-wool, no arsenic passes along.

According to H. Reckleben and co-workers, potassium hydroxide, soda-lime, or granular calcium chloride should not be used for drying purposes because they may decompose the gas. A. Güttich found that hexahydrated calcium chloride

exerts a slight catalytic action on the decomposition of arsine; likewise also when the salt has somewhat effloresced, potassium and sodium hydroxides, and soda-lime, calcium oxide, and phosphorus pentoxide, also decompose the gas. Of all the desiccating agents tried, hydrated and weathered calcium chloride exerts the least action; phosphorus pentoxide can be used when large quantities of the gas have to be dried and a small loss does not matter. P. Lebeau recommended preparing the gas by the action of water or dil. acid on normal calcium arsenide. The gas is then to be cooled to -20° to condense out most of the moisture; passed over metaphosphoric acid to remove the rest of the moisture; and then cooled by a mixture of acetone and solid carbon dioxide. The liquid so obtained is arsine of a high degree of purity.

The physical properties of arsine.—At ordinary temp. arsine is a colourless gas. The early estimates of the **vapour density** were made on the gas admixed with hydrogen; J. B. A. Dumas³ gave 2.695 (air unity), when the theoretical value for AsH_3 is 2.692. The litre weight of the gas under standard conditions is 3.4944 grms. H. Remy discussed the structure of arsine; and H. Henstock, the electronic structure of the family of trihydrides. A. O. Rankine gave 0.985×10^{-15} sq. cm. for the mean collision area of arsine. A. O. Rankine and C. J. Smith found the **viscosity** of the gas at 0° to be 0.0001470 at 0° ; 0.0001552 at 15° ; and 0.0001997 at 100° ; and he gave 300 for the constant *C*. They also calculated the collision area of the mols. of the gas to be 0.985×10^{-15} sq. cm. F. Stromeyer found that the gas at -40° condenses to a transparent, colourless liquid which at higher temp. again becomes gaseous. M. Faraday was unable to solidify arsine at -110° . K. Olszewsky found the liquid has a **boiling point** of -54.8° —H. Schlundt and O. C. Schaefer said about -70° . M. Faraday gave for the **vapour pressure**, *p* atm., of the liquid.

	-59.4°	-46.6°	-30.6°	-17.8°	-12.2°	0°	10°	15.1°
<i>p</i>	0.94	1.73	3.33	5.21	6.24	8.95	11.56	13.19

K. Olszewsky obtained a white solid at -119° which had a **melting point** of -113.5° . J. Ogier gave $(\text{As}_3\text{H})=57.7$ Cals. for the **heat of formation**. The subject was studied by R. de Forcrand. J. C. Thomlinson found the heat of formation of the trihydrides of the phosphorus family decreases as the at. wt. of the elements increase. The reverse might have been anticipated. The discrepancy is due to the heats of formation being referred to the solid elements. L. Bleekrode found the liquid to have but a small **electrical conductivity**. According to G. Grube and H. Kleber, the potential imparted by arsine when it decomposes at an arsenic electrode in presence of sodium hydroxide soln. is also about 1.0 volt. Hence, whereas in acidic soln. formation and decomposition of arsine play a minor part, in alkaline soln. electrolysis leads primarily to arsine of which the hydrogen evolved is a decomposition product. H. Schlundt and O. C. Schaefer gave 2.58 for the **dielectric constant** at -50° , and 2.05, at 15° ; H. E. Watson gave for $(\epsilon-1) \times 10^{-5}$, 2.51 at -47° ; 1.916 at 16° ; and 1.46 at 100° , and these values satisfy Debye's equation. The effect of press. at -47° is:

<i>p</i>	669.5	405	205.5	103.5	81	42	23
$\epsilon-1$	701	420	212	106	82	40	21

Arsine has a repulsive nauseating odour. It is extremely poisonous, and when diluted with much air produces nausea, eructation, giddiness, and oppression. A. F. Gehlen⁴ was one of the first victims. According to L. Gmelin, in order to detect a leak in his apparatus he smelt strongly at the joints, he found the leak, but died in 8 to 9 days from the effects of the inhalation, in spite of all remedial measures; and M. Bullacker likewise terminated his life 12 days after accidentally inhaling the gas. Arsine is formed in some industrial work when arsenical metals are treated with acids or with arsenical acids—e.g. in pickling sheet iron for tinning; and in desilvering lead by the zinc process. The effect on dogs was studied by E. Stadelmann, and on man by M. Trost, A. Tardieu, etc. J. D. Mann and J. G. Clegg said

that arsine is a powerful blood poison which disintegrates the red blood corpuscles and sets free the hæmaglobin. The red blood corpuscles are thus greatly reduced in number. In the spectroscope the blood shows that the *D*- and *C*-bands have coalesced and almost vanished. H. Fühner found the minimum conc. of arsine in the atm. to cause the death of white mice from acute poisoning is 0.1 to 0.2 mgrm. per litre; and L. O. Dubitsky found that 0.005 per cent. is fatal to cats in 60–90 minutes; and 0.004 per cent. in 3 hrs. A. Hébert and F. Hein found 0.005 per cent. was fatal to guinea-pigs for long exposures and 0.35 per cent. for short exposures; while for birds the corresponding quantities were 0.002 and 0.009 per cent.

According to P. Lebeau,⁵ purified arsine is fairly stable; but M. Berthelot found that when kept in a sealed tube, in light or darkness, arsine is slowly decomposed. A. Vogel observed that in sunlight the gas deposits a black film of arsenic on the walls of the glass containing vessel in a few days; and in darkness black flecks appear in about 8 days. G. Lockemann found that the gas is perceptibly decomposed when passed through cotton-wool or glass-wool. J. L. Gay Lussac and L. J. Thénard said that the heat of a spirit-lamp is sufficient to resolve the gas into free hydrogen, and arsenic which settles on the walls of the containing vessel—one vol. of arsine, said E. Soubeiran, furnishes $1\frac{1}{2}$ vols. of hydrogen. The deposition of arsenic which occurs when arsine is passed through a heated glass tube is the foundation of J. Marsh's well-known method of detecting arsenic. O. Brunner observed that arsine is not appreciably decomposed when passed through a spiral tube at 225°, but at 230° some arsenic is deposited in the cooler part of the tube; and J. P. Cooke detected crystals in the arsenic deposited by the thermal decomposition of arsine. The thermal decomposition of arsine proceeds something like that of phosphine observed by D. M. Kooij—*vide supra*, phosphine. E. Cohen found that the velocity constant *K*, at 310°, is not constant until the walls of the reaction vessel are covered with a film of arsenic. With the same equation as that employed for phosphine (*q.v.*), $kt = \log \{P_0/(3P_0 - 2p)\}$, derived from $dC/dt = kC$, using a vessel previously employed in another series of observations:

<i>t</i>	.	.	0	5.5	6.5	8	9.5 hrs.
<i>p</i>	.	.	733.32	805.78	818.11	835.34	850.15 mm.
<i>k</i>	.	.	0.01738	0.01757	0.01770	0.01754	

E. Echeandia made a number of observations on this subject, and found the percentage decomposition at 304°, to be:

	24	48	71	99	121	146	167 hrs.
Decomposition	56.6	82.3	94.9	98.7	99.3	99.8	99.93 per cent.

The presence of hydrogen sulphide, or of oxygen, retards the rate of decomposition by "poisoning" the catalytic film of arsenic on the walls of the containing vessel. The reaction was studied by S. Dushman, and M. Trautz. M. Berthelot said that arsine cannot be made to decompose explosively by an electric spark, but it will do so when fired by a mercury fulminate cartridge. J. Ogier, N. Klobukoff, C. H. Wolff, and H. Reckleben and J. Scheiber found that when arsine is exposed to the silent electric discharge it decomposes into arsenic, hydrogen, and some solid hydrogen arsenide—*vide supra*.

The chemical properties of arsine.—Arsine can be inflamed when in contact with air or oxygen, and it burns with a bluish-white flame: $2AsH_3 + 3O_2 = As_2O_3 + 3H_2O$. J. B. A. Dumas, and E. Soubeiran observed that one vol. of arsine consumes $1\frac{1}{2}$ vols. of oxygen; but F. Stromeyer, and J. L. Gay Lussac and L. J. Thénard found other proportions owing to the contamination of the arsine they employed with hydrogen. If the quantity of air or oxygen in contact with the burning gas is deficient, the hydrogen is first consumed, and free arsenic is deposited on the sides of the vessel. G. Lockemann represented the reaction between oxygen and arsine: $4AsH_3 + 3O_2 = 4As + 6H_2O$. In the spontaneous oxidation of arsine by oxygen at ordinary temp., H. Reckleben and G. Lockemann found that arsenic is liberated in a free state, and only the hydrogen is oxidized;

when the mixture is exposed to β -rays or γ -rays, the reaction is accelerated, and arsenious acid is formed: $2\text{H}_3\text{As} + 3\text{O}_2 = 2\text{H}_3\text{AsO}_3$; since the α -rays are excluded it is supposed that the oxidation cannot be due to the intermediate formation of ozone. According to E. Soubeiran, 100 vols. of **water** absorb 20 vols. of arsine, and the aq. soln. can precipitate metals from metal salt soln.; and the aq. soln. in contact with air, deposits arsenic when allowed to stand for some time. F. Stromeyer obtained a similar result, and O. Brunn suggested the substance which separates from the soln. may be solid hydrogen arsenide. He also said that if the water is free from dissolved air or oxygen, it does not change after standing for a long time even in light. According to R. de Forcrand, **hexahydrated arsine**, $\text{AsH}_3 \cdot 6\text{H}_2\text{O}$, is formed by compressing the gas in the presence of a few drops of water, followed by a sudden expansion and a second compression. The solid hydrate can be kept indefinitely between 0° and $28 \cdot 2^\circ$, the dissociation press. at these two temp. being, respectively, 0.806 atm. and 17.5 atm. He calculated the heat of formation of the solid hydrate, from water and the gaseous hydride, to be +17.753 Cals., and from ice and the gaseous hydride +8.238 Cals., which values gave the formula of the hydrate as $\text{AsH}_3 \cdot 6\text{H}_2\text{O}$. H. Reckleben and co-workers found that arsine is completely oxidized after shaking with 3–30 per cent. **hydrogen dioxide** for over 3 hrs.

J. J. Berzelius showed that when **chlorine** is bubbled into arsine, each bubble produces a flame, forming hydrochloric acid, and a brown cloud of arsenic. F. Stromeyer, J. J. Berzelius, A. Vogel, and E. Soubeiran found that when chlorine is mixed with arsine, combustion occurs, and hydrogen chloride and arsenic are formed; if the chlorine is present in excess, arsenic trichloride is formed; if water be present, arsenious and arsenic acids are produced—as in the case where the gas comes in contact with chlorine-water; if hydrogen sulphide be present, arsenic sulphide is formed; if 50 times its vol. of air or hydrogen be present, a single bubble of chlorine separates arsenic; and if a large proportion of carbon dioxide be present, a single bubble of chlorine separates arsenic, but without inflammation. H. Reckleben and co-workers also examined the action of arsine on chlorine-water. A. Stock found that arsine reacts with liquid chlorine even at -140° , forming reddish products—possibly forming unstable intermediate products, arsenic dihydrochloride, AsH_2Cl , and arsenic hydrodichloride, AsHCl_2 ; even at -100° , chlorine reacts with arsine dissolved in liquid hydrogen chloride. According to J. E. Simon, an aq. soln. of **bromine** absorbs arsine, forming arsenic trioxide, arsenic acid, and hydrobromic acid; and, according to J. Ogier, if the bromine is in excess, arsenic and hydrobromic acid alone. H. Reckleben and co-workers also examined the action of arsine on bromine-water. E. Soubeiran found that **iodine** decomposes arsine, slowly in the cold, rapidly when hot, forming hydrogen and arsenic iodides. O. Jacobsen observed that at ordinary temp. arsine is readily decomposed when passed over solid iodine, and all the arsenic is removed from the gas. Observations to this effect were also made by C. Husson, and O. Brunn. H. Reckleben and G. Lockemann represented the reaction with iodine and water: $\text{AsH}_3 + 4\text{I}_2 + 4\text{H}_2\text{O} = \text{H}_3\text{AsO}_4 + 8\text{HI}$; H. Thoms and L. Hess showed that the reaction takes place in two stages, the first stage in neutral soln. being represented: $\text{AsH}_3 + 3\text{I}_2 + 3\text{H}_2\text{O} = \text{H}_3\text{AsO}_3 + 6\text{HI}$. J. E. Simon found that an alcoholic soln. of iodine is decolorized by arsine at ordinary temp.—part of the arsenic is retained as arsenious acid; a black precipitate is also formed. J. V. Janowsky showed that **hydrogen chloride** and arsine form a brown cloud of arsenic; and R. Napoli, that with **hydrochloric acid**, arsenic trichloride is produced. The removal of arsine from hydrogen sulphide, contaminated with that gas, by passing through hot dil. hydrochloric acid, is not complete. The subject was discussed by R. Otto, and W. Lenz. H. B. Parsons said that **hydrobromic acid** and **hydriodic acid** do not act on arsine. A. J. Balard said that in chlorine monoxide, arsine burns to arsenic pentoxide and hydrogen chloride, and if it is not in excess, some chlorine is formed. H. Reckleben and co-workers found that arsine is completely absorbed by a soln. of **sodium**

hypochlorite or **calcium hypochlorite** : $\text{AsH}_3 + 4\text{HOCl} = \text{H}_3\text{AsO}_4 + 4\text{HCl}$; if an excess is present, side reactions occur. H. B. Parsons said that **chloric acid** in acidic soln. has no action on arsine, but in neutral soln., arsenic and a chloride of the metal are formed. H. Reckleben and G. Lockemann found that a neutral soln. of **potassium chlorate** acts only slowly, but if the soln. is acidified and a trace of silver nitrate is employed as a catalyst, the reaction : $\text{AsH}_3 + \text{HClO}_3 = \text{As}(\text{OH})_3 + \text{HCl}$ occupies some hours ; they found that **bromic acid** is indifferent towards arsine, but if a trace of silver nitrate is present : $5\text{AsH}_3 + 8\text{HBrO}_3 = 5\text{H}_3\text{AsO}_4 + 4\text{Br}_2 + 4\text{H}_2\text{O}$. The acidified soln. acts more rapidly and without the catalyst. H. B. Parsons said that **iodic acid** forms free iodine and arsenic trioxide, and H. Reckleben and G. Lockemann represented the reaction : $5\text{AsH}_3 + 8\text{HIO}_3 = 5\text{H}_3\text{AsO}_4 + 4\text{I}_2 + 4\text{H}_2\text{O}$; and with **periodic acid** : $\text{AsH}_3 + 4\text{HIO}_4 = \text{H}_3\text{AsO}_4 + 4\text{HIO}_3$.

According to J. L. Gay Lussac and L. J. Thénard, and E. Soubeiran, when **sulphur** is heated with arsine, hydrogen sulphide, arsenic, and, later, arsenic sulphide are formed. F. Jones found that sulphur reacts slowly with arsine in sunlight at ordinary temp., but not in darkness ; it also reacts slowly at 100° . The reaction with stibine is much faster than with arsine. Both **selenium** and **tellurium** react with arsine in sunlight, but not in darkness or at 100° . O. Brunn found that a mixture of equal vols. of arsine and **hydrogen sulphide** did not change in a week's time, in darkness or in sunlight ; but if a little air be present, arsenic trisulphide is quickly formed in darkness or in light. O. Brunn said that at 230° the reaction between the two gases proceeds slowly with the separation of arsenic, which is converted by the hydrogen sulphide into arsenic trisulphide. J. Myers observed that at 357° , arsine and hydrogen sulphide form hydrogen and arsenic trisulphide. O. von der Pfordten said that the transformation is incomplete. If a mixture of the two gases be passed into air-free water, O. Brunn observed the clear liquid becomes turbid, by the separation of arsenic trisulphide, as oxygen is absorbed by the liquid. O. von der Pfordten represented the reaction with **potassium polysulphide** at $350^\circ\text{--}360^\circ$: $2\text{AsH}_3 + 3\text{K}_2\text{S}_3 = 2\text{K}_3\text{AsS}_3 + 3\text{H}_2\text{S}$; while a soln. of **silver sulphide** in potassium cyanide ; or a soln. of **molybdenum trisulphide** or **stannic sulphide** in potassium sulphide, does not remove arsine completely from hydrogen sulphide contaminated with that gas. H. B. Parsons found that arsine and **sulphur dioxide** form arsenic and its trisulphide ; and G. Aimé, that **sulphur trioxide** produces sulphur dioxide and arsenic which is then oxidized to the trioxide. According to E. Soubeiran, conc. **sulphuric acid** decomposes arsine at ordinary temp., forming brown flakes which are dissolved on gently heating the liquid ; sulphuric acid diluted with an equal vol. of water acts with difficulty, and when diluted with 3 vols. of water, not at all. E. Lyttkens, and W. Lenz dried arsine with sulphuric acid without loss of arsenic. The removal of arsine from hydrogen sulphide contaminated with that gas is not completely effected by passing through hot dil. sulphuric acid. The subject was discussed by R. Otto, and W. Lenz. M. Forbes said that when arsine is passed through sulphuric acid at $160^\circ\text{--}180^\circ$ a metal mirror is formed—as well as some sulphur dioxide, and arsenic trisulphide. According to T. Humpert, when arsine is passed into sulphuric acid of sp. gr. 1.75–1.84, it is coloured brown, brown flecks separate, and the liquid contains hydrogen sulphide and yellow arsenic sulphide. The brown flecks were thought to be solid arsenic hydride.

H. Reckleben and co-workers found that conc. aq. **ammonia** decomposes arsine incompletely with the separation of arsenic. F. Stromeier said that arsine is decomposed by **nitrogen peroxide** oxidizing the hydrogen and liberating the arsenic. H. B. Parsons found that **nitrous acid**, and C. Bozenhardt, that a soln. of potassium hydroxide containing some **potassium nitrite**, readily decompose arsine, forming a grey crust of arsenic. F. Stromeier showed that **nitric acid** acts similarly, while fuming nitric acid reacts explosively with inflammation. J. E. Simon said that conc. nitric acid has no action on arsine. E. Soubeiran observed that if arsine be passed into a receiver filled with nitric acid, it disappears entirely, covering the sides of the

vessel with a brown film. F. M. Bergstrom found that arsenic is slightly attacked by a soln. of **ammonium nitrate**. E. Soubeiran showed that if **phosphorus** be heated to its vaporizing temp. in arsine gas, arsenic phosphide is formed, and some phosphine. H. B. Parsons found **hypophosphorous acid** to be without action. A. Güttich examined **phosphorus pentoxide** as a desiccating agent for the gas—*vide supra*. J. V. Janowsky found that arsine reacts with **phosphorus trichloride**, forming hydrogen chloride and arsenic phosphide; with **phosphorus pentachloride** he represented the reaction: $\text{PCl}_5 + \text{AsH}_3 = \text{PCl}_3 + \text{AsH} + 2\text{HCl}$; and with **arsenic trichloride**, arsenic and hydrogen chloride are formed. D. Tivoli found that arsine furnishes arsenic and water in contact with a soln. of arsenic trioxide in hydrochloric acid.

A. Stock found that the addition product, **boron arsenotribromide**, $\text{BBr}_3 \cdot \text{AsH}_3$, is obtained when boron bromide is gradually dropped into liquefied hydrogen arsenide at -80° to -100° . It is essential that all moisture and oxygen be previously removed, and the operation is best carried out while a stream of dry hydrogen is passed through the apparatus. The product is a white, amorphous substance which, when heated, decomposes, but does not melt. It may be obtained in a crystalline form by careful sublimation in a closed vessel. It is insoluble in carbon disulphide, but dissolves in boron tribromide. In contact with air or oxygen, it is readily oxidized, and in most cases is spontaneously inflammable, yielding boric and arsenious oxides, and hydrogen bromide. It is not acted on by oxygen at temp. below -40° . If the amount of oxygen is carefully regulated and the temp. kept moderately low, the products are boric oxide, hydrogen bromide, and free arsenic, together with arsenic tribromide. Even at 0° , slow decomposition into its constituents occurs, and this is accelerated if a current of some indifferent gas is employed to remove the hydrogen arsenide as it is formed; a small amount of arsenic is also deposited. When kept for several weeks at the ordinary temp. in a closed vessel protected from light, it is completely decomposed into boron bromide, arsenic, and hydrogen. In contact with water, it is decomposed into boric acid, hydrogen bromide, hydrogen arsenide, and a small amount of free arsenic. Conc. sulphuric acid has no apparent action, but conc. nitric acid produces violent oxidation. Arsenic trichloride reacts with the compound, even at -50° . Ammonia at 10° yields the compound $2\text{BBr}_3 \cdot 9\text{NH}_3$. A. W. Hofmann found that triethylarsine is without action on **carbon disulphide** even at 100° . L. Gmelin said that arsine is not perceptibly absorbed by **alcohol** or **ether**; but is rapidly absorbed by **turpentine**, and slowly by **fixed oils**. H. Reckleben found that a 5 per cent. soln. of **lead acetate** absorbs arsine completely after many hours' shaking, and the reaction is analogous to that which occurs with silver nitrate. J. F. Simon said that lead acetate is not changed by arsine, likewise also with **tartar emetic**; while H. B. Parsons observed no change with **oxalic acid**. W. R. Hodgkinson found that arsine gives a reddish-brown precipitate with alcoholic soln. of **mercuric cyanide**. H. Reckleben and co-workers showed that arsine reacts very slowly with a neutral soln. of **potassium ferrocyanide**, but energetically with an alkaline soln. H. B. Parsons observed no change with **hydroferrocyanic and hydroferricyanic acids**. W. Steinkopf and W. Mieg prepared some organic thiocyanates of the type $\text{RAs}(\text{SCN})_2$ and $\text{R}_2\text{As}(\text{SCN})$. Numerous **organic arsines** have been made. A. Job and R. Reich reported **magnesium dibromophenylarsine**, $\text{C}_6\text{H}_5\text{As}(\text{MgBr})_2$. H. B. Parsons found that **thiocyanic acid** has no action on arsine. R. Meissner measured the solubility of arsine in various constituents of the **blood**, and in soln. of **sodium nitroprusside**.

J. L. Gay Lussac and L. J. Thénard observed that when arsine is passed over heated **potassium**, hydrogen is liberated, and the arsenic unites with the metal. J. V. Janowsky found that **sodium** acts in a similar manner; P. Lebeau, **calcium**; J. B. A. Dumas, **zinc**; and J. L. Gay Lussac and L. J. Thénard, **tin**. E. Soubeiran observed that since arsine is decomposed, the presence of tin is not a necessary factor. J. C. Draper found that hot **platinum** removes arsenic completely from

arsine. P. Lebeau found that the **metal-ammoniums** react with arsine, forming arsenides. According to E. Soubeiran, hot solid **potassium or sodium hydroxide** quickly decomposes the gas, forming arsenite which, at a higher temp., forms arsenate and arsenide—some arsenic trioxide is also formed. L. Gmelin said that an aq. soln. of the alkali hydroxide has no appreciable action on the gas; and J. J. Berzelius, that the gas is no more soluble in alkaline soln. than in water alone. C. B. Kühn and O. Saeger, A. Güttich, M. Scenkel and T. Rickher, and G. Dragen-dorff found that some arsenic is retained by the alkali when arsine is passed over solid alkali hydroxide. E. Soubeiran found that **barium oxide** heated in arsine liberates hydrogen, and forms a mixture of barium arsenite and arsenide; while heated **calcium oxide** produces no effect other than that of heat alone. For A. Güttich's observations, *vide supra*, the desiccation of the gas; I. Guareschi found that arsine is readily absorbed by **soda-lime**. H. B. Parsons said that **chromic anhydride** in neutral or acidic soln. suffers no change, while in alkaline soln. arsenic and chromic oxide are formed.

E. Soubeiran observed no reaction with **salts of the alkalis and alkaline earths**; he also said that soln. of many heavy **metal salts** decompose the gas, forming water and the metal arsenide. Thus, with **copper sulphate**, copper arsenide is formed: $3\text{CuSO}_4 + 2\text{AsH}_3 = \text{Cu}_3\text{As}_2 + 3\text{H}_2\text{SO}_4$. The absorption of arsine by soln. of copper sulphate was also examined by J. B. A. Dumas, and J. E. Simon. Paper soaked in a soln. of this salt was found by H. Hager to be blackened by arsine. R. J. Kane found dry copper sulphate to be decomposed by arsine; and likewise with dry **copper chloride**—copper arsenide and hydrogen chloride are formed. J. Riban observed that arsine is absorbed by a soln. of cuprous chloride in hydrochloric acid; E. Dowzard said that arsine is not absorbed by a 15 per cent. soln. of cuprous chloride in hydrochloric acid. The work of J. A. Wanklyn, H. Gutzeit, H. Hager, H. Strauss, A. H. Gotthelf, E. Dowzard, F. C. J. Bird, J. F. Lassaigne, A. W. Hofmann, J. F. Simon, E. Reichardt, E. Soubeiran, J. B. Senderens, L. Marchlewsky, K. Preis and B. Rayman, H. Reckleben and co-workers, D. Vitali, T. Poleck and C. Thümmel, R. Otto, and J. A. Goode and F. M. Perkin on the action of arsine on **silver nitrate** is discussed in connection with that salt—**3. 22, 21. Gold salts** precipitate the metal when treated with arsine, and A. Güttich made some observations on this subject. For H. Reckleben and co-workers', and A. Güttich's observations on drying the gas with **calcium chloride**, *vide supra*. E. Soubeiran found that **zinc salts** are slowly decomposed by arsine. R. Meissner examined the action of **cadmium chloride** on arsine. He also found that with arsine dry **mercurous chloride** or **mercuric chloride** forms hydrogen chloride and solid hydrogen arsenide; and H. Rose represented the reaction with a soln. of mercuric chloride: $3\text{HgCl}_2 + \text{AsH}_3 = 3\text{HCl} + \text{As}(\text{HgCl})_3$. D. Vitali, and J. Lohmann obtained a similar product. The brown *trischloromercuriarsine*, $\text{As}(\text{HgCl})_3$, passes into the black arsenide Hg_3As_2 with the continued passage of the gas. M. Mayençon and M. Bergeret represented the reaction: $3\text{HgCl}_2 + \text{AsH}_3 = 3\text{HgCl} + \text{As} + 3\text{HCl}$. A. Partheil and E. Amort observed a sequence of changes with alcoholic soln. of mercuric chloride, whereby *chloromercuriarsine*, $\text{AsH}_2(\text{HgCl})$; *bischloromercuriarsine*, $\text{AsH}(\text{HgCl})_2$; and *trischloromercuriarsine*, $\text{As}(\text{HgCl})_3$, are formed. Each of these three substances yields mercurous chloride, arsenious acid, and hydrochloric acid when treated with an excess of the mercuric chloride soln. G. Franceschi obtained bischloromercuriarsine by the action of arsine on a soln. of mercuric chloride in ether. According to W. R. Hodgkinson, a soln. of mercuric chloride used in place of silver nitrate in H. Gutzeit's test gives a lemon-yellow coloration with arsine, and it enables one part of arsenic trioxide in 120,000 parts of liquid to be detected. P. Lemoult found that a soln. of **potassium tetraiodo-mercuriate** in 2 to 5 litres of water yields with arsine a yellowish-brown crystalline precipitate of *triiodomercuriarsine*, $\text{As}(\text{HgI})_3$. E. Soubeiran found that **stannous salts** are slowly decomposed by arsine, while **stannic chloride** yields a yellowish-brown precipitate. E. Defacqz found that arsine reacts with **tungsten hexa-**

chloride at 200°–300°, forming tungsten arsenide, and with the salt dissolved in liquid ammonia, *tungsten arsenicenneachloride*, $2WCl_3 \cdot AsCl_3$, is formed. E. Schobig represented the reaction between arsine and a soln. of **potassium permanganate** by the equation: $10AsH_3 + 16KMnO_4 = 5K_3AsO_4 + KMnAsO_4 + 2Mn_3(AsO_4)_2 + 9Mn(OH)_2 + 6H_2O$; without giving any confirmatory evidence. H. B. Parsons represented the reaction: $6KMnO_4 + 4AsH_3 = 3Mn_2O_2(OH)_2 + 2As_2O_3 + 6KOH$; while F. Jones showed that the reaction is better represented by the effects of ammonia, phosphine, and stibine on the permanganate soln. H. Reckleben and G. Lockemann observed a slow change in acid and neutral soln., and added that the oxidation of arsine by neutral or acidic soln. of permanganate proceeds only slowly and incompletely. R. J. Kane studied the action of arsine on manganic alum. O. von der Pfordten found that a soln. of **bismuth salt**—nitrate or chloride—in conc. hydrochloric acid, or a soln. of a **nickel salt** mixed with acetic or citric acid did not remove arsine completely from hydrogen sulphide contaminated with that gas. E. Soubeiran found that **ferric salts** give no precipitate with arsine; he also found that soln. of **platinum and rhodium salts** give precipitates of the metals when treated with arsine. J. F. Simon said that a soln. of hydrochloroplatinic acid removes all the arsenic from the gas and forms a black precipitate of arsenic and platinum. D. Tivoli said that a not too conc. soln. of the platinum salt gives a precipitate of *platinum oxyarsenide*, $HAsPtO$, and a conc. soln., of platinum alone.

§ 10. The Arsenides

W. Guertler¹ studied the affinity of arsenic for the metals. H. Davy, J. L. Gay Lussac and L. J. Thénard, and E. Soubeiran found that potassium unites with arsenic with incandescence; and when potassium is heated in an atm. of arsine, it forms an arsenide, and liberates the hydrogen. H. Davy also found that when potassium hydroxide is electrolyzed with an arsenic cathode, a dark grey alloy of arsenic and potassium is formed. A. F. Gehlen also obtained an impure alloy by igniting a mixture of arsenic and potassium hydroxide to dull redness. The alloy obtained by J. L. Gay Lussac and L. J. Thénard by heating potassium in an atm. of arsine; and by E. Soubeiran by heating the correct proportions of potassium and arsenic in a glass-tube corresponded with **potassium tritarsenide**, K_3As . P. Lebeau also obtained it by heating a mixture of the elements in the correct proportions at a red-heat—washing with liquid ammonia to remove the excess of potassium, and heating in nitrogen to remove the ammonia; but he was unable to obtain potassium arsenide by the method he used for normal calcium arsenide—*vide infra*. C. Hugot obtained it by heating the ammino-compound in vacuo at 300° . The early observers noted that when treated with water, arsine is evolved and some solid hydrogen arsenide is formed. C. Hugot prepared brick-red **potassium amminoarsenide**, $K_3As.NH_3$, by the action of an excess of a soln. of potassium in liquid ammonia on arsenic; if the arsenic be in excess, orange-coloured **potassium amminotetrarsenide**, $K_2As_4NH_3$, is formed, which when heated in vacuo at 300° produces **potassium tetrarsenide**, K_2As_4 , as a red powder. P. Lebeau prepared **lithium tritarsenide**, Li_3As , by heating a mixture of the constituent elements in the right proportions at a red-heat; and also by heating a mixture of dried lithium arsenite and sugar charcoal in an electric arc furnace for 2–3 minutes. The molten mass when cold forms a reddish-brown crystalline mass, which at a red-heat burns in oxygen with a violet light. It is decomposed by water, giving off arsine and acetylene. The hydrocarbon is derived from the lithium carbide as an impurity formed at the same time. The impure arsenide becomes red-hot when placed in cold fluorine, chlorine, or bromine; and it unites with iodine when a mixture is triturated in a mortar. It reacts vigorously with conc. nitric acid; and at a comparatively low temp., it reduces metal oxides. An impure sodium arsenide was obtained by J. L. Gay Lussac and L. J. Thénard, J. V. Janowsky, and H. H. Landolt by the direct union of arsenic and sodium. A. P. Saunders obtained an arsenide by heating sodium with arsenic trioxide. P. Lebeau prepared impure **sodium tritarsenide**, Na_3As , by the action of arsine on sodium, or on a soln. of sodium in liquid ammonia. He also made this compound by heating a mixture of the elements to redness. The product was digested with liquid ammonia to remove the excess of sodium, and heated in nitrogen to remove the ammonia. He was unable to make this arsenide

by the method used for normal calcium arsenide—*vide infra*. C. Hugot obtained **sodium amminoarsenide**, $\text{Na}_3\text{As}\cdot\text{NH}_3$, by the action of liquid ammonia on a mixture of arsenic and sodium. The reddish-brown substance, which is slowly formed, is washed with liquid ammonia. The brick-red, crystalline mass forms impure sodium tritarsenide when heated in vacuo at 300° . Some sodium amide is always present. G. Bredig and F. Haber obtained colloidal soln. of potassium and sodium arsenides by the submerged arc process.

As indicated in connection with copper—**3. 21, 6**—T. Bergman² thought that copper can be alloyed with five-sixths its weight of arsenic, but by fusion K. Friedrich could not obtain alloys with more than 44 per cent. of arsenic. P. Berthier made the same alloys. H. Weiss studied the rate of formation of homogeneous alloys from the heterogeneous state. Many more or less impure **copper arsenides** occur in nature. J. H. Stansbie, A. H. Hiorns, and C. D. Bengough and B. P. Hill prepared alloys of these elements by fusion. The f.p. curve—Fig. 18, of **3. 21, 6**—by K. Friedrich shows the existence of two arsenides, Cu_3As , and Cu_5As_2 ; while A. H. Hiorns said that there is an additional arsenide, Cu_2As . There are solid soln. with up to 4 per cent. of arsenic; J. H. Stansbie said 0.25 per cent. of arsenic. C. D. Bengough and B. P. Hill believed that the two arsenides Cu_3As and Cu_5As_2 form solid soln. The observations of W. C. Roberts-Austen, C. J. B. Karsten, P. Jolibois and M. Merle, P. Thomas, W. Stahl, E. A. Lewis, D. Hanson and C. B. Marryat, C. D. Bengough and B. P. Hill, F. Johnson, R. H. Greaves, L. Archbutt, P. Oberhoffer, C. Blazey, H. D. Law, H. Baulcke, A. Mathiessen and C. Vogt, A. Mathiessen and M. Holzmann, A. Pinkerton and W. H. Tait, and J. H. Stansbie on the properties of these alloys were previously indicated—**3. 21, 6**. H. Weiss studied the diffusion of arsenic in copper; E. Kordes, the eutectic mixtures; E. Ruhrmann, the mechanical properties; A. Rietzsch, the thermal and electrical conductivities; J. Arnold and J. Jefferson, the effect of small traces of arsenic on copper; A. Gibb, the elimination of arsenic from copper; W. Hampe, the effect of arsenic on the metallurgy of copper; G. Lippert, the effect of arsenic on the copper in H. Reinsch's test; P. Jolibois and M. Merle, the constitution; C. A. Kraus, the electrical conductivity. The various natural and artificial arsenides with a higher mol. proportion of copper than $\text{Cu}:\text{As}=3:1$ are probably mixtures of copper with more or less arsenide or arsenic.

A variety of whitneyite called *semi-whitneyite* was found by G. A. Koenig in the Mohawk mine, Keweenaw Co., Michigan; it contained about 3.8 per cent. of free arsenic and 96.2 per cent. of copper; he found that the molar ratio of copper to arsenic in the copper arsenides from this mine reached as high as 30:1; and added that they are rather of the nature of indefinite alloys than definite mineral species. As mixtures, they have no particular interest to the chemist. The arsenide, Cu_{30}As , obtained by C. Lefèvre by the action of carbon monoxide on cupric arsenate at 550° is probably a mixture. The crystalline mineral **whitneyite**,—named after J. D. Whitney—was described by F. A. Genth. D. Forbes called a similar mineral from Chili, *darwinite*. Whitneyite was also described by I. Domeyko, G. J. Brush, J. D. Dana, G. A. Koenig, and A. Bertrand. It was analyzed by F. A. Genth, T. Scheerer, and D. Forbes. Its composition approximates Cu_9As ; its sp. gr. is 8.3 to 8.7, and its hardness 3–4. J. Joly found that a sublimation occurs at 395° . T. W. Case observed that the resistance is less than a megohm, and darkness has no measurable influence. The Chilian ore, described by A. Bertrand, corresponded with Cu_{15}As , and is probably an impure whitneyite. The crystalline mineral **algodonite** was obtained by F. Field from Algodones, near Coquimbo. Its sp. gr. is 6.90–7.62, and its hardness 4. It was analyzed by F. Field, F. A. Genth, and G. A. Koenig; and its composition approximates Cu_4As . The last-named synthesized *argento-algodonite*, $(\text{CuAg})_8\text{As}$ —*vide infra*. T. W. Case observed that the resistance is less than a megohm, and that insolation has no measurable effect. H. Reinsch obtained a substance of the same composition by heating the arsenide Cu_5As_2 ; and A. Descamps, by heating copper tritarsenide with molten boric acid for a long time. A sample of algodonite from the Mohawk mine was found by G. A. Koenig to have the sp. gr. 8.364–8.378, and to have a composition approximating Cu_5As . J. B. Senderens obtained a substance of this composition by treating a soln. of cupric nitrate with arsenic. J. Joly said that a sublimation occurs at 350° . L. Ledoux applied the term *mohawkite* to a mineral of sp. gr. 8.07 from the Mohawk mine, and he assigned to it the formula Cu_4As . Since G. A. Koenig applied this term to a variety of domeykite, J. W. Richards suggested calling L. Ledoux's mineral *ledouxite*. C. Winkler

melted copper with an excess of silicon under cryolite, and obtained a brittle, crystalline *copper silicoarsenide*, approximating $\text{Cu}_4\text{As}_4\text{Si}_3$.

As indicated above, K. Friedrich, and A. H. Hiorns found that **copper tritarsenide**, Cu_3As , appears as a maximum on the f.p. curve of mixtures of copper and arsenic. It also occurs in nature as the mineral **domeykite**—named by W. Haidinger after I. Domeyko. I. Domeyko called it *arséniure de cuivre*, and J. F. L. Hausman, *cobre blanco* or *white-copper*. The mineral occurs in various localities, and has been described by C. F. Zincken, A. Krantz, J. D. Whitney, F. A. Genth, T. S. Hunt, A. Frenzel, C. F. de Landero, W. Phillips, R. P. Greg and W. G. Lettsom, C. F. Rammelsberg, J. Blyth, F. Field, F. Navarro, C. Winkler, J. A. Weisbach, D. Forbes, G. A. Koenig, T. Haegge, etc. The analyses are in agreement with the empirical formula Cu_3As . According to G. A. Koenig, the analysis of a yellowish-grey mineral in the Mohawk mine, Keweenaw Co., Michigan, corresponds with nickeliferous domeykite, $(\text{Cu},\text{Ni},\text{Co})_3\text{As}$ —*nickelodomeykite*, or *mohawkite*; of an argentiferous domeykite, $(\text{Cu},\text{Ag})_3\text{As}$ —*argento-domeykite*; and an antimoniferous domeykite, $\text{Cu}_3(\text{As},\text{Sb})$ —*stibio-domeykite*; the last-named mineral has a sp. gr. 7.902 at 21° , a hardness under 4; and is incompletely soluble in conc. nitric acid. Domeykite occurs massive and in reniform and botryoidal forms, as well as being disseminated in other minerals and rocks. The colour ranges from tin-white to steel-grey; and it may be yellowish or brown with an iridescent tarnish. G. A. Koenig described hexagonal plates. According to S. Stevanovic, the crystals of artificial domeykite are pseudo-hexagonal, rhombic bipyramids, and have the axial ratios $a : b : c = 0.5771 : 1 : 1.0206$; on the other hand, F. E. Wright added that the crystals are holohedral hexagonal, not rhombic, and A. Descamps added that they are isomorphous with dyscrasite. E. Herlinger examined the crystals. The sp. gr. ranges from 6.7 to 7.8; F. E. Wright gave 7.0–7.5; F. Cornu and K. A. Redlich, 6.708 at 26° ; A. Descamps, 7.81; G. A. Koenig, 8.05 at 21° ; and S. Stevanovic, 7.92–8.10. The hardness is 3–4; F. E. Wright gave 3–3.5. T. W. Case observed that the resistance is less than a megohm in darkness, and light has no measurable effect.

The tritarsenide was prepared by W. Spring by compressing an intimate mixture of the powdered elements at 6500 atm. press.; by A. Descamps, by melting together a mixture of the components under fused boric acid; by G. Lippert, by heating the Cu_5As_2 -oxide in an atm. of hydrogen; by W. Ipatieff and W. Nikolaieff, by the action of hydrogen at a high temp. and press. on copper arsenate; and by G. A. Koenig, by heating a mixture of the hemiarsenide and copper, or by the action of arsenic vapour on copper. A. Granger obtained it in preparing the dipentitarsenide at too high a temp.—*vide infra*; and A. Brukl obtained it by the action of arsine on a soln. of potassium cuprous chloride; he added that if the reaction occurs in soln., with an excess of the metal, there is a secondary reaction, $\text{M}_3\text{As} + 3\text{M}' + 3\text{H}_2\text{O} = 6\text{M} + 3\text{H}' + \text{As}(\text{OH})_3$. According to G. A. Koenig, a glass tube containing arsenic at one end and metallic copper (filings, turnings, or wire) in the middle is heated to dull redness (about 600°) by means of an electric current passing through a platinum wire wound around the tube. As the arsenic sublimes over the heated copper, brilliant crystals grow out from the surface of the copper. The growth takes place in such a manner as to suggest that there must be a free movement of the copper mols. Using, in place of copper, an alloy of copper, nickel, and cobalt, crystals of $(\text{Cu},\text{Ni},\text{Co})_3\text{As}$ (mohawkite) were obtained; with an alloy of copper and silver, crystals of $(\text{Cu},\text{Ag})_3\text{As}$ (argento-domeykite) and of $(\text{Cu},\text{Ag})_4\text{As}$ (argento-aldodonite); and with an alloy of copper and antimony, crystals of $\text{Cu}(\text{As},\text{Sb})$ (stibio-domeykite). When arsenic vapours are passed over zinc, lead, or nickel, there is also some action, but no crystals were formed. A. Granger said that this arsenide decomposes when strongly heated. A. Sella found the sp. ht. to be 0.0919. J. Joly said that a sublimation occurs at 345° – 370° . A. de Gramont examined the spark spectrum of the mineral. E. T. Wherry found domeykite to be a poor radio-detector. F. Cornu and K. A. Redlich found that the mineral can be completely reduced when

heated in hydrogen; and by natural processes is transformed into cuprite. F. E. Wright examined the corrosion figures with cold nitric acid of sp. gr. 1.426; and hydrochloric acid which has only a slight attack on domeykite. Nitric acid alone acts energetically on domeykite and causes a strong evolution of gas.

K. Friedrich, and A. H. Hiorns found that **copper dipentitarsenide**, Cu_5As_2 , appears as an unstable compound on the f.p. curve of the constituent elements—*vide supra*. A. Granger obtained it by passing arsenic vapour in a stream of carbon dioxide over finely divided copper at 444.5° , and also by the action of arsenic trichloride on copper, or of arsenic on cuprous chloride. H. Reinsch obtained it by the action of copper on arsenic dissolved in hydrochloric acid. B. H. Paul and A. J. Cownley also obtained this compound. According to A. Granger, it forms regular crystals with a metallic lustre, has a sp. gr. 7.56, and is soluble in nitric acid. It is easily attacked by chlorine and bromine and tarnishes in the air. At a higher temp., crystals of copper arsenide, Cu_3As , are formed. Both of these arsenides decompose when strongly heated.

K. Friedrich could not obtain any evidence of the formation of **copper hemiarсениde**, Cu_2As , on the f.p. curve of copper and arsenic; but A. H. Hiorns alleged that it is formed. G. A. Koenig also reported its formation along with the tritarsenide when the vapour of arsenic is passed over copper. A. F. Gehlen also said that it is produced when the elements are melted together; and A. Descamps, when the black precipitate obtained by adding arsenic to a soln. of a copper salt, is fused under borax. The grey crystalline mass has a sp. gr. 7.71 at 21° according to G. A. Koenig, and 7.76 according to A. Descamps. G. A. Koenig found a mineral which he called **keweenawite** associated with domeykite and mohawkite in the rock of the Mohawk mine, Keweenaw Co., Michigan. Its composition shows that it is a nickeliferous hemiarсениde, $(\text{Cu},\text{Ni},\text{Co})_2\text{As}$. It is massive, very finely granular, and of a pale pinkish-brown colour with metallic lustre; on exposure, it tarnishes to brownish-red; sp. gr. 7.681. The mineral *orileyite* of D. Waldie, C. F. Rammelsberg, and F. R. Mallet is an impure form of the hemiarсениde, $(\text{Cu},\text{Fe})_2(\text{As},\text{Sb})$. R. J. Kane reported that he had made **copper ditritarsenide**, Cu_3As_2 , by the action of arsine on dry copper sulphate or chloride—A. Brukl confirmed this; J. B. A. Dumas obtained it by the action of arsine on a soln. of cupric sulphate; A. Descamps, by reducing cupric arsenite with fused potassium cyanide; A. Mazzucchelli and A. Vercillo, by the action of a soln. of arsenic trichloride in hydrochloric acid on copper at 100° ; and W. Spring, by compressing a mixture of the powdered elements at 6500 atm. press. A. Descamps found that the bluish-grey crystalline mass is brittle and has a sp. gr. 6.94.

A number of **silver-arsenic alloys** of different composition have been reported by A. F. Gehlen,³ T. Bergman, P. Berthier, J. Percy, P. Hautefeuille and A. Perrey, and K. Friedrich and A. Leroux. The alloys were made by the action of molten silver on arsenic. S. Hilpert and F. Herrmann did not make arsenic and silver unite directly even when the vap. of the arsenic under press. is passed over heated silver. Impure **silver arsenides** occur in nature. A number of these have been described by S. R. I. Eques a Born, A. des Cloizeaux, J. D. Dana, I. Domeyko, L. A. Emmerling, J. D. Forbes, J. B. Hannay, J. F. L. Hausmann, R. J. Haiiy, J. L. Jordan, C. A. S. Hofmann, G. A. Kenngott, M. H. Klaproth, G. A. Koenig, O. Luedecke, T. Macfarlane, A. P. J. du Mênil, A. Raimondi, C. F. Rammelsberg, and H. Wurtz. The analyses correspond roughly with **silver tritarsenide**, Ag_3As . E. V. Zappi and J. J. Landaburu did not produce silver arsenide by reducing the arsenate with formaldehyde.

The *pyritolamprite* of M. Adam, analyzed by M. H. Klaproth, and A. P. J. du Mênil, was considered by C. F. Rammelsberg to be a mixture of arsenical pyrites, arsenical iron, and dyscrasite. The name *macfarlanite*—after T. Macfarlane—was given to a complex arsenical silver ore from Silver Islet, Lake Superior, and it was investigated by T. Macfarlane. Another impure arsenical silver ore was named by H. Wurtz *huntite*—after T. S. Hunt. Its sp. gr. is 6.27–7.47. The *arsenargentite* of J. B. Hannay occurs in rhombic crystals of sp. gr. 8.825, and composition Ag_3As . Little is known about it. The

chanarcillite of J. D. Dana occurring in Chanarcillo, is represented by the formula $\text{Ag}_4(\text{Sb,As})_3$. W. Spring made alloys corresponding with Ag_6As and Ag_3As by compressing intimate mixtures of the powdered constituents at 6500 atm. press.

A portion of the f.p. curve of mixtures of silver and arsenic was worked out by K. Friedrich and A. Leroux. There is evidence of the formation of the tritarsenide—*vide* Fig. 10, 3, 22, 7. A. Brukl made the tritarsenide by the action of arsine on a dil. soln. of silver nitrate or acetate. A. Descamps said that this same compound is formed when the monoarsenide is melted at a high temp. Its sp. gr. is 9.01. H. E. McKinstry observed no effect on exposing huntillite to the electric arc-light. The formation of an unstable **silver nitratearsenide**, $\text{Ag}_3\text{As} \cdot 3\text{AgNO}_3$, was indicated in connection with the action of arsine on silver nitrate—3, 22, 7. The reaction has been discussed by T. Poleck and K. Thümmel, H. Reckleben and co-workers, A. Brukl, A. Eckardt, D. Vitali, R. Fanto, R. Otto, J. B. Senderens, etc.—*loc. cit.* A. Descamps reported **silver monarsenide**, AgAs , to be formed by reducing silver arsenate with molten potassium cyanide. The white, brittle alloy has a sp. gr. of 8.51. S. Hilpert and F. Herrmann reported **silver diarsenide**, AgAs_2 , to be formed when silver arsenic chloride, $\text{Ag}_7\text{As}_2\text{Cl}_6$, is treated for 24 hrs. with a conc. soln. of potassium cyanide. More silver is lost if the digestion be continued for a longer time. It is not clear if the brown powder is a chemical individual; and similar remarks apply to the **silver tetraarsenide**, AgAs_4 , obtained as a residue by the action of a conc. soln. of potassium cyanide on silver arsenic bromide, Ag_3AsBr_3 .

The action of arsenic on gold has been indicated in 3, 23, 6. T. Bergman⁴ noticed that gold dissolves only a small proportion of arsenic; and C. Hatchett, and A. Liversidge prepared **gold-arsenic alloys**. A. P. Schleicher could prepare alloys with over 74.53 at. per cent. of gold by the ordinary methods; and his study of a portion of the equilibrium diagram is indicated in Fig. 4. A. Descamps believed that he had prepared **gold hemiarsenide**, Au_2As , by reducing gold chloride with arsenic; and **gold tritetraarsenide**, Au_4As_3 , by melting the hemiarsenide and arsenic under molten potassium cyanide. The sp. gr. is 16.2. D. Tivoli reported **gold monarsenide**, AuAs , which is unstable and loses its arsenic at 120°–130°. A. Brukl obtained this compound by the action of arsine on a soln. of sodium chloraurate. J. Arnold and J. Jefferson examined the effect of small traces of arsenic on gold.

FIG. 4.—Portion of Freezing-point Curve of Gold-Arsenic Alloys.

E. Soubeiran⁵ did not obtain **calcium arsenide**, Ca_3As_2 , by the action of arsenic vap. on red-hot calcium oxide, but H. Moissan, and P. Lebeau did obtain it by the action of arsenic vap. on calcium at dull redness. An arsenide of the same composition was prepared by P. Lebeau by heating 100 parts of calcium arsenate and 31 parts of petroleum coke in a carbon crucible in an electric furnace for two or three minutes, using a current of 950–1000 ampères and 45 volts. It forms a crystalline mass, which is transparent and reddish-brown in small fragments, has a sp. gr. = 2.5 at 15°, and in hardness lies between calcite and glass. It is not affected by dry air or oxygen at the ordinary temp., but when heated burns brilliantly, especially in oxygen, with formation of the arsenate if the oxygen is in large excess, but with sublimation of arsenic trioxide and even of arsenic if it is not. Sulphur attacks the arsenide at a dull red-heat, but boron and carbon have no action at 1000°; in the electrical furnace, however, carbon rapidly and completely decomposes it. In contact with water, the arsenide is completely converted into hydrogen arsenide and calcium hydroxide, without any liberation of hydrogen or separation of a solid brown arsenide as in the action of water on the arsenide obtained by direct synthesis. Moist air somewhat quickly decomposes the arsenide, and it is attacked at a dull red-heat by hydrogen sulphide, by the gaseous hydrides and various oxidizing agents. The arsenide reduces sulphuric

acid in the cold, and fuming nitric acid on gently heating; it also decomposes many metallic salts. J. Riedel made an alloy by heating calcium and arsenic with sand as a diluent. O. Ruff and H. Hartmann studied the velocity of absorption of nitrogen by the alloys at 400°–520°. P. Lebeau prepared **strontium arsenide**, Sr_3As_2 , by reducing strontium arsenate with petroleum coke as in the case of calcium arsenide. It is a crystalline mass which is transparent and reddish-brown in thin sections, has a sp. gr. 3.6 at 15°, and closely resembles the corresponding calcium compound in its reactions. It is attacked by fluorine at the ordinary temp. with incandescence and production of arsenious fluoride, and a similar reaction takes place with chlorine at 160°, with bromine at 200°, and with iodine vap. at higher temp. Vivid combustion also occurs when the arsenide is heated to dull redness in oxygen and in sulphur vap. It is converted into strontium carbide when heated with carbon in the electric furnace. In contact with water, it is decomposed, with production of strontium hydroxide and hydrogen arsenide. Strontium arsenide reduces most metallic oxides and is violently attacked by oxidizing agents. E. Soubeiran prepared **barium arsenide**, Ba_3As_2 , mixed with the arsenite by heating barium oxide in an atm. of arsine. P. Lebeau obtained barium arsenide by reducing the arsenate as in the case of the calcium and strontium arsenides. It has a darker colour, is more fusible, and is more chemically active than the arsenides of calcium and strontium. Its sp. gr. is 4.1 at 15°. It burns at ordinary temp. when placed in an atm. of fluorine, chlorine, or bromine. It burns in oxygen at 300°, and in sulphur at dull redness.

F. Wöhler⁶ observed that an arsenic beryllium alloy can be made by heating the two elements together; **beryllium arsenide** is formed with incandescence. The alloy is decomposed by water giving off arsine. J. Parkinson heated to redness a mixture of arsenic and magnesium filings in a current of hydrogen, and obtained **magnesium arsenide**, approximating Mg_3As_2 . The brittle, chocolate-brown mass decomposed rapidly on exposure to air. J. Riedel made the alloy by heating arsenic and magnesium with sand as a diluent. G. Natta studied its action on alcohols and ethers.

As indicated in connection with the action of arsenic on zinc—4. 30, 6—T. Bergman,⁷ E. Soubeiran, J. P. Cooke, F. H. Storer, A. Vogel, and A. F. Gehlen found that arsenic readily alloys with zinc; and W. Spring observed the union of the two elements under a press. 6500 atm. E. Soubeiran, A. Vogel, and W. Spring observed that the alloys are decomposed by dil. acids. E. Kordes studied the eutectic mixtures. The f.p. diagram was worked out by K. Friedrich and A. Leroux, and W. Heike—Fig. 17, 4. 30, 6. The diagram shows the existence of two compounds—**zinc ditritarsenide**, Zn_3As_2 , which melts at 1015°, and at 672° undergoes a reversible transformation, $\alpha\text{-Zn}_3\text{As}_2 \rightleftharpoons \beta\text{-Zn}_3\text{As}_2$. A. Descamps obtained this compound by the action of arsenic vap. in a current of hydrogen on heated zinc. The second compound, **zinc diarsenide**, ZnAs_2 , melts at 771°. Both compounds are brittle, and have an approximate hardness of 3 on Mohs' scale. They have a marked thermoelectric force towards zinc. A. Descamps fused arsenic with zinc under molten boric acid and obtained what he regarded as **zinc tritarsenide**, Zn_3As . G. A. Koenig obtained **zinc hemiarsenide**, Zn_2As , by the action of arsenic vap. on heated zinc, as in the case of copper arsenide (*q.v.*). W. Heike found alloys with less than the molar ratio $\text{Zn} : \text{As} = 1 : 2$ were not very sensitive as radio-detectors; with this proportion the results were as good as with pyrite; a little silver improved the sensitivity of the diarsenide.

The f.p. curve of the **cadmium-arsenic alloys** was partially examined by S. F. Schemtschuschny,⁸ and the result was indicated in connection with the action of arsenic on cadmium—Fig. 18, 4. 30, 6. The required mixture was melted under alkali-chloride. W. Spring made the alloys by compressing the mixture at 6500 atm. press. The colour of alloys with 22–55 at. per cent. of arsenic is dark grey with a tinge of red; those with more arsenic acquire a bluish tinge. The sp. gr. curve has a marked maximum with 40 at. per cent. of arsenic, and a small break

with 66.6 at. per cent. C. T. Heycock and F. H. Neville examined the lowering of the f.p. of cadmium by arsenic. W. Zimmer suggested using these alloys in the preparation of bearing metals, etc. No mixed crystals were observed by S. F. Schemtschuschny. A. Descamps prepared an alloy corresponding with **cadmium triarsenide**, Cd_3As , by reducing cadmium arsenate under molten potassium cyanide. Its sp. gr. was 6.26. There is no evidence of its existence on the f.p. diagram. W. Spring obtained **cadmium ditritarsenide**, Cd_3As_2 , by compressing the powdered elements; S. F. Schemtschuschny, by fusing a mixture of the components beneath a layer of fused lithium and potassium chlorides; A. Granger, by passing the vap. of arsenic in a current of hydrogen over cadmium; and A. Brukl, by slowly dropping a soln. of cadmium sulphate in dil. aq. ammonia into a globe filled with arsine. The conditions of equilibrium are shown in the diagram, Fig. 18, 4. 30, 6. A. Granger obtained octahedra and cubes. S. F. Schemtschuschny's preparation was dark grey with a reddish tinge, and a sp. gr. of 6.25 at $4^\circ/20^\circ$, the sp. gr. calculated by the mixture rule is 7.47. A. Granger gave 6.211 for the sp. gr. at 15° . The hardness is nearly 3.5. S. F. Schemtschuschny found the m.p. to be 721° , and the compound undergoes a transformation at 578° , $\alpha\text{-Cd}_3\text{As}_2 \rightleftharpoons \beta\text{-Cd}_3\text{As}_2$. According to W. Spring, and A. Brukl, cadmium arsenide dissolves slowly in cold dil. acids giving off arsine; and A. Granger found that it is soluble in dil. nitric acid, while chlorine, bromine, aqua regia, and oxidizing agents readily attack the arsenide, and A. Brukl said that strong oxidizing agents attack the arsenide with incandescence; some arsine is given off in the attack by conc. nitric acid. S. F. Schemtschuschny found a second compound, **cadmium diarsenide**, CdAs_2 , appears on the equilibrium diagram. It furnishes greyish-black crystals. The sp. gr. is 5.86 at $20^\circ/4^\circ$ when the value calculated by the mixture rule is 6.69. The hardness is 3.5–4.0 on Mohs' scale. The m.p. is 621° .

T. Bergman⁹ reported a grey **arsenic amalgam** to be formed by stirring arsenic into heated mercury; but W. Ramsay said that arsenic is insoluble even in boiling mercury, and that no amalgam is formed by the electrolysis of a dil. soln. of arsenic trichloride using a mercury cathode. W. J. Humphreys also said that arsenic is insoluble in mercury. G. Tammann and J. Hinnüber obtained a very dil. soln. by the electrolysis of arsenic trichloride with a mercury cathode; but the solubility of arsenic in mercury is too small for measurement. R. Böttger failed to make an amalgam by bringing sodium amalgam in contact with moist arsenic trioxide. The mass becomes heated, and brownish-black arsenic is formed. M. Dranty said that arsenic amalgam sublimes when an intimate mixture of arsenic trioxide, mercuric oxide, and charcoal is heated in a tube; but J. F. Lassaigne asserted that the sublimate is a mixture of mercury, arsenic, and arsenic trioxide. According to G. Vortmann, arsenic amalgam can be made by the electrolysis of a hydrochloric acid soln. of mercuric and arsenic chlorides after the addition of potassium iodide to prevent the precipitation of basic salts. The amalgam is brownish-black in colour and is stable in air. A. Brukl obtained **mercurous arsenide**, Hg_3As , by the action of arsine on a soln. of a mercurous salt. The black precipitate is soluble in nitric acid. He also obtained a black precipitate of **mercuric arsenide**, Hg_3As_2 , from an alcoholic soln. of mercuric chloride. It is easily oxidized, and inflames spontaneously when dry and exposed to air. F. Stromeyer said that mercuric arsenide is the end-product of the action of potassium tritarsenide on a soln. of mercuric chloride. H. Rose had his doubts about this, and A. Partheil and E. Amort were able to confirm the result—*vide supra*, the action of arsine on mercuric chloride. E. Dumesnil recommended the following process: 10 grms. of arsenious oxide dissolved in 100 grms. of conc. hydrochloric acid are treated with 40.65 grms. of mercuric chloride in 700–800 grms. of dil. hydrochloric acid (1:5). After filtration, 60 grms. of sodium hypophosphite are added, the mixture is shaken from time to time, and allowed to remain for several hours. On heating to boiling, a black precipitate of microscopic, mamellated crystals appears. These approximate in composition to the formula Hg_3As_2 . Mercuric arsenide is easily

oxidized on exposure to air; and when heated in a tube it volatilizes without melting, forming a mixture of arsenic, mercury, and a little arsenic trioxide. The behaviour of the amalgam towards alkyl iodide was considered by A. Partheil and E. Amort to indicate that it is truly a chemical individual.

No **boron arsenide** has been reported. C. Winkler¹⁰ said that molten aluminium does not dissolve arsenic. F. Wöhler said that when a mixture of powdered arsenic and aluminium is heated, a dark grey powder is formed with incandescence, and the resulting **aluminium arsenide** is decomposed slowly by cold water and rapidly by hot water with the evolution of arsine. Q. A. Mansuri found that the two elements unite to form a compound **aluminium tritarsenide**, Al_3As_2 . The action commences at about 750° and a low press., where yellow arsenic is formed and acts upon the aluminium. The compound Al_3As_2 is stable at high temp., but begins to break up at lower temp. When the compound breaks up, yellow arsenic is first formed. The equilibrium diagram of the system is probably like that of the system aluminium-antimony. The compound Al_3As_2 is a brown, amorphous powder which looks like iron rust and does not melt up to the temp. of fusion of silica (about 1600°). It is very reactive and evolves arsenic trihydride freely when exposed to moisture. For this reason, the alloys were always stored in stoppered bottles, and all polishing, etc., was done in fume chambers. When heated in air, the compound oxidizes to alumina and arsenious oxide. G. Natta studied its action on alcohols and ethers. The solid compound does not seem to dissolve in molten aluminium to any appreciable extent, but separates from it almost completely at its f.p., nor does it alloy with arsenic to form a eutectic. No **gallium or indium arsenide** has been reported. E. Carstanjen found that mol. proportions of thallium and arsenic readily dissolve when melted, forming crystalline **thallium arsenide**, Tl_2As . The alloy is soft enough to be cut with a knife, and the freshly cut surface is silvery-white, but it soon acquires a yellowish film on exposure to air; it readily dissolves in dil. sulphuric acid with the evolution of arsine. The observations of Q. A. Mansuri on the f.p. curve of alloys of arsenic and thallium—Fig. 2, 5. 36, 4—render it very probable that no definite arsenide of thallium has yet been isolated. A. Hirsch said that the reaction between arsenic and cerium appears to be exothermal. Possibly **cerium arsenide** is formed. The alloy is soft and non-pyrophoric; and does not decompose on keeping.

For *carbon arsenide*, vide arsenic carbide—5. 39, 19; for *silicon arsenide*, vide arsenic silicide—6. 40, 12. *Titanium* and *zirconium arsenides* have not been reported. C. Winkler prepared a series of silicoarsenides by melting the metal with silicon and an excess of arsenic under a layer of molten cryolite and sodium chloride. Thus, **copper silicoarsenide** is a grey, crystalline, brittle mass; **zinc silicoarsenide** is soluble in hydrochloric acid, giving off arsine at the same time; **iron silicoarsenide**, $\text{Fe}_2\text{Si}_9\text{As}_4$, is a grey, brittle, crystalline mass; **cobalt silicoarsenide**, $\text{Co}_2\text{Si}_9\text{As}_4$, is a grey, fine-grained, brittle mass; and **nickel silicoarsenide**, $\text{Ni}_2\text{Si}_9\text{As}_4$, is grey. The general properties of the alloys of tin and arsenic have been discussed in connection with the action of arsenic on tin—7. 46, 5. E. Kordes¹¹ studied the eutectic mixtures. The equilibrium diagram shows the existence of **tin monoarsenide**, SnAs , and of **tin tritarsenide**, Sn_3As_2 . The possible existence of **tin hemitrisarsenide**, Sn_2As_3 ; of **tin tritartetrasenide**, Sn_3As_4 ; of **tin ditritarsenide**, Sn_3As_2 ; of **tin tetrilatrisarsenide**, Sn_4As_3 ; and of **tin hexitarsenide**, Sn_6As , is there discussed. The general properties of the lead-arsenic alloys were indicated in connection with the action of arsenic on lead—7. 47, 5. Five **lead arsenides** have been reported, although K. Friedrich, working with alloys containing up to 40 per cent. of arsenic, observed no signs of the formation of a definite compound. S. Stevanovic showed that the crystals of the hexitarsenide reported by W. P. Headden to be found in the Cornish tin mines, are six-sided trigonal plates with the axial ratio $a : c = 1.2299$; and L. J. Spencer, that the trigonal crystals of the ditritarsenide prepared by J. E. Stead have the axial ratio $a : c = 1 : 1.2538$; while arsenic itself has the axial ratio $a : c = 1 : 1.4013$.

G. A. Koenig obtained **lead enneatitarsenide**, Pb_9As , by the action of arsenic on molten lead for 20 hrs. The crystalline alloy was malleable; A. Descamps obtained **lead hemiarsenide**, Pb_2As , by heating lead tetratritarsenide in molten boric acid; and at a higher temp. **lead tritadiarsenide**, Pb_3As_2 , was formed—the sp. gr. was 9.76. A. Brukl obtained it by the action of arsine on a soln. of lead acetate; ammonia should be added to prevent the decomposition of the arsenide by the liberated acid. A. Descamps obtained **lead monarsenide**, $PbAs$, of sp. gr. 9.55, by reducing lead arsenate under molten potassium cyanide; and **lead tritetrarsenide**, Pb_3As_4 , by melting an excess of arsenic with lead under molten boric acid at as low a temp. as possible, and also by passing arsenic vap. in a current of hydrogen over molten lead. The sp. gr. was reported to be 9.65, although in comparison with the sp. gr. of the other lead arsenides there seems to be something wrong. K. Kawai described a mineral—named **reniformite**—occurring as reniform aggregates in the Yanosawe Mine of Mutsu, Japan. Its composition approximates $5PbS.As_2S_3$, or **lead disulphorthosulpharsenate**, $2PbS.Pb_3(AsS_4)_2$. Its sp. gr. is 6.451. No **thorium arsenide** has yet been isolated.

For **nitrogen arsenide**, *vide* arsenic nitride—8. 49, 12; and for **phosphorus arsenide**, *vide* arsenic phosphide—8. 50, 12. T. Bergman,¹² and A. F. Gehlen prepared alloys of antimony and arsenic by melting the elements together; and J. von Liebig said that when these alloys are heated white-hot in a current of hydrogen or in the absence of air, the arsenic is volatilized. A. Descamps reported crystalline **antimony hemiarsenide**, Sb_2As , to be formed by heating a mixture of the constituent elements under molten boric oxide. The sp. gr. is 6.46. R. J. Haiiy mentioned an *antimoine natif arsenifere*, and F. X. M. Zippe an *Arsenikspiessglanz* which was called **allemontite** by W. Haidinger. It occurs in reniform and amorphous masses, granular, and in crystals at Allemont, France; Pribram, Bohemia; Schladming, Styria; Andreasberg, Harz; etc. The composition corresponds with **antimony triarsenide**, $SbAs_3$; the crystals of the tin-white or reddish-grey mineral are trigonal. The hardness is 3.5; and the sp. gr. 6.203. J. Joly said that sublimation occurs at 200°–250°. There is,

however, no satisfactory evidence of chemical combination. N. Parravano and P. de Cesaris found that only alloys with 0 to 40 per cent. arsenic can be prepared under ordinary atm. press. Within this range, the continuous series of solid soln. is formed, the f.p. curve, Fig. 5, has a minimum at 612°, with 17.5 per cent. of arsenic. Q. A. Mansuri obtained similar results. G. Kalb found that at a high temp. arsenic-antimony alloys have a gel-like structure which is retained when the alloys are rapidly cooled. With slower cooling, crystals of one or both metals are formed. The eutectic with allemontite ($\times 220$) is shown in Fig. 6. M. Padoa measured the electrical conductivity of the alloys. Antimony associated with a little arsenic, and arsenic associated with a little antimony are not uncommon in nature. Varieties specially rich in arsenic were called *allemontite*—from its occurrence at Allemont, Dept. de

FIG. 5.—Freezing-point Curve of Arsenic-Antimony Alloys.

FIG. 6.—Eutectic Structure with Allemontite.

electrical conductivity of the alloys. Antimony associated with a little arsenic, and arsenic associated with a little antimony are not uncommon in nature. Varieties specially rich in arsenic were called *allemontite*—from its occurrence at Allemont, Dept. de

l'Isère—by W. Haidinger. Native arsenical antimony or antimonial arsenic was described by D. Bizzarri and G. Campani, F. Babanek, G. Benko, F. S. Beudant, P. A. Dufrenoy, F. A. Genth, W. Haidinger, R. J. Haiy, J. F. L. Hausmann, C. C. von Leonhard, A. Madelung, F. Mohs, W. Phillips, C. F. Rammelsberg, A. Raimondi, F. A. Reuss, J. B. L. Romé de l'Isle, B. G. le Sage, T. Thomson, V. R. von Zepharovich, and F. X. M. Zippe. It resembles pyrolusite, and is a hard greyish-white mass of sp. gr. 5.55. When exposed to air it becomes covered with a black powder. The spark spectrum was examined by A. de Gramont.

Alloys of bismuth and arsenic were made by T. Bergman,¹³ and C. M. Marx; and by melting bismuth and an excess of arsenic at as low a temp. as possible while under molten boric oxide, A. Descamps obtained what he regarded as **bismuth tetrarsenide**, Bi_3As_4 , of sp. gr. 8.45. There is, however, no satisfactory evidence of chemical combination. C. T. Heycock and F. H. Neville made some observations on the f.p. of the alloy. K. Friedrich and A. Leroux found that bismuth and arsenic are only slightly miscible in the molten state, and they separate completely

FIG. 7. — Freezing-point Curves of the Arsenic - Bismuth Alloys.

on solidification so that the f.p. curve has two arrests, one corresponding with the soln. of bismuth in arsenic, the other of arsenic in bismuth—Fig. 7. W. Heike said that the two elements are perfectly miscible in sealed tubes, but not in open tubes, and that there is a eutectic close to the bismuth end of the f.p. curve. E. Becquerel studied the thermoelectric properties. Arsenical bismuth occurring in nature has been described by C. M. Kersten, C. Hintze, A. Frenzel, and A. Weisbach. A. Brukl obtained **bismuth monarsenide**, BiAs , as a black precipitate, by the action of arsine on a soln. of bismuth trichloride with a minimum of hydrochloric acid. The product is not attacked by water, dil. acids, or

alkali-lye, but is decomposed by conc. hydrochloric acid with the liberation of arsine.

T. Dieckmann¹⁴ prepared **chromium diarsenide** by heating a mixture of chromium and arsenic in a sealed tube for 10 hrs. at 700° . The product was washed with hot dil. hydrochloric acid. It is non-magnetic. W. F. de Jong and H. W. V. Willems found that the X-radiogram shows that **chromium monarsenide**, CrAs , is hexagonal, but does not have the pyrrhotine structure. E. Defacqz prepared **tungsten diarsenide**, WAs_2 , by heating tungsten hexachloride in a current of hydrogen arsenide from 150° to 350° . The product is a black, crystalline substance insoluble in water and other solvents, and having a sp. gr. 6.9 at 18° . The compound is stable in air at the ordinary temp., but is readily oxidized at a dull red-heat to arsenious and tungstic oxides; hydrogen reduces it completely at 400° – 550° , chlorine under these conditions yields arsenious chloride and tungsten hexachloride, whilst tungsten disulphide and phosphide are produced by the action of heated sulphur and phosphorus respectively. Hot sulphuric acid attacks the arsenide, evolving sulphur dioxide; and hot nitric acid oxidizes the substance to tungstic acid. Hydrofluoric and hydrochloric acids have no action on the arsenide, but a mixture of either of these with nitric acid readily dissolves the substance. Tungsten arsenide is insoluble in aq. soln. of the alkaline hydroxides, but is readily decomposed by the fused reagents and also by potassium nitrate and carbonate, the final products being alkali arsenates and tungstates. Fused copper reduces the arsenides, yielding metallic tungsten; it was not found to produce a subarsenide corresponding with the lower phosphide. E. Defacqz also made **tungsten enneachloroarsenide**, W_2AsCl_9 , by heating a mixture of tungsten hexachloride and liquid hydrogen arsenide in a sealed tube at 60° – 75° . The product is in the form of bluish-black crystals resembling the hexachloride; the substance is hygroscopic and decomposed by water and acids; it is insoluble in the common anhydrous organic solvents, but readily dissolves in aq. soln. of the alkali hydroxides; dil. nitric acid readily oxidizes the substance, yielding a colourless soln. and a yellow precipitate of tungstic acid.

R. J. Kane¹⁵ reported a natural **manganese monarsenide**, $MnAs$. When arsenic is heated on platinum foil, it melts and alloys with the metal. The product burns when heated in air, and dissolves in aqua regia, and in a great excess of nitric acid. E. Wedekind reported the monarsenide to be formed by heating together manganese and arsenic, and freeing the resulting regulus from manganese by dil. hydrochloric acid, and from arsenic by heating it in chlorine or bromine. G. Arrivant could not prepare the monarsenide. S. Hilpert and T. Dieckmann found that manganese could not be satisfactorily prepared by the aluminothermic process, while the preparation from the amalgam gave good results. It forms octahedral and eight-sided columnar crystals which are strongly magnetic; it is very sensitive towards acids, with the exception of conc. hydrochloric acid, which reacts very slowly and may be used for purification. The same compound was also obtained, but with difficulty, by the direct fusion of the components in an atm. of hydrogen. The product is a black powder of sp. gr. 6.17 at $20^{\circ}/4^{\circ}$. W. F. de Jong and H. W. V. Willems found that the X-radiogram agreed with the hexagonal structure with $a=3.74$ A., and $c=5.75$; and sp. gr. 6.20. I. Oftedal gave $a=3.716$, and $c=5.704$ A., and $a:c=1:1.535$. When heated in a current

of hydrogen, arsenic is volatilized. The critical temp. at which manganese arsenide changes from the ferromagnetic to the paramagnetic state is 45° . When the substance cools it regains its ferromagnetic properties. The ferromagnetic substance shows a temp. hysteresis. L. F. Bates showed that the sp. ht. of one specimen, Fig. 8, rises slowly from 0.122 at 28° to 0.14 at 36° , and then rises with increasing rapidity to a value of 0.8 in the neighbourhood of 42° , and then falls rapidly to 0.13 at 45° and to a slight minimum of 0.10 at 46.5° . Hereafter, the sp. ht. rises slowly with temp. Hence, heat is rapidly absorbed as the arsenide changes

FIG. 8.—The Effect of Temperature on the Specific Heat, Magnetic Induction, and the Rate of Change of the Magnetic Induction of Manganese Arsenide.

from the ferromagnetic to the paramagnetic state. Fig. 8 represents the curve showing the effect of temp. on the magnetic induction, in arbitrary units, and also the curve showing the rate of change of magnetic induction, in arbitrary units, with temp., namely, dI/dT . This curve exhibits a maximum at 42.2° , and there is a marked resemblance between this curve and that of the sp. ht. E. Wedekind and T. Veit said that when the monarsenide is heated it forms **manganese hemiararsenide**, Mn_2As , but this was denied by S. Hilpert and T. Dieckmann, who observed no break corresponding with the hemiphosphide or with *manganese tritadiarsenide*, Mn_3As_2 . The monarsenide is strongly magnetic, but loses its magnetic property at 40° – 50° by a reversible action. G. Arrivant examined the e.m.f. of the alloys, Mn_3As_2 and Mn_2As .

T. Bergman,¹⁶ C. J. B. Karsten, and A. F. Gehlen prepared alloys of arsenic and iron by heating mixtures of the two elements in a closed vessel. The alloy was said to be white, brittle, easily pulverized, and infusible, whereas P. Berthier said that the alloy is very fusible. He also added that the alloy is non-magnetic, and is not attacked by hydrochloric and sulphuric acids, but is easily attacked by nitric acid and by aqua regia. The alloys were also described by J. Percy; his analysis of an iron cannon-ball from Sinope had 16 per cent. arsenic corresponding with Fe_7As . P. Berthier described some Spanish bombs and cannon-balls from the arsenal at Algiers, which contained respectively 9.8 and 27.0 per cent. of arsenic, and 88.7 and 72 per cent. of iron. The effect of arsenic on iron and steel was discussed by A. Carnot and E. Goutal, M. Merle, F. Osmond, and E. Kordes. K. Friedrich examined alloys of iron with up to 56 per cent. of arsenic. The f.p. curve, Fig. 8, falls from the f.p. of iron to a eutectic point at 30 per cent. of arsenic

and 835° , then rises to a maximum at 40.1 per cent. and 919° . Less distinct maxima are indicated at 51.7 per cent. of arsenic and 964° and at 57.3 per cent. and 1031° , the latter point being obtained by extrapolation of the curve of solidification times. The compounds indicated are Fe_2As , Fe_3As_2 , FeAs , and Fe_7As_4 , the existence of the last being uncertain. The microphotographs of the alloys, etched by means of a hot soln. of iodine in potassium iodide, confirm the conclusions drawn from the f.p. curve. The alloys are brittle, especially in the neighbourhood of a maximum. Alloys containing more than 40 per cent. of arsenic are not attracted by a magnet. G. Tammann and E. Schaarwächter found the reaction between iron and arsenic begins at about 420° ; and P. Oberhoffer and A. Gallaschik observed that the maximum solubility of arsenic in δ -iron is 0.9 per cent. and in γ -iron 6.8 per cent. Iron alone melts at 1528° . The change point of the δ mixed crystals with liquid to γ -mixed crystals is 1440° . No decomposition of γ -mixed crystals was found from 0 to 7 per cent. As. The magnetic change point on cooling was depressed 80° by 0.5 per cent. of As, and then remained constant. The change point on heating was not affected. Above 3 per cent. of As, no change point could be detected. Micro-examination showed homogeneous mixed crystals up to 6.67 per cent. As. Alloys richer in arsenic coloured more quickly on etching and showed a striped appearance. The alloy with 7.29 per cent. As contained traces of eutectic. The eutectic point is at 30.3 per cent. As above which a new constituent, X, appeared embedded in eutectic. For *arsenical pyrites*, *vide infra*, the iron arsenic sulphides.

According to J. Percy, in the dry assay of arsenical ores, a spieß is often produced consisting of iron and arsenic in the proportion required for **iron tritarsenide**, Fe_3As . It has the same composition when produced under varying conditions. It is greyish-white; hard, and brittle, and the fractured surface has a close texture, and is bright, and crystalline. It is formed at a temp. below the m.p. of wrought iron. It is very liquid when melted, and takes sharply the impression of the mould in which it solidifies. There is no sign of this as a compound on the f.p. curves, Fig. 9;

FIG. 9.—The Freezing-point Curve of the Arsenic-Iron Alloys.

rather does it correspond with the eutectic mixture E. J. Percy also described **iron hemiarsenide**, Fe_2As , obtained by fusing mixtures of iron and arsenic under fused plate-glass in a covered clay crucible. There is no sign of the existence of this compound on the f.p. curve, Fig. 9. P. Berthier heated mispickel with borax in a carbon crucible, and digested the product with hydrochloric acid—hydrogen sulphide was evolved, and the composition of the solid residue corresponded with iron hemiarsenide. K. Friedrich obtained this compound by melting a mixture of the two elements, and the conditions for its existence are indicated in Fig. 9. It melts at 919° . E. Vigouroux observed indications of this compound on the e.m.f. diagram. Alloys with 40 to 56 per cent. of arsenic react at about 800° , Fig. 9 and there is a maximum development of heat on the cooling curve corresponding with the formation of **iron ditarsenide**, Fe_3As_2 . The conditions of existence of **iron monarsenide**, FeAs , are indicated in K. Friedrich's diagram, Fig. 9. A. Beutell and F. Lorenz said that it is formed between 335° and 380° by heating iron in arsenic vapour. A. Brukl obtained it by dropping a soln. of a ferrous salt into an atm. of arsine. S. Hilpert and T. Dieckmann reported this compound to be formed as a non-magnetic, silver-grey powder, by heating the diarsenide in a current of hydrogen at 680° . Its sp. gr. is 7.83, and its m.p. 1020° —K. Friedrich

gave 1031° for the m.p. P. Lebeau obtained a compound of the same composition by heating a mixture of arsenic trioxide, iron, and carbon in the electric arc-furnace for a short time; and A. Descamps, by heating iron arsenate with molten potassium cyanide. W. F. de Jong and H. W. V. Willems found that the X-radiogram of the monarsenide agreed with the crystals having rhombic symmetry. K. Friedrich showed that **iron tetrapentitarsenide**, Fe_5As_4 , is probably formed when the elements in the right proportions are fused together. J. Percy reported a product with the composition of **iron diarsenide**, FeAs_2 , by passing the vapour of arsenic over red-hot iron for a long time. A. F. Gehlen's and T. Bergman's alloys approximated to this composition. The diarsenide also occurs in nature—*vide infra*; but it is not represented as a singular point on K. Friedrich's diagram, Fig. 9. W. P. Headden obtained iron monarsenide associated with stannous sulphide in masonry of a tin smelting furnace near Truro, Cornwall. G. Tammann and H. Bredemeier studied the surface oxidation of this compound. S. Hilpert and T. Dieckmann prepared **iron diarsenide**, FeAs_2 , by heating the finely-powdered metal and arsenic sealed up in an evacuated bomb-tube of Jena glass for several hours at 700°–750°, a temp. much higher than the b.p. of arsenic. After cooling, the almost chemically pure arsenide can be mechanically separated from the arsenic which has condensed on the walls of the tube, and it can then readily be purified by further treatment. After purification by dil. hydrochloric acid, the diarsenide appears as a silver-grey, microcrystalline powder with a sp. gr. 7.38, and m.p. 980°–1040°. It is non-magnetic. A. Beutell and F. Lorenz said that the temp. of formation is 480°–618° in arsenic vapour. J. Percy also reported what may have been **iron tetrarsenide**, FeAs_4 , which he obtained by passing the vap. of arsenic in a current of hydrogen over reduced iron at a bright red-heat. The product is not sensibly affected by hydrochloric or dil. sulphuric acid. E. Vigouroux observed indications of iron tetrapentitarsenide, Fe_4As , on the e.m.f. diagram. A. Brukl obtained **ferrous arsenide**, Fe_3As_2 , by the action of arsine on an alcoholic soln. of ferrous ammonium sulphate. The black precipitate is stable; is slightly attacked by conc. hydrochloric and sulphuric acids; is soluble in nitric acid, aqua regia, and bromine-water. It could not be obtained from acid or neutral soln., and with alkaline soln., the precipitate contains an excess of arsenic.

The mineral called **löllingite** by W. Haidinger approximates to iron diarsenide, although it passes through *ferric arsenide*, Fe_3As_4 , towards Fe_2As_3 . It occurs at Lölling in Carinthia, and elsewhere. It was called by R. Jameson *prismatic arsenical pyrites*, and later, *acotomous arsenic pyrites* by R. Jameson, and F. Mohs; *arsenical pyrites*, or an equivalent term by C. J. B. Karsten, E. Hoffmann, J. F. L. Hausmann, C. Hartmann, M. H. Klaproth, G. Rose, E. F. Glocker, and A. Breithaupt; *leucopyrite*—from *λευκός*, shining—by C. U. Shepard; *mohsine*, by E. J. Chaplan; *hoffmannite*, by E. F. Glocker; *pharmacopyrite*, by A. Weisbach; and *hüttenbergite*, by A. Breithaupt. Analyses were reported by G. A. Behncke, A. Breithaupt, L. Broz, I. Domeyko, A. Frenzel, F. A. Genth, C. Güttler, H. Hahn, W. F. Hillebrand, E. Hofmann, B. Illing, W. J. Jordan, C. J. B. Karsten, J. Loczka, L. W. McCay, W. Marzek, J. Niedzwiedzky, A. E. Nordenskjöld, T. Petersen, A. Raimondi, C. F. Rammelsberg, G. Rose, T. Scheerer, R. Scheibe, R. Senfter, T. L. Walker, and V. R. von Zepharovich, etc. G. A. Kenngott called the diarsenide, *sätersbergite*, and Fe_2As_3 or $\text{FeAs}.\text{FeAs}_2$, löllingite; while J. D. Dana called the diarsenide, löllingite, and Fe_2As_3 , leucopyrite. V. R. von Zepharovich likewise assumed that FeAs_2 and Fe_2As_3 or Fe_3As_4 represent two different mineral species; but C. F. Rammelsberg, G. Tschermak, and P. Groth did not agree with this, and supposed that mechanical mixtures are involved. The subject was discussed by A. Beutell and F. Lorenz, and A. Beutell. Löllingite is also associated with some sulphur and merges gradually into mispickel, FeSAs , and safflorite, CoAs_2 . A. Breithaupt called the sulphurous arsenide from Geyer, *geyerite*, and that from La Paz, *pazite*; and F. Sandberger called the cobaltiferous

arsenides *glaucopyrite*. Some varieties also contain antimony, and bismuth. In addition to the analyses mentioned above, the mineral from different localities has been described by A. d'Achiardi, L. Bombicci, A. Breithaupt, W. C. Brögger, A. Brunlechner, J. H. Collins, J. D. Dana, A. Frenzel, E. Fugger, E. F. Glocker, B. Hare, G. P. Jervis, F. A. Kohlenati, A. Lacroix, A. Liversidge, O. Luedecke, A. Ossent, W. F. Petterd, J. Rumpf, L. H. Bauer and H. Berman, F. Sandberger, R. Scheibe, C. J. Selb, G. Sillem, F. J. Wilk, etc. A. Beutell and F. Lorenz gave 305° – 514° as the temp. of formation of Fe_2As_3 when iron is heated in arsenic vapour.

Löllingite or arsenical pyrites is represented as a compact mineral with a granular or radiating structure; or in rhombic crystals which, according to W. C. Brögger, have the axial angles $a:b:c=0.66888:1:1.2331$. This sample came from Norway. L. H. Bauer and H. Berman gave for a sample from Franklin, New Jersey, $a:b:c=0.5438:1:1.130$. Arsenopyrite from Hokenstein had the ratio $0.6773:1:1.188$; and marcasite, $0.7580:1:1.212$. The measurements by A. Schrauf were shown by P. Groth to have been made on a sample of mispickel not löllingite. The crystals were also examined by F. Mohs. W. F. de Jong examined the X-radiogram and found the lattice constants of the rhombic crystals to be $a=6.35$ Å., $b=4.86$ Å., and $c=5.80$ Å.; and the calculated density is in agreement with the observed if 4 mols. are present per unit cell. N. S. Kurnakoff and N. S. Konstantinoff regard the crystals as isomorphous with safflorite and iron diantimonide:

The colour of löllingite is greyish-black, steel-grey, or silver-white. The lustre is metallic; the fracture uneven; and the cleavage basal, often distinct. The twinning planes (101) cross at angles of nearly 60° ; and sometimes trillings occur. The hardness ranges from 5.0 to 5.5; and the sp. gr. from 7.0 to 7.4. A. Sella gave 0.0864 for the sp. ht. A. de Gramont examined the spark spectrum; and F. Beijerinck found the mineral to conduct electricity. E. T. Wherry found the crystals to be fair radio-detectors. W. Hicks studied the magnetic properties of iron arsenides. According to J. Loczka, the arsenic is set free when löllingite is heated with sulphur: $\text{FeAs}_2 + \text{S} = \text{FeS} + 2\text{As}$; or with iron pyrites: $\text{FeAs}_2 + \text{FeS}_2 = 2\text{FeS} + 2\text{As}$. J. Lemberg found that an alkaline soln. of bromine oxidizes it to ferric oxide more slowly than is the case with mispickel; and when allowed to stand in a cold acidified soln. of silver sulphate, the mineral acquires a crust of silver crystals. C. A. Burghardt found that löllingite is decomposed when heated with ammonium nitrate. It dissolves in nitric acid with the separation of arsenic acid. E. Thomson studied the corrosion figures of löllingite produced by nitric acid, and soln. of mercurous and ferric chlorides; and T. L. Walker and A. L. Parsons, the oxidation of the mineral of aerated water—*vide rammelsbergite*.

Alloys of cobalt and arsenic were prepared by A. F. Gehlen,¹⁷ P. Berthier, H. Kopp, and C. F. Rammelsberg. T. Scheerer and W. Francis observed that truncated rhombic needles, and large plates, approximating $(\text{Co}, \text{Fe}, \text{Cu})_5\text{As}$, were formed in the furnaces of a cobalt-blue colour works at Modum. F. Ducelliez found that cobalt is transformed by the action of arsenic trichloride into a mixture of chloride and arsenide, the arsenide ranging from Co_3As_2 to CoAs_2 , according to the temp. of the reaction. The different arsenides can be prepared by heating mixtures of arsenic trichloride and cobalt, or alloys of arsenic and cobalt, or mixtures of the two powdered elements in an inert atm.—hydrogen or carbon monoxide—or by heating powdered cobalt in an atm. of arsenic vap. A. Beutell and F. Lorenz supposed that there are five arsenides with $\text{Co}:\text{As}=1:1$; $2:1$; $1:2$; $2:5$; and $1:3$. The f.p. curve was studied by K. Friedrich, and his results are summarized in Fig. 9. The alloys are particularly liable to under-cooling. The first

series of crystals consists of cobalt containing not more than 1 per cent. of arsenic in solid soln. There is a eutectic point at 916° and 30 per cent. As. There is a maximum at 926° and 33.7 per cent. As, corresponding with **cobalt dipentitarsenide**, Co_5As_2 . A second maximum, corresponding with **cobalt hemiarsenide**, Co_2As , occurs at 959° and 38.9 per cent. As. The existence of Co_3As_2 , dissociating without melting at 1014° , is also indicated, and the curve then rises, apparently reaching a maximum near 1180° , corresponding with the monoarsenide CoAs . It was not possible to follow the curve to higher percentages of arsenic. The three compounds first mentioned exist each in an α - and a β -form, the transformation occurring on cooling with development of heat whether the compound is present in primary crystals or as a constituent of a eutectic. The respective transition temp. are : for Co_5As_2 , 828° ; Co_2As , 352° ; and Co_3As_2 , 915° . Alloys containing from 12 per cent. to 46 per cent. As also undergo a transformation at temp. ranging from 250° to 350° , both temp. and heat development reaching a maximum at the composition Co_2As . This change is accompanied by a considerable increase of volume on cooling, sometimes causing disruption of the alloy. Its nature is not to be discovered by a microscopic examination of the alloys. The hardness of cobalt is progressively increased by the addition of arsenic. Only alloys containing 0–38 per cent. As are attracted by a magnet. E. Kordes studied the eutectic mixtures of cobalt and arsenic.

In addition to the dipentitarsenide, and the hemiarsenide, there is **cobalt ditritarsenide**, Co_3As_2 , whose conditions of existence are indicated in Fig. 10. This compound was prepared by F. Ducelliez by heating cobalt, or an alloy with 39 per cent. of arsenic in contact with arsenic trichloride between 800° and 1400° , by reducing cobalt arsenite or arsenate with hydrogen at 900° —the heat developed, volatilizing part of the arsenic, prevents the formation of cobalt monarsenide; or by passing the vap. of arsenic in a current of hydrogen over powdered cobalt at 800° – 1400° . When prepared below 1000° , it has a metallic lustre. Its sp. gr. is 7.82 at 0° ; at 1400° , it loses arsenic. Oxygen, chlorine, and sulphur react vigorously with this arsenide; hot, conc. hydrochloric acid acts feebly; sulphuric acid has very little action; nitric acid, and aqua regia dissolve it easily; and molten alkali hydroxides and carbonates attack it slowly. The conditions of formation of **cobalt monarsenide**, CoAs , are indicated in Fig. 10. F. Ducelliez made this compound by heating the ditritarsenide between 600° and 800° ; by heating cobalt with arsenic trichloride between 600° and 800° ; and by heating a mixture of arsenic and cobalt in hydrogen, or by passing the vap. of arsenic in a current of hydrogen over powdered cobalt at 600° – 800° . A. Beutell and F. Lorenz gave 275° – 335° for its temp. of formation from cobalt and arsenic vap. W. F. de Jong and H. W. V. Willems said that the X-radiogram did not enable them to determine the structure of the monarsenide. According to A. Beutell and F. Lorenz, the pale grey, crystalline mass has a sp. gr. of 7.62 at 0° ; and m.p. 1180° . When exposed to air, it becomes matte; and when heated in hydrogen above 800° , it loses arsenic. G. Tammann and H. Bredemeir studied the surface oxidation. Cobalt monarsenide reacts chemically like the ditritarsenide. When cobalt or the monarsenide is heated with arsenic trichloride between 400° and 600° , **cobalt hemitritarsenide**, Co_2As_3 , is formed; and the same compound is produced by heating

FIG. 10.—Freezing-point Curves of Cobalt-Arsenic Alloys.

at 400°-600° a mixture of powdered arsenic and cobalt, in hydrogen, or by heating at 400°-600° powdered cobalt in a current of arsenic vap. carried by hydrogen. A. Beutell and F. Lorenz gave 345°-365° for its temp. of formation from cobalt in arsenic vap. The product has a sp. gr. of 7.35 at 0°. It begins to decompose at 600°. Its chemical reactions are like those of the ditritarsenide. When the hemitritarsenide is heated below 400°, it slowly forms **cobalt diarsenide**, CoAs_2 . It cannot be obtained directly from cobalt and arsenic trichloride below 400°. A. Beutell and F. Lorenz gave 385°-405° for its temp. of formation from cobalt in arsenic vap. It is a grey powder of sp. gr. 6.97 at 0°, and is readily oxidized by exposure to air. It behaves chemically like the other cobalt arsenides. It occurs as a mineral in two forms—cubic *smaltite*, or cobalt speiss, and rhombic *safflorite*. The cubic diarsenide was reported by J. Durocher,¹⁸ and F. Fouqué and A. Michel-Lévy to have been made by the action of hydrogen at a high temp. on a mixture of cobalt and arsenic chlorides. The speiss of a cobalt-blue works was described by C. W. C. Fuchs.

The mineral called by G. Agricola¹⁹ *cobaltum cineraceum* received several other names: *Koboltmalm*, *Koboltglantz*, and *cobaltum arsenico mineralisatum* from J. G. Wallerius, and A. Cronstedt. J. B. L. Romé de l'Isle called it *mine de cobalt grise* or *mine de cobalt arsenicale*; while A. G. Werner, L. A. Emmerling, C. A. S. Hofmann, J. F. L. Hausmann and R. Kirwan called it *Speiskobalt*, or *cobalt speiss*, white or grey cobalt speiss, or equivalent terms. F. S. Beudant designated the mineral *smaltine*, and this name was altered by E. F. Glocker, and J. D. Dana to **smaltite**. J. G. Wallerius knew that the smaltite contained cobalt and arsenic, and the analyses of J. F. John, and F. Stromeyer agreed with the formula CoAs_2 , or $(\text{Co},\text{Fe})\text{As}_2$. E. Hoffmann observed that the mineral also contained some nickel; although A. Breithaupt obtained a variety from Schneeberg free from nickel. The analyses of P. Berthier, J. C. Booth, I. Domeyko, A. Frenzel, E. von Gerichten, H. Hahn, W. Harres, W. F. Hillebrand, F. von Kobell, G. A. Koenig, A. Löwe, L. W. McCay, T. Petersen, C. F. Rammelsberg, G. Rose, F. Sandberger, W. Sartorius, J. F. Vogel, and G. Vollhardt, etc., show that there are all intermediate forms. Hence, P. Groth used the generalized formula $(\text{Co},\text{Ni},\text{Fe})\text{As}_2$. The varieties richest in nickel were called by C. M. Kersten, *nickel biarseniet*; and by A. B. Breithaupt, **chloanthite**—from $\chi\lambda\omicron\alpha\nu\theta\acute{\eta}\varsigma$, greenish—because the colour of the metal salt obtained from it was green in contrast with the red colour of that from smaltite. C. U. Shepard called a variety from Chatham, *chathamite*; A. Frenzel called a variety containing bismuth, *chelentite*—from $\chi\eta\lambda\epsilon\nu\tau\acute{\omicron}\varsigma$,—and W. Haidinger, *kerstenite*—after C. M. Kersten—*cf.* lead selenite. There is only an arbitrary division between the two forms—smaltite has less nickel than cobalt, and chloanthite more nickel than cobalt.

Numerous other observations have been made as to the occurrence of these two minerals—*e.g.* by H. Baumhauer, F. Beyschlag, J. R. Blum, A. des Cloizeaux, J. H. Collins, A. Erdmann, E. Fugger, M. C. Grandjean, R. P. Greg and W. G. Lettsom, C. W. Gümbel, E. Hatle, C. von Hauer, W. Hisinger, G. C. Hoffmann, G. A. Kenngott, A. Koch, C. Koch, N. von Kokscharoff, F. A. Kolenati, A. Lacroix, C. F. de Landeroy, A. Laspeyres, G. Leonhard, O. Luedecke, C. F. Naumann, S. Navia, H. Oehmichen, A. Orio, A. Ossent, W. F. Petterd, A. Raimondi, G. vom Rath, J. Rumpf, A. Russell, N. von Szontagh, H. Traube, M. Websky, V. R. von Zepharovich, etc.

Observations on the crystals of smaltite and chloanthite were made by I. S. R. I. Eques a Born,²⁰ J. B. L. Romé de l'Isle, R. J. Haüy, F. Mohs, M. Bauer, P. Groth, and A. Breithaupt. The crystals belong to the cubic system, being usually in the form of cubes, and rarely show pyritohedral forms. The minerals also occur in compact and granular masses; these are penetration twins; the cleavage on the (111)-face is distinct, and that on the (100)-face in traces. H. Baumhauer reported that the crystals may have a zonal structure. A. Beutell found smaltite crystals with an outer zone of CoAs_2 , and an inner core of CoAs_3 or Co_2As_3 . H. Baumhauer, and G. Vollhardt studied the corrosion figures obtained

ARSENIC

with nitric acid, or chlorine-water. L. S. Ramsdall found a difficulty in interpreting the X-radiograms of smaltite and chloanthite. Assuming that the unit cell contains four mols. as in the case of pyrite, the unit cubic cell has a side of length 5.96 Å. I. Oftedal regarded speiscobalt and chloanthite as impure skutterudites, for the X-radiogram corresponded with a cubic lattice having $a=8.24$ Å; the mineral is not isomorphous with pyrite. The fracture of smaltite and chloanthite is granular and uneven. The colour is tin-white or steel-grey. The lustre is metallic. The surface may appear iridescent, or may be grey from tarnish. The sp. gr., given by many of those quoted in connection with the analyses of these minerals, ranges from 5.734 given by C. F. Rammelsberg, to 6.98 given by J. F. Vogl. I. I. Saslavsky studied the mol. vol. and the contraction which occurs when the diarsenide is formed from its elements. The hardness likewise ranges from 6.3 to 7.0. H. Fizeau gave 0.05919 for the linear coeff. of thermal expansion at 40°. F. E. Neumann found the sp. ht. to be 0.0920; A. Sella gave for a variety rich in iron 0.0848; and calculated for CoAs_2 , 0.0897, for NiAs_2 , 0.0900, and for FeCoNiAs_6 , 0.0902. H. Kopp also measured the sp. ht. A. de Gramont examined the spark spectrum. F. Beijerinck found these minerals to be good electrical conductors; while P. Groth, and A. Schrauf and E. S. Dana examined the thermoelectric qualities against copper. E. T. Wherry found smaltite and safflorite to be poor radio-detectors.

The mineral may occur in nature altered to erythrite—cobalt arsenite—owing to the oxidation of the cobalt and arsenic by exposure to moisture and air. Oxidation readily occurs when the minerals are heated in air, and arsenic trioxide is formed as a sublimate. P. Groth also found that the mineral is oxidized by water. F. von Kobell showed that the minerals are dissolved by nitric acid with the separation of arsenic acid, and C. A. Burghardt, by fused ammonium nitrate. E. F. Smith showed that sulphur monochloride at 180° completely decomposes the minerals; and J. Lemberg, that silver is rapidly precipitated when the minerals are placed in an acidified soln. of silver sulphate, and that an alkaline soln. of bromine oxidized the cobaltiferous more rapidly than the nickeliferous mineral. G. Vollhardt found that the minerals with a low proportion of arsenic readily dissolve in a mixture of hydrochloric acid and potassium chlorate, while those rich in arsenic require repeated treatments with the mixture. E. Thomson studied the etching reactions of smaltite, and chloanthite with nitric acid, and with soln. of mercurous and ferric chlorides.

The rhombic form of cobalt diarsenide was regarded by A. Breithaupt²¹ as a distinct mineral species, and named **safflorite**—from the German *Safflor*, safflower, or bastard saffron in allusion to its use as a blue pigment for glass, etc. It is the *flaserigen weissen Speiskobalt* of A. G. Werner; and it was also mentioned by F. von Kobell, F. Mohs, E. F. Glocker, G. Rose, and G. A. Kenngott. F. Sandberger called it *Quirlkies*, or *spathiopyrite*—from $\sigma\pi\alpha\theta\eta$, a quirl, or spatula. Analyses were made by E. Hoffmann, G. Rose, L. W. McCay, F. Sandberger, F. Varrentrapp, E. von Gerichten, T. Petersen, and H. Sjögren. These are in agreement with the formula CoAs_2 . Up to 18.48 per cent. of iron, and 7.39 per cent. nickel, 4.76 per cent. bismuth, and 4.22 per cent. copper has been found in the mineral. Safflorite was also described by A. Frenzel, P. Poni, and J. D. Dana. Safflorite occurs massive, and with a fibrous radiated structure. It also occurs in tin-white rhombic crystals resembling those of arsenopyrite. H. Sjögren gave for the axial ratios of the rhombic crystals $a:b:c=0.5085:1:0.8944$. Twinning occurs about the (110)-plane, and there are cruciform twins crossing at an angle of nearly 120°. The cleavage on the (010)-face is distinct. W. F. de Jong found the lattice constants deduced from the X-radiogram are in agreement with those obtained for löllingite. N. S. Kurnakoff and N. S. Konstantikoff represented the compound as isomorphous with löllingite, and iron diantimonide. The hardness is 4.5–5.0, and the sp. gr. determined on most of the samples analyzed ranged from G. Rose's 6.84 to H. Sjögren's 7.41. F. Beijerinck found that safflorite is a conductor of electricity. The lustre is metallic, but the mineral soon tarnishes on exposure to air. The

general properties are like those of smaltite. E. Thomson studied the etching reactions with nitric acid, and soln. of mercurous and ferric chlorides; and T. L. Walker and A. L. Parsons, the oxidizing action of aerated water—*vide rammelsbergite*.

A. Breithaupt²² described a mineral from Skutterud, near Modum, Norway, which he called *tesseral pyrites*, or *hard cobalt pyrites*. J. F. L. Hausmann used similar names. W. Haidinger called it **skutterudite**, and J. Nicol, *modumite*. Analyses reported by C. F. Rammelsberg, T. L. Walker, T. Scheerer, F. Wöhler, and L. Staudenmaier corresponded with **cobalt triarsenide**, CoAs_3 . The occurrence in Italy was described by L. Bombicci, and A. d'Achiardi. E. Waller and A. J. Moses, and G. Vollhardt described *nickel-skutterudite*, $(\text{Co}, \text{Ni}, \text{Fe})\text{As}_3$, containing up to nearly 13 per cent. of nickel and 5 per cent. of cobalt, and W. Ramsay, and A. Frenzel, *bismuth-skutterudite*, $\text{Co}(\text{As}, \text{Bi})_3$, with up to 30 per cent. of bismuth. J. D. Dana questioned the homogeneity of bismuth-skutterudite. A. Beutell and F. Lorenz gave $450^\circ\text{--}618^\circ$ as the temp. of its formation from the metal and arsenic vap. They said that at $415^\circ\text{--}430^\circ$, cobalt hemipentarsenide, Co_2As_5 , is formed. Skutterudite occurs massive and granular, and in octahedral or pyritohedral crystals belonging to the cubic system. The crystals were examined by T. Scheerer, G. vom Rath, L. Fletcher, and W. H. Miller. The cleavage on the (100)-face is distinct, and that on the (110)-face occurs in traces. A. Beutell regarded skutterudite as probably not cubic, but rather occurring as a pseudomorph after smaltite. The fracture is uneven, and the colour varies from tin-white to lead-grey with a bright metallic lustre, or there may be an iridescent film on the surface. The hardness is about 6; and the sp. gr. ranges from 6.664 to 6.934. I. Oftedal observed that the X-radiogram agreed with a cubic lattice having $a=8.189 \text{ \AA}$., and 8 mols. of CoAs_3 per unit cell. The shortest distance between the arsenic atoms is 2.46 \AA ., and between the cobalt and arsenic atoms, 2.35 \AA .. F. Beijerinck found the mineral to be a good conductor of electricity; and A. Schrauf and E. S. Dana showed that the thermoelectric properties may be positive or negative. E. Thomson examined the etching reactions with nitric acid, and soln. of mercurous and ferric chlorides; and T. L. Walker and A. L. Parsons, the oxidation of the mineral by aerated water—*vide rammelsbergite*.

Alloys of nickel and arsenic were made, by J. J. Berzelius,²³ and A. F. Gehlen,

by the action of arsenic on nickel; by P. Berthier, by reducing nickel arsenate with carbon; and by A. Granger, by heating nickel in the vap. of arsenic chloride. The composition of these products approximated *nickel hemiarsenide*, Ni_2As ; but there is nothing to show that this product is a chemical individual. K. Friedrich and F. Bennigson²⁴ studied the f.p. curves of alloys with up to 57.4 per cent. of arsenic. The results are illustrated by Fig. 11. The f.p. of nickel is lowered by the addition of arsenic until a eutectic point is reached at 900° and 27.8 per cent. The curve then rises to a maximum at 998° and 34.3 per cent. of arsenic, corresponding with the compound Ni_5As_2 . Another eutectic point is reached at 804° and 43.3 per cent., and the curve then rises to a second maximum at 968° and 56.0 per cent., corresponding with the compound NiAs . Solid soln. are formed

FIG. 11.—Freezing-point Curve of the Nickel-Arsenic Alloys.

between the limits 0–5.5 per cent. and 33.5–35.7 per cent. of arsenic. The compound Ni_5As_2 , holding nickel in soln., occurs in two modifications. Alloys containing

from 35.7 per cent. to 56 per cent. undergo a change at a temp. which could not be determined accurately owing to supercooling; the maximum development of heat occurs at 45.5 per cent. of arsenic, thus indicating the formation of a compound Ni_3As_2 . The microscopic structure of the alloys is in accordance with these conclusions. The alloys are hard, the maximum hardness corresponding with the compound Ni_5As_2 . The brittleness is greatest at the points indicated by maxima on the f.p. curve. Alloys containing more than 29 per cent. of arsenic are no longer attracted by a magnet. A. Beutell reported two nickel arsenides to be formed by the action of arsenic vapour on the powdered metal. O. Hackl reported **nickel tritarsenide**, Ni_3As_2 , to occur as a mineral, which he called **dienerite**—after C. Diener—without giving particulars.

K. Friedrich and F. Bennigson prepared **nickel dipentitarsenide**, Ni_5As_2 , and the conditions of stability are indicated in Fig. 10. It melts at 998° . As indicated above, there is some evidence on the fusion curve of the existence of **nickel ditritarsenide**, Ni_3As_2 . A. Descamps said that he made it by the reduction of nickel arsenate with molten potassium cyanide; E. Vigouroux obtained it by passing arsenic trichloride vap. over powdered nickel or a nickel arsenide at 800° – 1400° ; he also found that nickel monarsenide loses arsenic at 800° and passes into the ditritarsenide; and A. Granger and G. Didier, by heating the finely-divided metal at 600° in the vapour of arsenious chloride; the compound thus obtained forms reddish, crystalline granules having a metallic lustre and resembling the impure arsenide isolated by F. Wöhler from small residues. Although the arsenide differs in composition from the phosphide, Ni_2P , obtained under similar conditions, it resembles this compound in its chemical properties. A. Brukl made this arsenide by the method employed for ferrous arsenide. According to E. Vigouroux, the grey powder has a metallic lustre, it melts at 1000° , and freezes to a silver-white, hard mass of sp. gr. 7.86 at 0° . It begins to decompose near 1400° ; when heated with arsenic in an atm. of hydrogen, it takes up arsenic, and this the more the lower the temp., until, at 400° , it forms the grey, pulverulent diarsenide. The arsenides are attacked by heated chlorine, oxygen, or sulphur vap. They are rapidly dissolved by nitric acid and aqua regia, are very slightly attacked by hydrochloric and sulphuric acids, are decomposed by fused potassium chlorate and nitrate, but are only slowly attacked by alkali hydroxides or carbonates. By heating nickel tridiarsenide under molten boric oxide, A. Descamps believed that he had formed *nickel tritarsenide*, Ni_3As_2 . He also said that the same compound can be produced by reducing nickel oxide with molten potassium cyanide in the presence of a large proportion of arsenic, and at a temp. at which the excess of arsenic will volatilize. The individuality of this compound has not been established. R. Lorenz and W. Herz studied the relations between the transformation temp., 970° , and the m.p., 962° , of this and other compounds.

A substance occurring as a furnace product has been described as *nickel speise*. It was analyzed by J. W. Döbereiner, F. Wöhler, C. Schnabel, C. F. Plattner, W. Francis, C. F. Rammelsberg, G. Rose, E. F. Arthon, E. R. Schneider, and J. Braun. Its composition varies between Ni_4As_2 and Ni_3As_2 . A. Breithaupt described monoclinic plates of what he called *ein neuer Kies* from Müsen near Siegen, and he named it *placodine*—from $\mu\lambda\alpha\kappa\acute{\omega}\delta\eta\varsigma$, flat, plate-like—in reference to the tabular form of the crystals. G. Rose assigned the crystals to the tetragonal system, and J. Braun gave for the axial ratio $a : c = 1 : 1.125$. J. Braun gave 7.6941 for the sp. gr.; and A. Breithaupt, 7.988–8.062. C. F. Plattner, C. Schnabel, G. Rose, and A. Gurlt considered placodine as a furnace product analogous with the nickel speise of F. Wöhler. C. F. Rammelsberg explained the variable composition to its forming isomorphous mixtures or solid soln. with other arsenides or sulphides.

K. Friedrich and F. Bennigson's ²⁵ f.p. curve shows the conditions under which **nickel monarsenide**, NiAs , is formed. F. Fouqué and A. Michel-Lévy obtained a similar product by the action of arsenic trichloride vapour on nickelous chloride at a red-heat. E. Vigouroux prepared the monarsenide by passing the vap. of arsenic trichloride over powdered nickel or nickel arsenide at 400° – 800° . It is

said that the product is a pale red crystalline powder of sp. gr. 7.57 at 0°. W. F. de Jong and H. W. V. Willems found that the X-radiogram agreed with a hexagonal structure with $a=3.57$ Å., and $c=5.10$ Å.; and sp. gr. 7.88. K. Friedrich and F. Bennigson said that the monarsenide loses arsenic above 800°, and forms the ditritarsenide. It takes up arsenic at a low temp. as in the case of the ditritarsenide and forms the diarsenide at 400°. The chemical reactions of the monarsenide and the ditritarsenide are similar. W. Herz gave 5.84×10^{12} for the vibration frequency of NiAs.

This arsenide occurs in nature. It was called *Kupfernickel* by U. Hiärne,²⁶ in 1694, probably on account of its colour, and J. Woodward, through some mistake, called it *cuprum nicolai*. J. D. Denso recognized the presence of arsenic. J. G. Wallerius regarded it as *arsenicum sulphure et cupro mineralisatum*; A. Cronstedt as *niccolium ferro et cobalto arsenicatis et sulphuratis*; and B. G. Sage, and J. B. L. Romé de l'Isle, as *mine de cobalt arsenicale tenant cuivre*. F. Stromeyer analyzed the mineral in 1817, and showed that it consisted essentially of nickel and arsenic, nearly in the proportions required for NiAs. The original term *Kupfernickel*, used by L. A. Emmerling, A. Estner, C. A. S. Hofmann, etc., was gradually dropped, and the mineral came to be called *arsenical nickel* by R. J. Haiüy, and C. C. von Leonhard; *nickel pyrites*, by F. Mohs, and W. Haidinger; and *red nickel pyrites* by A. Breithaupt, and E. F. Glocker. F. S. Beudant called it *nickeline*, and J. D. Dana, **niccolite** or *niccoline*. Analyses were reported by P. Berthier, A. Breithaupt, I. Domeyko, J. J. Ebelmen, F. A. Genth, A. Grunow, H. Hahn, C. Heusler, T. Petersen, C. H. Pfaff, F. Pisani, C. F. Rammelsberg, T. Scheerer, L. Sipöcz, G. Suckow, and C. Winkler. The mineral usually contains sulphur, iron, and cobalt. Sometimes part of the arsenic is replaced by antimony; in the extreme case, breithauptite, NiSb, appears. Intermediate varieties, Ni(As,Sb), were called *aarite* by M. Adam, and *arite*, by F. Pisani.

Numerous occurrences have been reported—e.g. by F. Babanek, M. Bäumlér, A. Breithaupt, L. Brunrucker, A. des Cloizeaux, J. H. Collins, J. D. Dana, I. Domeyko, A. Frenzel, E. Fugger, P. Giebe, E. F. Glocker, R. P. Greg and W. G. Lettsom, C. W. Gumbel, E. Hatle, C. A. S. Hofmann, G. C. Hofmann, T. S. Hunt, G. P. Jervis, G. A. Kennigott, J. F. Kemp, G. A. Koenig, N. von Kokscharoff, A. Lacroix, A. von Lasaulx, H. Laspeyres, G. Leonhard, A. Liversidge, D. S. Lovisato, O. Luedecke, W. H. Miller, F. Navarro, J. S. Newberry, J. J. Nöggerath, A. Orío, W. F. Petterd, A. Raimondi, G. Rose, J. Rumpf, A. Russell, F. Sandberger, A. Sjögren, H. Traube, M. Websky, J. D. Whitney, and V. R. von Zepharovich.

Niccolite usually occurs massive with a fine texture; it also occurs in reniform masses with a columnar structure, and reticulated and arborescent. The colour is pale copper-red with a grey or black tarnish. Crystals are rare. W. Phillips said that the crystals are probably hexagonal, and A. Breithaupt, F. Mohs, and W. Haidinger, rhombic. E. F. Glocker, F. von Kobell, H. J. Brooke, and J. F. L. Hausmann showed that W. Phillips' opinion was correct; and A. Breithaupt gave for the axial ratio $a : c = 1 : 0.8194$. P. Groth gave $1 : 0.9462$. This agrees for the measurements of A. des Cloizeaux. G. Aminoff found that the X-radiogram corresponds with an hexagonal lattice with 2 mols. in each elementary parallelogram, and $a : c = 1 : 1.430$. W. F. de Jong obtained a different structure. He found that the elementary parallelepiped contains two molecules and has $a=3.57$ Å., $c=5.10$ Å., and the distance between the nickel and arsenic atoms is 2.42 Å. W. F. de Jong concluded that the nickel and arsenic form alternate layers along the c -axis, at distances $\frac{1}{2}c=1.27$ Å. The shortest distance is 2.42 Å., and $a=3.57$ Å.; he also found the lattice constants of the rhombic crystals closely resemble those of löllingite. W. F. de Jong and H. W. V. Willems found that the hexagonal lattice of arite, Ni(AsSb), agrees with a solid soln. having $a=3.80$ Å., and $c=5.20$ Å.; and a sp. gr. 7.19. I. Oftedal studied the lattices of a number of other compounds of the nickel arsenide type. The cleavage of the crystals is scarcely recognizable. The hardness is about 5.0–5.5; and

the sp. gr. reported by those who have analyzed samples ranges from 7.33 to 7.72. A. de Gramont examined the spark spectrum. F. Beijerinck found the mineral to be a good electrical conductor; though T. W. Case found it to be a non-conductor in the dark and observed no measurable effect by light. H. S. Roberts and L. H. Adams studied the rectifying action of crystals of niccolite used as radio-detectors. Arsenic trioxide sublimes when the mineral is roasted. T. L. Walker and A. L. Parsons studied the oxidation of niccolite by aerated water—*vide rammelsbergite*. Niccolite is soluble in aqua regia and in nitric acid with the separation of arsenic acid. J. Lemberg found that niccolite is scarcely affected by an alkali soln. of bromine; and that when placed in an acidified soln. of silver sulphate, silver is immediately precipitated. The mineral *keweenawrite* was shown by E. Thomson to be probably a mixture of niccolite with other related arsenides.

According to E. Vigouroux,²⁷ **nickel diarsenide**, NiAs_2 , is produced when the lower arsenides are heated to 400° with arsenic in an atm. of hydrogen. This compound is dimorphic, being represented in nature by the *cubic* mineral *chloanthite*—which has been described in connection with smaltite—and the *rhombic* mineral **rammelsbergite**. W. Haidinger applied the term rammelsbergite—after C. F. Rammelsberg—to the cubic white nickel ore from Schneeberg, called by C. M. Kersten nickel biarseniet; but after A. Breithaupt had established the dimorphism of the diarsenide, and applied the term chloanthite to the cubic form, J. D. Dana employed rammelsbergite for the rhombic form. Analyses were reported by T. L. Walker, F. Wöhler, E. Hoffmann, F. Sandberger, L. W. McCay, C. F. Rammelsberg, and I. Domeyko. Occurrences were also mentioned by A. Frenzel, T. L. Walker and A. L. Parsons, P. Groth, V. R. von Zepharovich, J. Habersfelner, G. A. Kennigott, and G. P. Jarvis. Rammelsbergite occurs massive, and also in rhombic crystals resembling arsenopyrite. A. Breithaupt's data correspond with $a:b:c=0.537:1:—$. The cleavage is prismatic. The colour is tin-white with a tinge of red. The hardness is 5.25 to 5.75; and the sp. gr. 6.9 to 7.2. T. L. Walker and A. L. Parsons gave 7.0 for the sp. gr. F. Beijerinck found the mineral is a conductor of electricity; and E. T. Wherry, a fair radio-detector. The general chemical properties resemble those of chloanthite, and niccolite. E. Thomson studied the etching reactions of rammelsbergite. E. F. Smith found that it dissolves in sulphur monochloride at 180° . T. L. Walker and A. L. Parsons found that the rate of oxidation of rammelsbergite by aerated water is four times as rapid as that of niccolite, eight times as rapid as a mixture consisting of löllingite seventy, safflorite ten, and skutterudite twenty, and seventy-five times as rapid as a mixture consisting of arsenopyrite one, löllingite eighty-five, safflorite six, and skutterudite eight. Meteoric waters might, therefore, be expected to remove rammelsbergite before attacking most of the other arsenides.

E. Waller and A. J. Moses²⁸ found a mineral, which they called *nickel-skutterudite*, in the Bullard's Peak district, New Mexico. The analysis corresponds with RA_3 , where R stands for Ni : Co : Fe in the proportions 4 : 2 : 1. This mineral is the nearest representative of **nickel triarsenide**, NiAs_3 . It occurs in grey, granular masses of hardness 5. A. Gibb²⁹ studied the elimination of arsenic from copper nickel alloys.

The arsenides of the elements of the platinum family have not been closely examined. According to W. H. Wollaston,³⁰ an alloy of *rhodium and arsenic* is produced when the two elements are fused together, and the arsenic is given off when the alloy is heated in air. N. W. Fischer, and R. Chenevix also found that *palladium and arsenic* unite with the evolution of heat, forming a brittle fusible alloy. C. Winkler obtained *platinum silicoarsenide* as an indefinite alloy by melting together platinum, arsenic, and silicon under molten cryolite and sodium chloride. The hard, white alloy is almost insoluble in nitric acid.

A. F. Gehlen³¹ found that when spongy platinum is heated with an excess of arsenic, the combination which occurs is attended by *lebhafter Feuererscheinung*, the alloy was also made by heating platinum mixed with arsenic trioxide and

sodium carbonate—if the alkali carbonate be omitted, A. F. Gehlen said that neither arsenic trioxide nor arsenic acid exerts any action on the metal. The arsenic alloys were also made by J. Murray, W. Lewis, R. W. Fox, and N. W. Fischer. W. R. Hodgkinson and F. K. S. Lowndes found that a platinum wire immediately fuses when heated in contact with arsenic. The binary system with up to about

FIG. 12.—Freezing-point Curves of the Arsenic-Platinum Alloys.

28 per cent. of arsenic was studied by K. Friedrich and A. Leroux, and the results are illustrated by Fig. 12. The two elements form a eutectic at 598° with 13 per cent. of arsenic, and there is a probable maximum in the curve near 1500° corresponding with **platinum hemitriarsenide**, Pt_2As_3 . It was not found possible to extend the curve beyond this region. E. Kordes studied the eutectic mixtures. D. Tivoli found that when platinum hydroxyarsenide is heated in an atm. of carbon dioxide at a high temp., the hemitriarsenide is formed, as a white mass with a metallic appearance. It is decomposed by hot conc. sulphuric acid.

H. L. Wells described a tin-white mineral from Algoma, near Sudbury, Ontario, and named it **sperrylite**—after F. L. Sperry, who first drew his attention to the mineral. Analyses by H. L. Wells, and F. Rössler showed that sperrylite approximates to **platinum diarsenide**, $PtAs_2$, with a trace of the platinum replaced by rhodium, and of arsenic by antimony. This arsenide was obtained as an alloy by A. F. Gehlen, and J. Murray; while H. L. Wells obtained it as a porous mass by passing the vap. of arsenic in a current of hydrogen over red-hot platinum; and by fusing the washed and dried anode mud from the copper refinery with borax and sodium carbonate. S. L. Penfield showed that the crystals belong to the cubic system—simple cubes are common, octahedra exceptional; the majority of the crystals show combinations of the cube and octahedron. L. J. Spencer also described the crystals of sperrylite from the Transvaal. L. S. Ramsdall examined the X-radiograms of sperrylite, and regarded the structure as pyritic with arsenic atoms occupying the same relative positions as the sulphur atoms of pyrite. The unit cubic cell has a side of length 5.94 Å.; G. Aminoff and A. L. Parsons, 6.00 Å.; W. F. de Jong gave 5.92 Å., and said that unit cube has 4 platinum and 8 arsenic atoms. Assuming that the 4 platinum atoms are equivalent, and also the 8 arsenic atoms, there is a dyakisdodecahedral symmetry; and with the pyritic structure, the smallest distance between the platinum and arsenic atoms is 2.47 Å.; and between two arsenic atoms, 2.46 Å. Sperrylite was described by W. E. Hidden and J. H. Pratt, and J. F. Donald, etc. L. J. Spencer gave 10.58 for the sp. gr. at 19.5°/4°. According to T. L. Walker, sperrylite is dissolved by aqua regia, and more slowly by hydrochloric acid, but it is almost insoluble in nitric, sulphuric, and hydrofluoric acids.

D. Tivoli obtained minute, black scales of **platinum hydroxyarsenide**, $PtAs(OH)$, by passing a rapid current of arsine into a soln. of platinum tetrachloride: $PtCl_4 + AsH_3 + H_2O = PtAs.OH + 4HCl$. This substance is insoluble in water, and is only altered to a slight extent by hydrochloric and nitric acids and potash; it is readily soluble in aqua regia. Conc. sulphuric acid decomposes it in accordance with the eq.: $2PtAs.OH + 2H_2SO_4 = 2Pt + As_2O_3 + 3H_2O + 2SO_2$. It may be dried at 130° without decomposition, but above that temp. is transformed into a platinum arsenide thus: $6PtAs.OH = As_2O_3 + 2Pt_3As_2 + 3H_2O$. These two decompositions served as a basis for the analysis of platinum hydroxyarsenide.

§ 11. Arsenic Suboxide, and Trioxide

J. J. Berzelius¹ regarded the black film which forms on the surface of arsenic as *arsenic suboxide*, and P. A. von Bonsdorff represented it as **arsenic hemioxide**, As_2O . J. J. Berzelius also said that the suboxide is produced as a dark brown sublimate which first appears during the preparation of arsenic; and J. W. Retgers observed the brown film as produced along with the arsenic mirror during the sublimation of commercial arsenic. E. Mitchell believed that the suboxide is an intermediate product in the oxidation of arsenic (*q.v.*), and is the cause of the garlic odour. He also said that the suboxide is more volatile than arsenic trioxide. It is not unlikely that E. Mitchell mistook the amorphous arsenic for arsenic hemioxide. J. W. Retgers supposed that the alleged suboxide is truly a chemical individual, but A. Geuther, and G. Suckow showed that the suboxide is probably a mixture of arsenic and arsenic trioxide.

As indicated in connection with the history of arsenic, the twelfth-century Arabian chemists alluded to white arsenic, and G. Brandt² showed that *arsenicum album* is the oxide or calx of arsenic. In 1747, J. G. Wallerius spoke of *arsenicum nativum*, *arsenicum faricaceum* or *farina arsenicalis*, and *arsenicum crystallinum*. The *arsenic-meal*, furnace fume, or white arsenic was the *arsenicum calciforme* of A. Cronstedt, and the *arsenicum cubicum* of C. Linnæus. This oxide received various names in the Middle Ages—*white arsenic*, *arsenic*, *flowers of arsenic*, *rat-poison*, *poison meal*, *furnace fume*, *arsenious acid*, etc. The modern designation is **arsenic trioxide**, As_2O_3 , or As_4O_6 . The formation of arsenic trioxide during the oxidation of arsenic has already been discussed. It is also produced when arsenic, mispickel, or arsenical pyrites alone or mixed with other ores, is roasted in air. With löllingite, arsenic vapour is given off at a dull red-heat, and at a higher temp., arsenic trioxide is produced; the iron is nearly all converted into ferric oxide, and but a small proportion of ferric arsenate is formed. When mispickel is heated in air, arsenic sulphide vapour is evolved below a red-heat; but at a higher temp., ferric oxide, sulphate, and arsenate are formed, while sulphur dioxide and arsenic trioxide are given off.

Arseniferous ores are a by-product from the tin-mines of Cornwall, and their treatment is accordingly connected with the production of tin, and tungsten. The ore is hand-picked, broken first with hammers, then in jaw-crushers, and finally in stamp-mills. The stamp pulp is then screened and passed through hydraulic classifiers. The ore is then calcined. There are different types of calciner; these were illustrated in connection with the extraction of tin—Figs. 2 and 3, **7**, 46, 3. In Cornwall, the calciner is a kind of reverberatory furnace with a revolving floor of cast-iron and firebrick sloping from the centre to the periphery, and revolving 4–6 times per hour. Three sets of scrapers are arranged over the floor. The ore is fed on the revolving floor by means of a hopper, and heated to dull redness for about 10 hours, it is at the same time raked into a central trough and thence into

a chamber beneath. The oxidized sulphur and arsenic vapours pass zig-zag over a large condensing surface. The sulphur vapours escape, and dark grey, crude arsenic or *arsenic soot* is collected. It contains 4–10 per cent. of carbon and sulphur. The arsenic soot is refined by recalcination in a flat-bottomed reverberatory furnace using a smokeless fuel—say a mixture of coke and anthracite—and connected with a series of zig-zag condensing chambers. The charge is fed from the top, and paddled down to the side-doors while being roasted. The first condensing chamber collects the *slag arsenic*, which is re-ground and calcined; in the other chambers, snow-white, crystalline arsenic trioxide collects on the walls, often in stalactitic forms. This is raked out, ground in stone-mills, and passed through leather pipes into 4 cwt. casks. Great care is taken to prevent the leakage of the poisonous dust during these operations. About 60 per cent. of arsenic is recovered from the ores, while 40 per cent. is lost in the slimes. The mispickel ores employed contain from 10 to 30 per cent. of arsenic. There are several types of chamber—*poison tower*—for condensing the white arsenic—*poison flour*, or *arsenical soot*. Modifications of the process were described by C. Doremus,³ G. J. Young, E. C. Williams, H. P. Bassett and S. S. Sadtler. C. L. Read discussed the purification from the less volatile antimony trioxide.

V. Kohlschütter and J. L. Tüscher⁴ prepared highly dispersed, or **colloidal arsenic trioxide** by vaporization in the electric arc. F. Schoucroum showed that it is a colloid with a negative charge which does not reverse with increasing conc. of H-ions. In addition to the white, glistening, minutely crystalline flowers of arsenic, white *arsenic-glass*, or *vitreous arsenic* is prepared by collecting the vaporized arsenic trioxide at so high a temp. that the sublimate fuses into a white glassy mass. **Vitreous arsenic trioxide** may be prepared by heating the trioxide—preferably under slight press.—in a cast-iron pan surmounted by wrought or cast-iron bell. The pans containing the arsenic are heated to redness, and a layer of vitreous arsenic collects in the bell. More white arsenic is introduced into the pan; and the operation is repeated until the glass has a thickness of about an inch. There are several different modifications of the process for converting ordinary white arsenic into the glassy form.⁵ As shown by H. A. L. Wiggers, and A. Streng, antimony oxide is one of the most likely impurities. L. Kessler tried to eliminate it by dissolving the oxide in warm aq. ammonia, evaporating the filtrate, and subliming the residue; but F. Wöhler did not succeed by this process. R. Suchy and J. Michel dissolved the crude trioxide in a soln. of sodium carbonate, and precipitated the trioxide from the filtered soln. by carbon dioxide. R. M. Chapin recommended the following mode of purification:

Ordinary arsenic trioxide is boiled for about one hour with a quantity of water insufficient to dissolve the whole of it, the soln. filtered while hot, the filtrate conc. until arsenic trioxide begins to precipitate, and the soln. again filtered. The separated oxide is tested for antimony by dissolving a portion in ammonia adding hydrogen sulphide, boiling the mixture, and then cooling in ice-water; a turbidity is obtained if more than 0.15 per cent. of antimony trioxide is present, and in such case the arsenic trioxide must be treated further as described. The purification depends on the fact that antimony, if present, is absorbed almost completely by the solid arsenic trioxide which remains undissolved in the aq. soln. The final crystallization of the pure arsenic trioxide is best made from a slightly hydrochloric acid soln., and the product is then sublimed.

The general methods employed for the preparation of the flowers of arsenic, and arsenic glass, are described by G. Vié, and by C. Schnabel, *Handbuch der Metallhüttenkunde*, (Berlin, 1904); T. E. Thorpe, *A Dictionary of Applied Chemistry*, (London, 1. 380, 1921); etc. C. P. Linville removed selenium by the addition of a reagent capable of forming a non-volatile selenide and volatilizing the arsenic trioxide.

The analyses of L. J. Thénard,⁶ H. Davy, J. L. Proust, J. J. Berzelius, E. Mitscherlich, T. Thomson, and C. F. Richter have shown that the composition can be represented by the empirical formula As_2O_3 . The impurities in commercial arsenic trioxide were discussed by W. D. Collins and co-workers. E. Mitscherlich

found that the vapour density at 563° is 13·85 when the value calculated for As_4O_6 is 13·68; V. and C. Meyer obtained analogous results at much higher temp.; and A. Scott, at 1050°. On the other hand, H. Biltz found that the dissociation of the complex mol. into a simpler form $\text{As}_4\text{O}_6 \rightleftharpoons 2\text{As}_2\text{O}_3$ is appreciable at 800°; and he found for the vap. density, D ,

	518°	769°	851°	1059°	1256°	1450°	1584°	1732°
D	13·92	13·62	13·15	12·76	12·36	9·41	8·81	7·32

The mol. wt. of the octahedral crystals in nitrobenzene soln. was found by H. Biltz to be 396 in agreement with the value required for As_4O_6 . R. M. Bozorth's examination of the X-radiograms of arsenic trioxide show that the molecules of the solid consist of As_4O_6 —*vide infra*. No suitable solvent was found for the vitreous arsenic trioxide, and its mol. wt. is unknown. E. Beckmann found the mol. wt. of arsenic trioxide from its effect on the f.p. of antimony trichloride to be about half the normal value—probably an effect of a chemical reaction—*vide* arsenic triiodide. H. Erdmann argued that since a certain amount of yellow arsenic is produced when arsenic trioxide is reduced with zinc dust in the presence of carbon disulphide, yellow arsenic and arsenic trioxide have a similar constitution.

Arsenic trioxide.

Yellow arsenic.

V. Meyer, however, preferred one of the following formulæ :

The octahedral form of the crystals was noted by T. Bergman,⁷ and by J. B. L. Romé de l'Isle. The crystals belong to the cubic systems, and they were described in detail by A. des Cloizeaux, whilst A. Grosse-Bohle compared the crystals with the cubic form of antimony trioxide. R. M. Bozorth examined the **X-radio-gram** of the octahedral crystals of arsenic trioxide and found that the corresponding space-lattice is of the diamond form, Fig. 13, with one mol. of As_4O_6 corresponding with one carbon atom. The mol. is a regular tetrahedron, and there are two orienta-

FIG. 13.—Arrangement of the Molecules of Arsenic Trioxide, As_4O_6 , in the Space-lattice.

FIGS. 14 and 15.—Arrangements of the Atoms in the Molecules of Arsenic Trioxide.

tions of the atoms, one being a reflection of the other in any plane parallel to a cube face. The four arsenic atoms lie on the four lines joining the centre of the tetrahedron to its corners, and the six oxygen atoms on the six perpendiculars from the

centre on the six sides. The unit cube with 8 mols. of As_4O_6 has a side 11.06 A.; and the shortest shows the arrangement of the atoms of arsenic, ●, and of oxygen, ○, in the ⊗ molecules of Fig. 14; and Fig. 15, the arrangement of these atoms in the ⊕ molecules. R. Brauns observed no optical anomalies. The cleavage of the crystals is octahedral. The octahedral crystals are produced during the sublimation of arsenic trioxide when the vap. is rapidly cooled without passing through a state of fusion; by cooling a hot sat. aq. soln. of arsenic trioxide; and, according to J. N. von Fuchs, when white arsenic glass is kept for a long time it becomes opaque, owing to devitrification. The crystallization was observed by J. F. L. Hausmann. H. V. Regnault said that the devitrification proceeds rapidly at 100°. H. Rose showed that if air be excluded, arsenic-glass can be kept over a year without devitrification; and C. Winkler found that the glass remains clear if kept in thoroughly dried hydrogen, air, or carbon dioxide. W. Krüger also found that moisture is necessary to develop the turbidity in air; and that the change is accompanied by an increase of 0.625 per cent. in weight. R. Christison said that the glass remains transparent for years if kept under water; and H. Rose obtained a similar result under alcohol. On the contrary, according to C. Winkler, the transformation of arsenic-glass into octahedral crystals proceeds quickly under water, under a cold aq. soln. of arsenic trioxide, or under ether or alcohol; and, according to H. A. L. Wiggers, under hydrochloric acid. C. Winkler said that if a stick of arsenic-glass be dipped in boiling water, octahedral crystals quickly form on the surface of the glass. A. Bussy found that if opaque arsenic-glass be treated with boiling water, it becomes transparent again, not, as A. Bussy supposed, on account of the greater solubility of the arsenic glass, but, according to C. Winkler, because of the conversion of the amorphous mass into a crystalline solid. C. Winkler explained the action of water by assuming that the film of water condensing on the surface of the glassy oxide forms a soln. which deposits crystals of the less soluble cubic form; the water then dissolves more vitreous oxide, and so there is a continuous cycle of changes involving the transformation of the vitreous oxide into octahedral crystals from the exterior towards the interior.

A. Scheurer-Kestner found that when arsenic trioxide is crystallized from a soln. containing colouring agents—say, sulphindigotic acid, brazil-wood, or curcuma—the crystals retain the dye, leaving the mother-liquor colourless. According to H. Rose, the crystallization of arsenic trioxide from soln. is attended by crystallo-luminescence. He said:

When from one to one and a half parts of transparent arsenic trioxide are dissolved by half an hour's boiling, in a mixture of six parts of fuming hydrochloric acid with two parts of water, and the soln. left to cool as slowly as possible, the arsenic trioxide crystallizes in transparent octahedra and the formation of each crystal is accompanied by a flash of light; on agitation, many new crystals are formed, and a corresponding number of sparks is produced. If from four to six parts of arsenic-glass are dissolved in the acid, the light produced by the crystallization is sufficient to illuminate a dark room. As long as the deposition of crystals goes on, so long is light perceived on agitating the liquid; and this appearance may be visible on the second, and even, though very faintly, on the third evening. If the liquid be then boiled, so as to dissolve the remaining portion of the glassy oxide, crystallization again takes place, accompanied by emission of light, though not so bright as before. If the liquid be rapidly cooled, the acid separates in the pulverulent state, and little or no light is emitted. A soln. of arsenic trioxide in a hot mixture of hydrochloric with sufficient nitric acid to convert the whole of the arsenic trioxide into the pentoxide, likewise emits a strong light as the acid crystallizes. Boiling dil. sulphuric acid dissolves arsenic trioxide in smaller quantity, and exhibits only occasional luminosity. Nitric and acetic acids, which dissolve still less of the arsenic trioxide, exhibit no luminosity whatever. Arsenic trioxide which has acquired the porcelain texture, and also arsenic-meal, likewise exhibits, when dissolved in hydrochloric acid, a very feeble luminosity on agitation.

E. von Bandrowsky found that the faculty is not lost if the arsenic trioxide has been recrystallized from acidic soln. J. Guinchant, and D. Gernez attribute the phenomenon to triboluminescence; and it is exhibited when the crystals are compressed; or when the crystals are stirred with a steel, iron, or platinum rod.

M. Trautz discussed the phenomenon. J. Guinchant found the spectrum of the light is continuous; and that an adjacent electroscope is not affected during the phenomenon.

L. A. Emmerling referred to the natural occurrence of white arsenic—*natürlichen Arsenikkalk*. D. L. G. Karsten called the mineral *Arsenikblüthe*; W. Haidinger, *arsenite*; and J. D. Dana, *arsenolite*. The occurrence of arsenolite in nature is a result of the weathering, or oxidation of arsenical ores; and it is found accompanying arsenical ores—*e.g.* mispickel, smaltite, etc. Arsenolite may appear earthy, stalactitic, or botryoidal; but it usually occurs in minute capillary crystals, in stellar aggregates or crusts. The dark grey, or greyish-black crust or powder found on native arsenic, sometimes regarded as a suboxide (*q.v.*), is, according to G. Suckow, a mixture of arsenic and arsenic trioxide. C. Hintze⁸ has described numerous occurrences of arsenolite.

In addition to the octahedral form crystallizing in the cubic system, F. Wöhler,⁹ in his paper *Ueber die Dimorphie der arsenigen Säure*, observed that the arsenical sublimate from a Hessian furnace roasting cobalt ores contained some monoclinic crystals. This was verified by L. Pasteur, F. Ulrich, M. Bauer, A. Scheurer-Kestner, P. Groth, and F. Claudet. According to N. Zenzen and co-workers, the reported occurrence of arsenophyllite at Dalarne, Sweden, is a decomposition product of arsenopyrite caused by fire in the mines. The prismatic crystals were at first thought to be rhombic, and isomorphous with valentinite, the rhombic form of antimony trioxide, but the measurements made by A. des Cloizeaux, and A. Schmidt, showed that the crystals of the prismatic form of antimony trioxide are monoclinic. A. Schmidt showed that the crystals of the prismatic form of arsenic trioxide are monoclinic. A. Schmidt gave for the axial ratios $a : b : c = 0.4040 : 1 : 0.3445$, and $\beta = 86^\circ 3'$. The crystals may appear in thin plates resembling selenite, and there may be penetration twins, and P. Groth said that the pseudo-rhombic form of the crystals is due to twinning about the (100)-plane. The cleavage on the (010)-face is perfect. A. Schmidt found that the optical character is negative, and the optical axial angle $2H = 66^\circ 14'$ for red-light, and $2H = 65^\circ 21'$ for yellow-light. The natural, monoclinic, prismatic form of arsenic trioxide was designated *rhombarsenite* by M. Adam, and *claudetite*, by J. D. Dana. It is assumed by A. Schmidt that the discovery of a rhombic modification of arsenic trioxide, and of a monoclinic form of antimony trioxide, will make these two trioxides iso-trimorphous. J. D. Dana called the hypothetical rhombic form of arsenic trioxide *arsenophyllite* isomorphous with valentinite. This term was first employed by A. Breithaupt for a mineral which he considered to be the rhombic form isomorphous with valentinite, but he later said that the statement was based on *eine ganz falsche Annahme*. The facts permit only the statement that arsenic trioxide is dimorphous.

H. Debray¹⁰ prepared the monoclinic form of arsenic trioxide by heating the octahedral crystals or the vitreous form in a sealed glass tube so that the temp. near one end is about 400° , and at the other end, 200° . In a few hours, octahedral crystals collect at the cooler end, the vitreous oxide at the hotter end, and the monoclinic form in the middle. C. Gänge used a similar process. According to H. V. Welch and L. H. Duschak, when the cubic crystals are fused in an evacuated capillary tube, and kept at a temp. between 251° and 300° , star-like masses of crystals of the monoclinic form appear in half an hour, but the transformation proceeds very slowly, requiring days for its completion. The change is very sluggish at 218° . The rate of transformation at this temp. is greatly increased if a trace of water be present. The change from the octahedral to the monoclinic crystals was observed after several hours' heating at 100° in the presence of water, or dil. or conc. sulphuric acid; but no perceptible change occurred during several months at room temp. Hence, the monoclinic oxide is the stable form at temp. above 100° and possibly even at room temp. There is indeed no evidence to show that the transformation from the cubic to the monoclinic form is not monotropic, *i.e.* irreversible.

H. Debray also found that when the octahedral crystals and a little water are heated in a sealed tube at 250° for some time, both octahedral and monoclinic crystals appear in the cold tube. L. Pasteur, and A. E. Nordenskjöld obtained monoclinic crystals from a boiling sat. soln. of arsenic trioxide in potash-lye; A. Scheurer-Kestner, from a hot sat. soln. of arsenic trioxide in one of arsenic pentoxide; O. B. Kühn, from a soln. of silver arsenite in nitric acid; and C. H. Hürzel, by adding ammonia to a boiling sat. soln. of arsenic trioxide in aq. ammonia, and cooling the mixture rapidly—if slowly cooled, the octahedral crystals are formed. F. Wöhler also seems to have obtained what he called *ungewöhnlich* crystals of arsenic trioxide by heating a soln. of the trioxide in aq. ammonia. F. Ulrich observed octahedral crystals of this form of arsenic which were paramorphs after the cubic form. F. Ulrich's, and F. Claudet's observations on the sp. gr. indicate that the monoclinic crystals are slowly transformed into the cubic form. According to F. Wöhler, and F. Claudet, the monoclinic trioxide is converted into the octahedral form when it is sublimed, or when it is crystallized from an aq. soln. The prismatic form of arsenic trioxide was found by F. Claudet in the arsenical pyrites of a mine near San Domingo, Portugal. The mineral also appears to have been formed as a result of fires in mines containing arsenical ores; and as a furnace product. C. Hintze¹¹ has indicated a number of these occurrences.

The **vapour density** of arsenic trioxide has been previously discussed. The **specific gravity** of the cubic trioxide as it occurs in nature—arsenolite—ranges from 3.69 to 3.72; and for the artificially prepared oxide, N. J. B. G. Guibourt¹² gave 3.695; W. Herapath, 3.729 at 17.2° ; E. Filhol, 3.884; C. F. Rammelsberg, 3.80; L. Troost and P. Hautefeuille, 3.689; C. J. B. Karsten, 3.703–3.720; and C. Winkler, 3.6461 at 12.5° when weighed under petroleum, and 3.6283 when weighed under water. In the latter case, the results are affected by the slight solubility of the trioxide in water. A. S. Taylor gave 3.529 for the sp. gr. of devitrified arsenic-glass. G. P. Baxter and C. F. Hawkins found for the sp. gr. of cubic arsenic, 3.874 at 0° ; 3.865 at 25° ; and 3.851 at 50° . F. Claudet found the sp. gr. of claudetite to be 3.85; P. Groth gave 4.15. For arsenic-glass, A. le Royer and J. B. A. Dumas gave 3.698 at 4° ; C. J. B. Karsten, 3.7026; N. J. B. G. Guibourt, 3.7385; C. F. Rammelsberg, 4.00; L. Troost and P. Hautefeuille, 3.738; A. S. Taylor, 3.798; and C. Winkler, 3.7165 at 12.5° when weighed under water, and 3.6815 when weighed under petroleum. For E. Anderson and L. G. Story's measurements of the sp. gr. of aq. soln. of arsenic trioxide, *vide infra*, the refractive index of aq. soln. of the trioxide. The **hardness** of arsenolite is 1.5; and that of claudetite, 2.5. P. Groth said that claudetite is softer and tougher than gypsum. The glass is very brittle, and, according to C. Winkler, it is as hard as calcite. R. Schaefer studied the **diffusion** of arsenic trioxide dissolved in gelatin—the mixture was also made into a paste with water, and laid on a sheet of gelatin. In the case of arsenic gel, it was found that the amount of arsenic diffused quite regularly as the distance travelled increases, but with the paste there is no apparent diffusion beyond the surface of the gelatin, although this has undoubtedly taken place. R. Schaefer suggested that in the paste simple mols. are present, but in the gel more complicated mols. are present, and these move more slowly, but the total amount of arsenic diffused is greater in the latter case than in the former. H. Fizeau gave 0.00012378 at 40° for the linear coeff. of **thermal expansion** of the cubic crystals. G. P. Baxter and C. F. Hawkins found the coeff. of cubical expansion between 0° and 25° to be 0.00011; and between 25° and 50° , 0.00012. H. V. Regnault gave 0.1279 for the **specific heat** of the cubic crystals. A. de la Rive and F. Marcet gave 0.1309 for the crystalline oxide, and 0.1320 for the glassy oxide. A. S. Russell obtained $C_p=28.83$ for the mol. ht. of the octahedral crystals between 3° and 41° ; and R. Schuhmann, $C_p=1.64+0.0015T$. G. Nonhebel and co-workers studied the coagulation of the aerosol. According to F. Wöhler, glassy arsenic trioxide melts before **volatilization** begins, while the crystals, as M. Faraday observed, sublime without melting; if the vap. condenses on a hot

enough part of the tube in which the trioxide is volatilized, H. Ludwig found that the oxide may fuse. H. V. Welch and L. H. Duschak gave 251° for the **melting point** of the cubic form of arsenic trioxide, and 313° for that of the monoclinic form; E. R. Rushton and F. Daniels gave respectively 275° , and approximately 315° . J. K. Mitchell found that the trioxide volatilizes more easily than the metal at 218° ; and F. Selmi showed that some trioxide volatilizes even at 100° – 125° . H. Saito found that with a rising temp., sublimation occurs rapidly at 190° and is completed at 300° . P. Smellie found the **vapour pressure** of the trioxide to be 2.4×10^{-7} at 60° – 61° ; 2.5×10^{-5} at 81° – 86° ; 4.6×10^{-4} at 101° – 105° ; 1.9×10^{-3} at 117° – 124° ; 2.2×10^{-3} at 119° – 126° ; and 2.6×10^{-2} mm. at 149° – 152° . G. Niederschulte measured the vap. press. of arsenic trioxide below 165° , and K. Stelzner, above that temp.

	129°	153.5°	165°	240.8°	253.1°	268.6°	290.9°	306.8°
<i>p</i> mm.	0.00	0.01	0.027	6.3	12.2	24.4	65.4	100.6

K. Stelzner represented his data by the formula $\log p = 482.72051 - 46645.204132T^{-1} - 62.50645 \log T$; and H. V. Welch and L. H. Duschak believe that these results refer to the vap. press. of the glassy oxide; and that the following determinations, *p* mm., apply to the unstable cubic form between 100° and 251° , while above that temp. apply to the glassy form:

	100°	120°	140°	160°	180°	200°	220°	240°	260°	280°	300°
<i>p</i>	0.0,266	0.00180	0.01035	0.0473	0.186	0.653	2.065	5.96	15.7	38.5	89.1

E. R. Rushton and F. Daniels measured the vap. press. of arsenic from about 220° to 520° . The curves are shown in Fig. 16. The curve for liquid arsenic trioxide, upwards of 275° , can be represented by $\log p = 2722T^{-1} + 6.513$, and that for octahedral arsenic trioxide, by $\log p = -6670T^{-1} + 13.728$ for temp. up to 250° . *ABC*, Fig. 16, is the curve for the octahedral trioxide; and *BDE*, the curve for liquid arsenic trioxide; the intersection at *B*, 275° , represents the m.p. of octahedral arsenic trioxide. The line *FD* represents the estimated vap. press. curve of monoclinic arsenic trioxide, and the point of intersection, *D*, 315° , represents the m.p. of the monoclinic trioxide. W. M. Mott calculated 500° for the b.p. H. V. Welch and L. H. Duschak found the total and inner **heats of vaporization**—respectively *Q* cal. and *E* cal.—increase with rising temp.; the latter so rapidly that the sp. ht. of the solid and undercooled liquid

FIG. 16.—Vapour Pressure of Arsenic Trioxide.

at temp. above 251° are greater than that of the vapour:

	110°	150°	170°	190°	210°	230°	270°	290°
<i>Q</i>	27,930	27,210	26,710	26,750	26,610	26,656	26,240	26,500
<i>E</i>	27,170	26,370	25,830	25,830	25,650	25,650	25,160	25,380

E. R. Rushton and F. Daniels gave for the heat of vaporizing a gram of the trioxide as liquid, 31.5 cal., as octahedral crystals, 77.1 cal.; and as monoclinic crystals, 71 cal.; for the **heat of fusion** of octahedral trioxide, 45.6 cal.; and monoclinic trioxide, 39 cal.; and for the **heat of transition** of octahedral to monoclinic arsenic trioxide, 6 cal.

J. Thomsen¹³ gave for the **heat of formation** $(2As_{\text{cryst.}}3O) = As_2O_3^{\text{cubic}} + 156.4$ Cals.; and M. Berthelot gave 148.9 Cals. R. Schuhmann calculated the **free energy**, *E*, of formation of the cubic trioxide from arsenic and oxygen at 25° to be -137.3 Cals., and the heat content, *Q*, to be -153.8 Cals. He also gave for the effect of temp. between 0° and 100° on the free energy change accompanying the formation of the octahedral crystals, $E = -154.200 - 164T \log T + 0.00075T^2 + 65.8T$

cals.; and $Q = -154200 - 1.64T - 0.00075T^2$. P. A. Favre gave for the **heat of transformation** of the glassy trioxide into cubic crystals, 2.70 Cals., and M. Berthelot, 2.40 Cals.; L. Troost and P. Hautefeuille found the heat of transformation of the monoclinic into the glassy form, 1.30 Cals., and M. Berthelot, 1.20 Cals. J. Thomsen found the **heat of solution** of the cubic crystals to be 7.55 Cals. at 18°. L. Bruner and S. Tolloczko hence calculated that the mol. wt. of the trioxide in aq. soln. is represented $\frac{1}{2}As_2O_3 \cdot yH_2O$, not $As_2O_3 \cdot xH_2O$. J. Thomsen found the **heat of neutralization** of a mol of the trioxide, As_2O_3 , to be 73.0 Cals. per mol NaOH; 137.8 Cals. for 2 mols; 150.7 Cals. for 4 mols; and 155.8 Cals. for 6 mols.

According to A. des Cloizeaux,¹⁴ the **index of refraction** of the cubic trioxide for red-light is 1.748, and for yellow-light, F. Klocke found that the sublimed crystals exhibited a double refraction without regular interference figures, although R. Brauns observed the crystals are isotropic without showing any optical anomaly. E. Anderson and L. G. Story found the sp. gr., D , of aq. soln. with w grms. of arsenic trioxide per litre at 25°, and the refractive indices, μ , at 22°, to be :

w	1.796	3.212	5.060	7.184	10.13	12.85	14.368
D	1.0014	1.0025	1.0039	1.0057	1.0080	1.0102	1.0113
μ	1.33309	1.33326	1.3334	1.33376	1.33417	1.33450	1.33469

Each increase of 1° between 21° and 27° caused the refractive index of the soln. to decrease 0.000097. A. des Cloizeaux found the **birefringence** of the monoclinic crystals is strong. J. C. Ghosh and S. C. Bisvas measured the extinction coeff. of aq. soln. of arsenic trioxide; and R. Wright found that while the absorption spectrum of the strong acids is the same as that of the sodium salts, the reverse is the case with weak acids like aq. soln. of arsenic trioxide. It is assumed that a non-ionized molecule capable of ionization exists in a state of stress, and is more capable of absorbing light than a similar free ion, or a molecule incapable of ionization. H. R. Robinson studied the **X-ray spectrum** of arsenic trioxide. R. Whiddington measured the velocity of the electrons liberated by X-rays impinging on arsenic trioxide. H. R. Robinson and A. M. Cassie studied the line spectra of secondary and tertiary radiations from arsenious oxide—using the primary K-rays.

L. Bleekrode showed that the **electrical conductivity** of the cubic trioxide is feeble; and F. Beijerinck said that both the crystalline forms are non-conductors. Observations on the electrical conductivity of aq. soln. of arsenic trioxide were made by L. Bleekrode, and E. Bouty. P. Walden measured the mol. conductivity of aq. soln. of sodium meta- and ortho-arsenites (*q.v.*); and J. von Zawidzky gave for the mol. conductivity μ of a soln. of a mol of H_3AsO_4 in v litres of water at 25°:

	16	32	64	128	256	512	1024
μ	0.22	0.30	0.40	0.60	0.96	1.45	2.11
$K \times 10^9$	22	21	19	21	(27)	(30)	(32)

The acid **ionization constant**, K , has an average value of 21×10^{-9} —*vide infra*. E. W. Washburn found the basic ionization constant for $[AsO_4^{3-}][OH^-]/[H_3AsO_3] = 0.15 \times 10^{-14}$ in a soln. with an ion conc. of 0.1 eq. per litre at 25°. J. K. Wood also measured the electrical conductivity of these soln., and he found for metarsenious acid the ionization constant $K = 16.9 \times 10^{-10}$ for 0.1385*N*-acid; 20.1×10^{-10} for 0.0542*N*-acid; 23.9×10^{-10} for 0.086*N*-acid; and 38.6×10^{-10} for 0.195*N*-acid. The mean value is 26.5×10^{-10} , which is smaller than J. von Zawidzky's value. N. R. Dhar calculated values for the ionization constants from the solubility data. E. Anderson and L. G. Story found the **hydrogen-ion** conc. of arsenious acid to be $p_H = 6.60$, or $[H^+] = 0.25 \times 10^{-6}$, using phenol-red, or bromothymol-blue as indicators—the hydrogen electrode process was unsatisfactory. E. Blanc found that when the neutralization of a soln. of 0.0104*N*-arsenious acid with 0.588*N*-NaOH has proceeded to NaH_2AsO_3 , $C_H = 2 \times 10^{-10}$, and $C_{OH} = 4.1 \times 10^{-5}$. G. Bischof, and J. F. Simon found that an aq. soln. of arsenic trioxide is electrolyzed more slowly than one of the pentoxide; oxygen is given off at the anode, and arsenic

and arsine appear at the cathode. B. Neumann said that a part of the arsenic trioxide is oxidized to the pentoxide at the anode. L. Ramberg compared the nature of the cathode surface with different metals on the reduction of arsenic acid to arsine. The nature of the surface has less influence in the case of arsenic trioxide than in the case with arsenic acid (*q.v.*). When the metals are arranged in the order of their reducing power, a different series is obtained with arsenious and arsenic acids. A mercury cathode is unsuited for the reduction of considerable quantities of arsenic trioxide since the arsenic is not hydrogenated as rapidly as it is formed, and a solid phase of arsenic and arsenic amalgam is formed which is but slowly transformed into arsine. N. Isgarischeff and E. Koldaewa found that arsenic trioxide reduced the potential of the hydrogen electrode which rises to its normal value in a few hours; but the oxygen electrode is "poisoned" and does not return to its normal value. It is supposed that the effects are not due to depolarization, but rather to a combination of platinum and the arsenic forming compounds with a lower potential. The compound is unstable in the acidic soln., and the arsenic is carried off in a few hours by the stream of hydrogen. The subject was discussed by A. H. W. Aten, P. Bruin and W. de Lange. For the electrolytic oxidation of arsenic trioxide, *vide infra*, calcium arsenate. R. Schuhmann found the e.m.f. of the cell $\text{As} | \text{As}_2\text{O}_3$ and $\text{HClO}_4 | 0.22-0.94N\text{-H}$ at 25° and 45° was respectively -0.2340 volt and -0.2250 volt. R. J. Clark estimated the electrostatic moment of the molecule to be rather greater than 10^{-18} electrostatic unit.

Chemical reactions of arsenic trioxide.—Arsenic trioxide is reduced by hydrogen at a temp. below redness; possibly the reduction occurs only with the vap. of the trioxide. P. Hautefeuille¹⁵ said that if arsenic trioxide be heated in a sealed tube filled with hydrogen, it passes into the pentoxide, but this statement needs verification. It is, however, in agreement with J. F. Simon's observation that the action of heat on many arsenites involves a kind of autoxidation: $5\text{As}_2\text{O}_3 = 3\text{As}_2\text{O}_5 + 4\text{As}$. Nascent hydrogen reduces arsenic trioxide in aq. soln., forming arsine (*q.v.*). W. Thomson found the velocity of the electrolytic reduction followed the unimolecular law $dx/dt = k(a-x)$, where a denotes the original conc. of the soln.; x , the conc. at the time t ; and k , the velocity constant. He tried to correlate the overvoltage with different metals with the power of the metal cathode to reduce arsenic trioxide, but concluded that this power is a peculiarity of the individual metal, and is independent of its overvoltage. J. H. Gladstone and A. Tribe found that an aq. soln. of arsenic trioxide is reduced to arsenic by the occluded hydrogen in palladium, and the occluded hydrogen in platinum at 100° ; and to arsine, by the copper-zinc couple. L. Vallery examined the effect of traces of arsine in hydrogen on the catalytic activity of palladinized asbestos in burning the hydrogen. According to M. Berthelot, oxygen does not oxidize the trioxide either at ordinary temp. or at 100° ; but T. E. Thorpe found that the trioxide is thermoluminescent in oxygen. According to C. Matignon and J. A. Lecanu, it should be possible directly to oxidize arsenic trioxide to the pentoxide, and experiments were carried out at temp. between 400° and 450° , the press. of the oxygen being 130, 127, and 138 atm. The production of the pentoxide was proved, but the oxidation of the arsenic trioxide was not complete: $\text{As}_2\text{O}_3 + \text{O}_2 = \text{As}_2\text{O}_5 + 62.2$ Cals. A conc. soln. of the trioxide in sodium hydroxide at 80° and with oxygen at 50 atm. press. suffered 10.9 per cent. oxidation in 5 hrs. When an aq. soln. of arsenic trioxide is treated with an excess of sodium carbonate, it is readily oxidized by the oxygen of the air. The reaction was examined by H. Croft, H. Ludwig, J. M'Donnell, and A. Vogel. C. C. Palit and N. R. Dhar observed that copper, lead, manganese, cobalt, and nickel nitrates, cuprous, mercuric, uranium and ferric chlorides, and ferrous sulphate act as catalytic agents. F. Mohr said that a soln. containing sodium dihydroarsenite and hydrocarbonate is not oxidized when warmed in air, but F. Reinthaler said that a slow oxidation does occur; both observers, however, agree that at ordinary temp. no oxidation occurs after 4 months' exposure to air. J. B. Tingle said that arsenic trioxide, dissolved

in a mixture of 95 per cent. alcohol and 60 per cent. of water, is oxidized to arsenic pentoxide when boiled for 26 hrs., but P. Edgerton could not verify this statement. I. M. Kolthoff found that neutral or weakly acidic soln. of arsenic trioxide are stable, and may be kept indefinitely without change, but in alkaline soln., the trioxide is oxidized to the pentoxide. According to G. Gire, the absorption of oxygen by a soln. of arsenic trioxide and ferrous sulphate in the presence of sodium hydroxide varies with the amount of alkali present. The vol. of oxygen absorbed at first diminishes as the amount of alkali increases, reaching a minimum when the alkali is slightly in excess of that required to form the metarsenite. It then increases to a constant maximum, when the amount of alkali present is slightly in excess of that required to form the pyroarsenite. If the amount of alkali present is kept constant, the oxygen absorbed is proportional to the amount of iron present, but is always in excess of that required to oxidize the ferrous salt to the ferric state. F. Kessler found that when sodium arsenite is undergoing oxidation by chromic acid, it is simultaneously oxidized by air; F. Mohr observed a similar phenomenon in the presence of an oxidizing soln. of sodium sulphite. The reaction was studied by W. P. Jorissen. A. K. Goard and E. K. Rideal measured the oxidation potential of soln. of arsenic tri- and penta-oxides, and found for soln. containing different molar percentages of ter- and quinquevalent arsenic: $97.5 \text{ As}''' + 2.5 \text{ As}''$, 0.2075 volt., and $2.5 \text{ As}''' + 97.5 \text{ As}''$, 0.1536 volt. The oxidizing powers of the soln. can be inferred from these values, and the results applied to the oxidation of arsenite (acceptor) with a cerous salt (acceptor) as catalyst. W. D. Bancroft and H. B. Weiser obtained the familiar arsenic mirror when a cold surface is placed in a flame to which a little arsenic trioxide has been added. N. N. Mittra and N. R. Dhar found that the reaction with mercuric chloride and sodium sulphite, or phosphite or formic acid, as primary reaction, is accelerated by the simultaneous secondary reaction of mercuric chloride with arsenious acid or sodium arsenite. C. F. Schönbein found that ozone and **hydrogen dioxide** oxidize the trioxide to the pentoxide; and C. F. Schönbein, P. Thénard, J. L. Soret, and A. Ladenburg found that **ozone** incompletely oxidizes an alkaline soln. of arsenic trioxide.

C. Winkler¹⁶ was unable to prepare a hydrated form of arsenic trioxide; the turbidity produced when arsenic-glass is exposed to moist air is attended by the absorption of up to 0.33 per cent. moisture which cannot be completely expelled in a desiccator with phosphorus pentoxide, or by heating at 110°. Cubic arsenic trioxide dissolves slowly in cold **water**, the glassy form dissolves more quickly; both forms dissolve more rapidly in boiling water. For the effect of moisture in the transformation of the glassy trioxide into octahedral crystals, *vide supra*. The aq. soln. of arsenic trioxide is colourless, and tastes feebly acid. A. Bussy found that aq. soln. of the octahedral crystals, and of the glassy oxide redden litmus very feebly; while G. Favrel said that the aq. soln. has no action on cochineal-red; and A. L. Cohn, that arsenious acid is neutral towards lacmoid; it behaves like a monobasic acid towards methyl orange; and shows only about 90 per cent. of combined sodium or potassium when the acid is treated with standard alkali-lye with phenolphthalein as an indicator. The action of indicators was examined by R. T. Thomson, G. Favrel, and F. A. Flückiger. According to the first-named, arsenious acid behaves like a monobasic acid when titrated with soda-lye, and litmus, methyl orange, rosolic acid, and phenacetolin as indicators.

Numerous observations have been reported on the solubility of arsenic trioxide in water—*e.g.* E. Bacaloglo, A. Baumé, T. Bergman, G. Brandt, L. A. Buchner, C. F. Bucholz, J. Dalton, J. C. Delamétherie, N. W. Fischer, N. J. B. G. Guibourt, J. F. Hagen, J. H. G. Justi, C. F. S. Hahnemann, M. H. Klaproth, W. Nasse, P. T. Navier, P. von Musschenbroek, K. W. Pörner, H. Rose, J. R. Spielmann, A. S. Taylor, A. Vogel, and C. F. Wenzel. The reported values here range from N. W. Fischer's 16.6 parts of the trioxide per 100 parts of water to W. Nasse's 0.312 part of the trioxide at ordinary temp. The extraordinary diversity of the early observations is attributed by C. Winkler to the difference in the solubility

of the cubic and glassy forms ; to the length of time necessary to obtain a sat. soln. with these two modifications ; and to the tendency of the glassy form to pass into the octahedral crystals. He also added that while the glassy form is easily wetted with water, the crystalline oxide is not easily moistened. According to N. J. B. G. Guibourt, the glassy form is less soluble in water than the cubic form ; on the contrary, A. S. Taylor, C. Winkler, and A. Bussy attribute the greater solubility to the glassy form. A. Bussy said that when the aq. soln. is boiled for a long time, the cubic form is converted into the glassy variety and acquires the solubility of the latter, *viz.*, 11 parts of the trioxide in 100 parts of boiling water ; but at low temp., the glassy form is converted into the cubic form and hence the soln. becomes more dil. on standing, retaining for equilibrium only the proportion of trioxide corresponding with the cubic form. Comminution hastens the speed of dissolution of the cubic form without increasing the amount dissolved, but it lowers the speed of dissolution of the glassy form because of its conversion into the cubic form by the friction or contact with water. According to C. Winkler, 100 parts of water at ordinary temp. dissolve the following proportion of the cubic, *A*, and glassy, *B*, forms of arsenic trioxide in the stated time (in hours) :

Hrs.	1	3	6	12	24	48	96	168	504	19710
<i>A</i> .	0.023	0.088	0.353	0.364	0.956	1.627	1.814	1.673	1.776	1.712
<i>B</i> .	1.589	2.356	3.666	3.361	3.306	2.629	2.429	1.763	1.713	1.707

When the glassy form was dissolving, octahedral crystals were deposited on the sides of the vessel after 12 hrs., and these continued to increase ; there was no such deposit in the case of the glassy form. The maximum values in the above table are taken to represent the solubilities of the two forms of arsenic trioxide at ordinary temp., namely, 1.70 parts of the cubic form and 3.7 parts of the glassy form at ordinary temp. He also found that 100 parts of boiling water dissolve 10.140 parts of the cubic crystals in 3 hrs., and 10.176 parts in 12 hrs., and 11.46 parts of the glassy oxide in 3 hrs., and 11.86 parts in 12 hrs. The following results, expressed in grams of trioxide per 100 c.c. of sat. soln., for the cubic modification were found by L. Bruner and S. Tolloczko : 1.201 at 2° ; 1.657 at 15° ; 2.038 at 25° ; 2.930 at 39.8° ; and 6.000 at 100°. K. Chodounsky gave 0.8507 gm. per 100 c.c. for the solubility of glassy arsenic trioxide in water at 18.5°. For the octahedral crystals, J. K. Wood gave 1.495 to 1.55 gm. per 100 c.c. at 15° ; F. A. H. Schreinemakers and W. C. de Baat, 2.26 per cent. at 30° ; and F. Claudet, 100 parts of water at ordinary temp. dissolve 1.75 parts of the monoclinic form, and at 100°, 2.75 parts. E. Anderson and L. G. Story found the following amounts, *S*, of the octahedral trioxide in grams were dissolved by 100 grms. of water :

	0°	15°	25°	39.8°	48.2°	62°	75°	98.5°
<i>S</i>	1.21	1.66	2.05	2.93	3.43	4.45	5.62	8.18

They represented the results at θ° by $S=1.21+0.021\theta+0.000505\theta^2$.

According to K. Drucker, hydrogen ions—*i.e.* acidic soln.—accelerate the rate of dissolution of arsenic trioxide ; and the hydroxyl ion acts more strongly than the hydrogen ion. In both cases, the action is proportional to the sq. root of the conc. of the respective ions. Excepting with soln. approaching saturation, the rate of dissolution is not dependent on the conc. of the arsenic trioxide in soln., but only on that of the catalyzing acid or alkali. Non-ionized sodium acetate accelerates the action, while amyl alcohol retards the speed. E. Brunner said that the rate of dissolution is governed both by the rate of diffusion ; by the rate of hydration of the trioxide in soln. ; by the conc. of the dissolved trioxide, and by the conc. of the hydrogen or hydroxyl ions ; but it is independent of the speed of agitation of the liquid. While C. S. Hudson did not consider the dissolution of arsenic trioxide as a chemical process, E. Brunner showed that some hydration probably takes place. P. Walden inferred from their observations on the electrical conductivity of the sodium arsenites (*q.v.*), that *tribasic orthoarsenious acid*, H_3AsO_3 , does not exist,

and that in soln., arsenious acid behaves like *dimetarsenious acid*, $(\text{HO})\text{OAs}\cdot\text{AsO}(\text{OH})$. J. von Zawidzky, H. Biltz, and F. M. Raoult showed that the mol. wt. of arsenic trioxide in aq. soln. is in agreement with the assumption that the mol. of arsenious acid contains one atom of arsenic. H. Remy discussed the structure of arsenious acid. The acid is a poor conductor, and is only slightly ionized; the conductivity of sodium dihydroarsenite, NaH_2AsO_3 , determined in the presence of arsenious acid to prevent hydrolysis, resembles that of a monobasic acid. The increased conductivity at high dilutions is attributed to hydrolysis, and not to further ionization of the H_2AsO_3 -ion. This is taken to be in agreement with J. Thomsen's observation that 137.8 Cals. are liberated when arsenic trioxide is neutralized with 2 mols of sodium hydroxide, and only 12.9 Cals. more when another 2 mols of sodium hydroxide are added. E. Cornec's observations on the effect of alkalis on the f.p. of soln. of arsenic trioxide, A. Miolati and E. Masceti's observations on the electrical conductivity, W. Böttger's on the e.m.f., and J. Thomsen's, on the heats of neutralization agree that in aq. soln. arsenic trioxide behaves like a feeble monobasic acid; arsenious acid, $\text{HO}(\text{H}_2\text{AsO}_2)$, is also an extremely feeble base, but the basic properties were too small for accurate measurement. J. K. Wood, however, found the ionization constant of arsenious hydroxide as a base to be of the order 10^{-14} ; and for arsenious acid, 6.3×10^{-11} —*vide supra*. He symbolized the reaction with water: $\text{HO}' + \text{As}(\text{OH})_2 \rightleftharpoons \text{As}(\text{OH})_3 \rightleftharpoons \text{AsO}(\text{OH})_2' + \text{H}'$. W. A. Roth and O. Schwartz found that in the most dil. soln. which can be cryoscopically examined the arsenic trioxide is weakly associated, and almost completely converted into HAsO_2 , or H_3AsO_3 .

Some derivatives of ortho- (more accurately meso-) arsenic acid, $\text{AsO}(\text{OH})_3$, have been prepared. Thus by replacing one hydroxyl group by a univalent hydrocarbon radicle, R, the so-called **arsonic acid**, $\text{RAsO}(\text{OH})_2$, is obtained; and by replacing two hydroxyl radicles in a similar way, the **arsinic acids**, $\text{R}_2\text{AsO}\cdot\text{OH}$, result graphically:

The first member of the arsinic acids has the methyl radicle, CH_3 , and is hence called **methylarsinic acid**, $(\text{CH}_3)_2\text{AsO}\cdot\text{OH}$. The derivatives of the univalent radicle, $(\text{CH}_3)_2\text{As}$ —discovered by R. Bunsen, 1837–1843—were called cacodyl compounds, by J. J. Berzelius from *κακῶδος* (*cacodos*, stinking), in allusion to their disgusting odour. Hence, methylarsinic acid is called cacodylic acid, and the series of arsinic acids are also called the *cacodylic acids*. A series of over thirty arsonic acids has been prepared, all dibasic, and over a dozen monobasic arsinic acids have been prepared by organic chemists. There is evidence of a polymerization of methylarsonic acid to a tribasic acid in the presence of an excess of a soln. of potassium hydroxide over $\frac{1}{33}$ th normality. The quinquevalency of the arsenic is evidenced by their indifference towards nitric acid and bromine water, for all known soluble trivalent arsenic compounds reduce the former and decolorize the latter. This subject is discussed in the works on the organic derivatives of arsenic cited below.

According to H. Moissan,¹⁷ **fluorine** reacts violently with arsenic trioxide, forming a colourless liquid containing arsenic trifluoride, and oxyfluoride; he also found that **hydrogen fluoride** reacts with incandescence. When distilled with a mixture of sulphuric acid and calcium fluoride, arsenic trifluoride is formed (*q.v.*). R. Weber showed that when heated at a suitable temp., **chlorine** forms arsenic trichloride and pentoxide, and C. L. Bloxam represented the reaction: $11\text{As}_2\text{O}_3 + 6\text{Cl}_2 = 4\text{AsCl}_3 + 3(\text{As}_4\text{O}_6\cdot\text{As}_2\text{O}_5)$. L. Cambi represented the reaction with dil. soln.: $\text{AsCl}_3 + \text{Cl}_2 + (2.5 + n\text{H}_2\text{O}) \rightleftharpoons 0.5\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O} + 5\text{HCl}$; with conc. soln., $0.5\text{As}_2\text{O}_3 + 3\text{HCl} \rightleftharpoons \text{AsCl}_3 + 1.5\text{H}_2\text{O}$. L. Cambi found that when chlorine is passed into an aq. suspension of 70–80 per cent. of arsenic trioxide, with agitation, at

60°–70°, about 70 per cent. of arsenic trioxide is changed to the pentoxide, and the remainder to trichloride. E. Anderson and L. G. Story found the mol. wt. of arsenic trioxide in aq. soln. by the b.p. method is 92.5; and 99.17 by the f.p. process. This seems to indicate that at 0° the trioxide is present in the hydrated form—probably **metarsenious acid**, HAsO_2 . A soln. of arsenic trioxide in hydrochloric acid is completely oxidized by chlorine, and in the presence of alkali hydroxide, an arsenate is formed. The action of **bromine** is analogous to that of chlorine. W. Manchot and F. Oberhauser found that the oxidation of arsenic trioxide by bromine, and the reduction of sodium hydroarsenate by hydrobromic acid can be represented by the equation $\text{As}_2\text{O}_5 + 4\text{HBr} \rightleftharpoons \text{As}_2\text{O}_3 + 4\text{Br} + 2\text{H}_2\text{O}$. If the conc. of the hydrobromic acid is less than 24 per cent., the reaction proceeds entirely from right to left; under these conditions, arsenious acid may be accurately titrated with bromine, the end-point of the titration being unaffected by the exact conc. of hydrochloric acid. The reverse reaction, however, may take place if the conc. of hydrochloric acid exceeds 24 per cent.; the equilibrium conditions depend on the conc. of arsenate, bromide, and hydrochloric acid. A. W. Francis also studied the speed of oxidation of sodium arsenite by bromine-water. J. Guinchant said that in the presence of **hydrochloric acid**, some arsenic trioxide is converted into arsenic trichloride—*vide supra*, the crystalloluminescence of the trioxide—and H. Davy said that when distilled with a mixture of sulphuric and hydrochloric acids, and L. Gmelin, with a mixture of sodium chloride and sulphuric acid, arsenic trichloride is formed. According to B. J. Smart and J. T. Philpot, when soln. of arsenic trioxide in hydrochloric acid are distilled, those which contain the **greatest** conc. of hydrochloric acid give off the **arsenic** most rapidly. When the hydrochloric acid is present to the extent of about 190 grms. per litre or more, the conc. of arsenic in the soln. remaining undistilled rapidly falls as the soln. is fractionated. With soln. containing less than 180 grms. of hydrochloric acid per litre, the conc. of arsenic in the soln. remaining undistilled rises, although some of the arsenic passes over, the ratio between acid and arsenic remaining practically constant until the soln. contains about 185 grms. of hydrochloric acid per litre. This point corresponds approximately with a hydrate of the formula $\text{HCl} \cdot 10\text{H}_2\text{O}$. According to E. Oeman, arsenic trichloride accumulates in the distillate although its b.p., 130.2°, exceeds the maximum b.p. of aq. hydrochloric acid, 110°. Hydrochloric acid may be freed from arsenic trichloride by the passage of hydrogen chloride. Vaporization occurs only at the surface of the liquid which becomes relatively poorer in hydrochloric acid, and a greater quantity of distillate is required to remove the arsenic trichloride. When the acid becomes more conc. the proportion of arsenic volatilized increases rapidly. J. T. D. Hinds also studied this reaction. The effect of hydrochloric acid is to raise the solubility of arsenic trioxide; thus, K. Chodounsky, and C. Schultz-Sellac found that arsenic trioxide is more soluble in hydrochloric acid than in water, and that the glassy form dissolves more rapidly than the octahedral crystals. K. Chodounsky found that while 100 c.c. of water dissolve 0.8507 gm. of glassy arsenic trioxide at 18.5°, if the water contained 1.3196 grms. of HCl, 1.1513 grms. of the trioxide are dissolved, and if 6.09 grms. of HCl are present, 1.2724 grms. of the trioxide are dissolved. Expressing the solubility, *S*, of arsenic trioxide in grams per 100 c.c. of soln., J. K. Wood found with hydrochloric acid of different conc. at 15°:

HCl .	0	0.46N-	0.98N-	2.03N-	3.13N-	3.81N-	5.32N-	6.50N-	7.85N-	9.17N-
<i>S</i> .	1.55	1.52	1.41	1.17	1.11	1.13	2.20	5.11	12.28	18.16

As the conc. of the acid increases, the solubility of the trioxide decreases, and a minimum is reached when the conc. of the acid is about 3.2N-HCl; beyond this point an increase in the conc. of the solvent leads to a corresponding increase in solubility. This agrees with K. Drucker's observation that the presence of hydrogen ions augments the solubility of the trioxide. The decreased solubility is assumed to show that in aq. soln. the arsenic trioxide is acting as an acid so that in the presence

of another acid, the H^+ -ion conc. of the arsenious acid is diminished; on the other hand, when arsenic trioxide acts as a base, the solubility is augmented by the acid.

C. Brame found that whilst **iodine** vapour does not act on the octahedral crystals of arsenic trioxide, the vitreous form is coloured brown. J. R. Roebuck studied the oxidizing action of iodine on arsenic trioxide in alkaline soln., and he represented the reaction: $AsO_3''' + I_3 + H_2O \rightleftharpoons AsO_4''' + 3I' + 2H'$. The velocity of the direct reaction was directly proportional to the first power of the conc. of the arsenious acid and the I_3 -ion; and inversely proportional both to the square of the conc. of the iodine-ions and to the conc. of the hydriodic or sulphuric acid—when this conc. is not too high. The velocity of the reverse reaction was found to be proportional to the first power of the conc. of the arsenic acid, the iodine-ion, and the acid-ion provided the conc. of the acid is sufficiently low, but if the acid be more conc., the velocity is proportional to higher powers of the iodine-ion and acid conc. values as high as 2.4 and 3.7 being obtained. He explained his results by assuming that the reverse reaction proceeds in two stages: $H' + I' + H_3AsO_4 = H_3AsO_4.HI$; and $H_3AsO_4.HI = HIO + H_3AsO_3$. He found the equilibrium constant $[AsO_3'''] [I_3] = K [AsO_4'''] [I']^3 [H]^2$ to be 1.5×10^5 ; and the temp. coeff. between 0° and 10° is 1.41. E. W. Washburn and E. K. Strachan showed that the equilibrium $H_3AsO_3 + I_3 + H_2O \rightleftharpoons H_3AsO_4 + 2H' + 3I'$ obeys the mass law over a fairly wide range of conc., and that $[H_3AsO_4] [H']^2 [I]^3 = K [H_3AsO_3] [I_3]$, where $K = 0.55$. The effect of temp. is represented by $\log_{10} K = -1.3495 + 0.00372\theta$. The heat of the reaction between arsenious acid and iodine is 1360 cal., and the free energy $RT \log_e K = 5690 \times 5.42T$ joules in an aq. soln. with a constant ion conc. of 0.1 eq. per litre. The reaction was also studied by W. C. Bray, K. P. Bjergaard, and P. Fleury. I. M. Kolthoff examined the reaction $As_2O_3 + 2I_2 + 2H_2O \rightleftharpoons As_2O_5 + 4HI$ with reference to the limits of the acid conc., within which a definite end-point is obtained. He found that in titrating 0.1N- As_2O_3 and 0.01N- As_2O_3 soln. with iodine, the final acidity must be between 10^{-11} and 10^{-15} mol. hydrogen-ion per litre; and in titrating 0.1N-, or 0.01N-iodine soln. with soln. of arsenious acid, the initial limits are $10^{-9.0}$ and $10^{-5.5}$, and the final limits 10^{-8} and 10^{-5} . D. A. MacInnes discussed the electro-metric titration of arsenic trioxide with iodine soln. F. C. Bowman inquired whether the oxidation of arsenic trioxide in soln. containing **bromic acid** and hydriodic acid is effected by the hydriodic acid, or by the iodine which is the end-product of the oxidation of the hydriodic acid. He found that the rate of reduction of bromic acid by hydriodic acid is not affected by the presence of arsenious acid except in so far as the oxidation of the latter affects the conc. of acid and iodide in the soln. The arsenious acid oxidized corresponds with the iodine liberated during the reaction, and is very much smaller than the amount which would be oxidized if the oxidation were affected by hypobromous and bromic acids formed as intermediate products. The reduction of bromic acid by hydriodic acid does not therefore "induce" the oxidation of arsenious acid. I. N. Schiloff suggested that the oxidation of arsenious acid by bromic acid is too slow for measurement unless in the presence of sulphurous acid. J. S. Chodkowsky showed that at 40° in the presence of an excess of hydrogenions, the reaction proceeds spontaneously and at a measurable rate. The reaction is autocatalytic, and of the second order $dx/dt = kax(1-x)$, where the velocity constant $k = 9.7$ at 30.7° , and in the presence of 0.1M- H_2SO_4 . The arsenious acid does not appear to exert any influence on the reaction and merely acts as an inductor of the reaction between bromic and hydrobromic acid. The initial production of hydrobromic acid must, however, be due to the interaction of arsenious acid with bromic acid. The action of sulphuric acid is proportional to the square of the conc. of hydrogen-ions; the addition of neutral sulphates which reduce this conc. retards the reaction. The addition of hydrogen bromide causes the reaction to proceed in accordance with $dx/dt = ka(b-x)(1-x)$, where b is the conc. of the hydrobromic acid; k is the same as before. Hydriodic acid acts like hydrobromic acid, but the effect is greater; and hydrochloric acid acts more vigorously than sulphuric acid on account of the

simultaneous effect of both hydrogen and chlorine ions. The relative accelerating effects of potassium chloride, bromide, and iodide are as 1:15:3000. Arsenic acid acts as a positive catalyst, but its effect is 9 times weaker than sulphuric acid. The thermal coeff. of the reaction is 2.14. According to R. P. Sanyal and N. R. Dhar, the period of induction between **iodic acid** and a soln. of arsenic trioxide is curtailed by (1) excess of iodic acid, (2) increase in the conc. of the reactants, (3) addition of a trace of arsenic acid, (4) addition of many mineral acids, and (5) exposure to sunlight; it is prolonged by addition of mercuric chloride or by violent shaking. The fraction of the iodine liberated increases with the arsenious acid conc. and passes through a maximum. The iodine appears on the surface of the soln. even if the latter is covered with benzene or hydrogen; occasionally it appears at a nucleus on the glass. H. Kubina showed that the reduction of **chlorates** by arsenic trioxide is a coupled reaction being independent of the conc. of the arsenious acid—there is a slow reduction of the chlorate by the halide followed by the rapid oxidation of the arsenite. The mechanism of the reaction is considered to involve: (a) A measurable reaction: $\text{ClO}'_3 + \text{Cl}' + 2\text{H} \rightarrow \text{H}_2\text{ClO}_3 + \text{Cl}$, followed by the rapid reactions, (b) $\text{H}_2\text{ClO}_3 + 4\text{Cl}' + 4\text{H} \rightarrow 5\text{Cl} + 3\text{H}_2\text{O}$, and $3\text{Cl}_2 + 3\text{AsO}_3''' + 3\text{H}_2\text{O} \rightarrow 3\text{AsO}_4''' + 6\text{Cl}' + 6\text{H}$. The initial velocity of interaction of chloric acid and arsenite does not increase rapidly; catalytic acceleration by chloride-ion is not observed, owing to the high initial conc. of this ion. Were the latter present, initially, in small quantities, such catalytic accelerative influence should be in evidence. On this supposition, the velocity of chlorate reduction by arsenite would be expressed by the equation: $dx/dt = [K_1 + K_2(S)x(\text{Cl}')](\text{ClO}'_3)$. The reduction of **iodates** is also an induced reaction in which there is an initial acceleration owing to the catalytic effect of the chloride ion. The mechanism is assumed to involve (a) A measurable reaction: $\text{IO}'_3 + 2\text{I}' + \text{H}' \rightarrow \text{HIO} + 2\text{IO}'$, followed by the rapid reactions (b) $2\text{IO}' + 2\text{AsO}_3''' \rightarrow 2\text{AsO}_4''' + 2\text{I}'$, and $\text{HIO} + \text{AsO}_3''' \rightarrow \text{AsO}_4''' + \text{H}' + \text{I}'$, giving the velocity equation: $dx/dt = [K_1 + K_2(\text{I}')_2](\text{IO}_3)(\text{H}')$. E. Abel and A. Fürth studied the reduction of **periodates** to iodates by arsenites, and found the reaction to be bimolecular. The speed of the reaction is independent of the conc. of acids between 1.3×10^{-3} and $3.4 \times 10^{-7}[\text{H}']$.

According to J. J. Berzelius,¹⁸ when a mixture of arsenic trioxide and **sulphur** is heated, arsenic disulphide is formed; and L. F. Nilson represented the reaction: $2\text{As}_2\text{O}_3 + 7\text{S} = 2\text{As}_2\text{S}_2 + 3\text{SO}_2$; with an excess of sulphur, the reaction was symbolized: $2\text{As}_2\text{O}_3 + 9\text{S} = 2\text{As}_2\text{S}_3 + 3\text{SO}_2$, but W. Marckwald and A. Foizik showed that some sulphur trioxide is at the same time probably formed. G. Vortmann and C. Padberg found that an acid soln. of arsenic trioxide does not react with sulphur. The action of **hydrogen sulphide** on acidified soln. of arsenic trioxide has been studied by J. F. Lassaigne, H. Reinsch, R. Brandes, E. Becker, J. Lefort and P. Thibault, etc.—*vide supra*, reactions of arsenic. Aq. soln. of arsenites give a yellow coloration with hydrogen sulphide, and a yellow precipitate if an acid be added. The action of metal sulphides was discussed by E. Schürmann. H. Prinz, and G. Oddo and E. Serra found that in a sealed tube at 120° arsenic trioxide and **sulphur monochloride** react: $2\text{As}_2\text{O}_3 + 6\text{S}_2\text{Cl}_2 = 4\text{AsCl}_3 + 3\text{SO}_2 + 9\text{S}$. K. Chodounsky found that the solubility of arsenic trioxide in dil. **sulphuric acid** depends on the conc. of the acid and is not so great as in hydrochloric acid; it is of the order 0.5422–0.7203 at 18.5°, and, nearly twice this value at 80°. C. Schultz-Sellac found that the trioxide is readily soluble in fuming sulphuric acid, forming a sulphate (*q.v.*). F. Schweser found that when air is bubbled through sulphuric acid containing 0.001–0.015 per cent. of arsenic trioxide, small but appreciable quantities of arsenic are carried forward, in amounts proportional to the conc. of the trioxide dissolved in the acid. P. Smellie found the vap. press. of the trioxide in sulphuric acid at 60°–64° to be 2.7×10^{-7} to 9.0×10^{-7} mm. According to F. Faktor, when the trioxide is fused with **sodium thiosulphate** a mixture of arsenic di- and trisulphides is formed. G. Vortmann found the trisulphide is precipitated when aq. soln. of arsenic trioxide, or acidified soln. of the arsenites, are

treated with sodium thiosulphate. R. F. Weinland and A. Gutmann represent the reaction with normal arsenites: $\text{Na}_3\text{AsO}_3 + \text{Na}_2\text{S}_2\text{O}_3 = \text{Na}_3\text{AsO}_3\text{S} + \text{Na}_2\text{SO}_3$; with hydroarsenites: $\text{Na}_2\text{HASO}_3 + \text{Na}_2\text{S}_2\text{O}_3 = \text{Na}_3\text{AsO}_3\text{S} + \text{NaHSO}_3$; and with dihydro-arsenites, the reaction is more complex—thiooxides are formed (*q.v.*). The reaction was also examined by J. von Szilagyi, and J. E. Mackenzie and H. Marshall. G. S. Forbes and co-workers found that the precipitation of arsenic trisulphide is preceded by a well-defined period of induction when a soln. containing sodium thiosulphate and an arsenite is acidified with acetic acid—thus furnishing a so-called *clock-reaction* analogous with the reduction of an iodate by sulphurous acid (2. 19, 12). The duration of the period of induction is inversely proportional to the conc. of the thiosulphate, but independent of the conc. of the arsenite or acetic acid. Hydrochloric acid prolongs the period of induction. O. Brunck observed that brown arsenic is precipitated by **sodium hyposulphite** from an aq. soln. of arsenic trioxide. A. Gutmann said that **sodium dithionate** is not changed in soln. of sodium arsenite; **sodium trithionate** reacts: $\text{Na}_2\text{S}_3\text{O}_6 + 2\text{Na}_3\text{AsO}_3 + 2\text{NaOH} = 2\text{Na}_2\text{SO}_3 + \text{Na}_3\text{AsO}_3\text{S} + \text{Na}_3\text{AsO}_4 + \text{H}_2\text{O}$; and **sodium tetrathionate** reacts: $\text{Na}_2\text{S}_4\text{O}_6 + 3\text{Na}_3\text{AsO}_3 + 2\text{NaOH} = 2\text{Na}_2\text{SO}_3 + 2\text{Na}_3\text{AsO}_3\text{S} + \text{Na}_3\text{AsO}_4 + \text{H}_2\text{O}$. B. Grütznar represented the reaction with **potassium persulphate**: $\text{As}_2\text{O}_3 + 2\text{H}_2\text{O} + 2\text{K}_2\text{S}_2\text{O}_8 = \text{As}_2\text{O}_5 + 2\text{K}_2\text{SO}_4 + 2\text{H}_2\text{SO}_4$, and G. Newbery utilized the reaction for oxidizing the combined arsenic in organic substances to arsenic acid.

I. A. Bachman¹⁹ observed no evidence of the formation of arsenic nitride when the trioxide is heated in **ammonia gas**—*vide infra*, ammonium arsenites. G. Gore, and E. C. Franklin and C. A. Kraus found that liquid ammonia does not dissolve arsenic trioxide. V. de Luynes observed that with **ammonium chloride**, much ammonia is evolved and some arsenic trichloride is formed. L. Möser and W. Eidmann found that **boron nitride** reduces arsenic trioxide to the metal; and F. D. Chattaway and H. P. Stevens represented the reaction with **nitrogen iodide**: $3\text{As}_2\text{O}_3 + 2\text{N}_2\text{H}_3\text{I}_3 + 6\text{H}_2\text{O} = 3\text{As}_2\text{O}_5 + 6\text{HI} + 4\text{NH}_3$. The oxidation of arsenious acid by **nitric oxide** (*q.v.*) was studied by A. Gutmann. A. Klemenc regarded the reaction as termolecular: $\text{H}_3\text{AsO}_3 + 2\text{NO} = \text{H}_3\text{AsO}_4 + \text{N}_2\text{O}$. The speed of the reaction increases with increasing concentration of the alkali hydroxide. T. L. Bailey found that arsenious acid is oxidized by **nitrous acid** in the presence of sulphuric acid; the maximum rate occurs when the acid has a sp. gr. 1.39 to 1.47. Arsenic trioxide is oxidized to the pentoxide by **nitric acid**; and, as shown by A. Geuther, G. Lunge, etc., with the conc. acid, nitrogen oxides are formed (*q.v.*). P. Askenasy and co-workers found that arsenic trioxide is oxidized to arsenic acid by nitric acid over 50 per cent. conc., but under an oxygen press. of 20 atm., the nitrous acid so formed is regenerated, and the nitric acid acts merely as a catalyst. A. Klemenc and F. Pollak showed that mercuric salts inhibit the oxidation of arsenic trioxide by nitric acid. The effect is dependent on the conc. At a conc. of 7×10^{-6} mol per litre, the oxidation is prevented; with a conc. between 7.7×10^{-8} and 7.7×10^{-9} the effect passes through zero; and at a conc. of 7.7×10^{-11} mol per litre mercuric salts act as a strong positive catalyst—*vide nitric acid*. The reaction was also studied by A. Klemenc and R. Schöller. The effect of mercury and other salts on the oxidation of the trioxide by nitric acid was studied by C. M. Smith and G. E. Miller. J. A. Buchner examined the solubility of arsenic trioxide in nitric acid. According to J. J. Berzelius, **phosphorus** reduces arsenic trioxide, forming arsenic phosphide, and phosphorus pentoxide. R. Engel, N. W. Fischer, J. Thiele, J. V. Janowsky, etc., found that arsenic trioxide is reduced to brown arsenic (*q.v.*) by aq. soln. of **hypophosphorous acid**, or by **phosphorous acid**. T. Bergman found that arsenic trioxide is soluble in a hot soln. of **phosphoric acid**, and it does not separate out again on cooling. According to A. Oppenheim, phosphorus forms a phosphide with an aq. soln. of the trioxide at 200°. A. Michaelis represented the reaction of arsenic trioxide on **phosphorus trichloride** in a sealed tube at 110°–130°: $5\text{As}_2\text{O}_3 + 6\text{PCl}_3 = 4\text{As} + 3\text{P}_2\text{O}_5 + 6\text{AsCl}_3$. N. N. Sen found that when **phosphorus**

trichloride is added to an aq. soln. of arsenic trioxide, the soln. turns yellow, then opaque brown, and finally deposits amorphous arsenic insoluble in carbon disulphide: $\text{As}_2\text{O}_3 + 3\text{PCl}_3 + 9\text{H}_2\text{O} = 2\text{As} + 3\text{H}_3\text{PO}_4 + 9\text{HCl}$. The reaction is visible with 0.000075 grm. of arsenic per c.c. It also occurs with arsenates. The reaction does not occur with hypophosphorous acid, or with an aq. soln. of the trichloride; the reaction is slower with **phosphorus tribromide and triiodide**, and it also occurs with aq. soln. of these compounds. E. Deussen, and E. Rupp and E. Muschiol found that **calcium hypophosphite** gives a brown coloration or precipitation with soln. containing arsenious acid. L. Hurtzig and A. Geuther represented the reaction of arsenic trioxide with **phosphorus pentachloride** by $\text{As}_2\text{O}_3 + 3\text{PCl}_5 = 2\text{AsCl}_3 + 3\text{POCl}_3$; and B. Reinitzer and H. Goldschmidt, on **phosphoryl chloride**: $\text{As}_2\text{O}_3 + 2\text{POCl}_3 = 2\text{AsCl}_3 + \text{P}_2\text{O}_5$, at 250° , but at 160° , A. Michaelis observed no reaction. J. J. Berzelius found that arsenic trioxide dissolves in a soln. of **ammonium arsenite** at 70° – 80° , and it crystallizes out from the soln. on cooling. W. Wallace and F. Penny, and L. Hurtzig and A. Geuther found that **arsenic trichloride** dissolves the trioxide, forming an oxychloride.

According to J. J. Berzelius,²⁰ **carbon**, and **carbon monoxide**, below a red-heat, reduce arsenic trioxide to arsenic. Thus when a mixture of arsenic trioxide and carbon is heated in a narrow glass tube, arsenic sublimes on to the cooler part of the tube. A. C. Pereira modified the experiment. A. Vogel ignited a mixture of the trioxide and charcoal moistened with alcohol, and observed the garlic odour of arsenic. J. Marshall and L. A. Ryan found that when an aq. soln. of arsenic trioxide is filtered through animal charcoal, a part is retained by that solid. M. Dubinin studied this subject. I. W. Fay and co-workers found 60° to be the lowest temp. at which the reduction of arsenic trioxide occurs in an atm. of carbon monoxide. E. H. Büchner found the trioxide to be insoluble in liquid **carbon dioxide**. C. Winkler²¹ found that 100 parts of **carbon disulphide** dissolved 0.001 part of glassy arsenic trioxide in $2\frac{1}{2}$ years at ordinary temp. Glassy arsenic trioxide under carbon disulphide is coloured reddish, but remains transparent until it begins to crystallize. F. Ephraim prepared complexes with **potassium thiocyanate**. C. Winkler also found that 100 parts of absolute **ethyl alcohol**, at ordinary temp., dissolved 0.446 part of the trioxide in $2\frac{1}{2}$ years; and J. Girardin showed that, expressing the solubility, *S*, grams of the trioxide per 100 parts of solvent:

Alcohol	56	79	84	86	88	100 vol. per cent.
<i>S</i> at 15° {Cubic	1.680	1.430	—	0.715	—	0.025
{Glassy	0.504	0.540	0.565	—	0.717	1.060
<i>S</i> at b.p. Cubic	4.895	4.551	—	3.197	—	3.402

Isolated observations were also made by C. F. Wenzel, L. Thompson, A. Vogel, F. Selmi, and N. W. Fischer. H. Meerwein studied the alcoholates of arsenic trioxide. The trioxide was also found by F. Selmi to be soluble in **methyl alcohol**; and F. Auerbach found the solubility in **amyl alcohol** and the partition coeff. between water and amyl alcohol is 5.47. A. Naumann, and W. Eidmann showed that the trioxide is insoluble in **acetone**; and 100 parts of **ether** were found by C. Winkler to dissolve 0.454 part of the glassy trioxide in $2\frac{1}{2}$ years. F. Selmi showed that every 15 c.c. of ether extracts a milligram of the trioxide from a sat. aq. soln.—less is extracted if the soln. be acidified with hydrochloric acid, and none if acidified with sulphuric or acetic acid. P. A. Cap observed that a little arsenic trioxide dissolves in **glycerol**. F. Selmi found that the cubic trioxide is soluble in **chloroform**, and very slightly soluble in **petroleum ether**, and in **benzene**. F. Auerbach showed that the octahedral crystals dissolve in boiling **nitrobenzene**, but not so with the glassy trioxide. F. Selmi observed that while the glassy form dissolves in **turpentine**, the octahedral crystals are insoluble. J. J. Berzelius, J. J. Heimpel, and K. von Grundner stated that the trioxide is slightly soluble in **fatty oils**, 1000 parts dissolving 0.6–0.8 part of the trioxide in the cold, and about 1.7 parts on boiling; 1000 parts of **castor oil** also dissolve 1.33 parts of the trioxide at ordinary temp., and 9 parts when boiling. E. Beckmann

and W. Gabel said that the trioxide is moderately soluble in **quinoline**, while A. W. Hofmann found it to be insoluble in that menstruum, and also in **aniline**. O. Aschan said that 100 grms. of 95 per cent. **formic acid** dissolve 0.02 gm. of the trioxide at 19.8°. The trioxide is less soluble in **acetic acid** than in sulphuric acid. The reaction with this acid was studied by A. Pictet and A. Bon, A. Rack, P. Schützenberger, T. Bergman, and A. Souchay; and E. Lenssen said that the trioxide is easily soluble in a cold soln. of **oxalic acid**, and the trioxide crystallizes out on cooling a hot sat. soln. of the trioxide in oxalic acid; the trioxide is also easily soluble in a soln. of **tartaric acid**, and of **benzoic acid**. The action of tartaric acid was examined by T. Bergman, J. Pelouze, G. Baudran, and G. G. Henderson and A. R. Ewing. G. Lockemann and M. Pauke found that arsenic trioxide is adsorbed from soln. by coagulating **egg-albumen** and by **blood-serum**. The organic compounds of arsenic are discussed by G. T. Morgan, *Organic Compounds of Arsenic and Antimony* (London, 1918); G. W. Raiziss and L. J. Gavron, *Organic Arsenical Compounds* (New York, 1923); and A. Berthelm, *Handbuch der organischen Arsenverbindungen* (Stuttgart, 1913).

L. Kahlenberg and W. J. Trautmann²² observed that when heated with **silicon**, the arsenic oxide volatilizes. W. Biltz found the amount of arsenic trioxide absorbed from soln. by **silicic acid** is very small, and practically independent of the conc. of the soln. Arsenic trioxide is used in the manufacture of **glass** on account of its decolorizing qualities; and its influence in accelerating the corrosive action of glass has been discussed by D. J. McSwiney and W. E. S. Turner, S. English and co-workers, and K. Fuwa. E. Vigouroux found that arsenic trioxide is reduced to arsenic by **silicon**; and E. Berger, by **calcium silicide**. O. Ruff and K. Albert represented the reaction with **silicochloroform** by: $\text{As}_2\text{O}_3 + 9\text{NaOH} + 3\text{SiHCl}_3 = 9\text{NaCl} + 2\text{As} + 3\text{Si}(\text{OH})_4$; and G. Rauter, the reaction with **silicon tetrachloride** by $2\text{As}_2\text{O}_3 + 3\text{SiCl}_4 = 3\text{SiO}_2 + 4\text{AsCl}_3$.

F. Auerbach found that with a mixture of **boric acid**, and an aq. soln. of arsenic trioxide—arsenious acid—containing an insufficiency of sodium hydroxide for complete neutralization, a complicated condition of equilibrium is established between the two simple acids, several complex acids, and their salts. The relationship in amount of the total borate to the total arsenite in such a soln. is accordingly dependent on the extent to which both acids form complex compounds. According to E. Wedekind and H. Wilke, the adsorption of arsenious acid by **zirconium dioxide** gels is normal and reversible, equilibrium being attained in a few hours; the amount of arsenious acid removed from soln. continues to increase for some days, and only part of the acid can be recovered from the gel by washing. It is supposed that slow chemical combination occurs, forming $\text{Zr}(\text{HAsO}_4)_2$.

J. L. Gay Lussac and L. J. Thénard,²³ and A. F. Gehlen found that **potassium, sodium, zinc**, and other **metals** reduce arsenic trioxide at a red-heat, and the reaction in many cases is accompanied by *une lumière vive*. E. Berger observed its reduction by **aluminium**. The action of various metals—copper, zinc, cadmium, aluminium, tin, lead, antimony, and bismuth—on aq. soln. of arsenic trioxide in the production of hydrogen arsenides has been discussed in connection with those gases; and the action of copper, in connection with the analytical reactions of arsenic. The reducing action of sodium-amalgam on aq. soln. of arsenic trioxide was examined by E. Frémy—*vide supra*, solid hydrogen arsenides. For the poisoning of the platinum catalyst in the oxidation of sulphur dioxide, *vide* the contact process for sulphuric acid. W. Biltz examined the absorptive power of **iron hydrosol** for arsenic trioxide in aq. soln.; and K. C. Sen, the adsorptive power of the hydrated oxides of aluminium, chromium, and iron.

Aq. soln. of the **alkali hydroxides** and aq. ammonia react with arsenic trioxide, forming arsenites (*q.v.*). The arsenites give a white precipitate when treated with **calcium hydroxide** soln., or a soln. of a calcium salt, forming the arsenite. W. H. Wollaston²⁴ also found that **calcium oxide** when heated with arsenic trioxide calcium arsenate and arsenic are formed, and, added J. F. Simon, some arsenite is

produced—the proportion of arsenite is greater the lower the temp. C. Brame found that **barium oxide**, and J. L. Gay Lussac that the **alkali carbonates**, react similarly. B. L. Vanzetti found that on heating a mixture of arsenic trioxide and alkali carbonate, carbon dioxide is eliminated slowly and incompletely; the reaction can be represented by the equation: $3\text{Na}_2\text{CO}_3 + \text{As}_2\text{O}_3 \rightarrow 2\text{Na}_3\text{AsO}_3 + 3\text{CO}_2$, but the reaction is completed only by removing the carbon dioxide as it is formed. The orthoarsenate may be hydrolyzed. L. G. Story and E. Anderson examined the absorption of arsenic trioxide from aq. soln. by **calcium, barium, lead and magnesium hydroxides**. Equilibrium was attained in 3 days at 99° , but several more days are required at a lower temp.—*vide infra*, the arsenites. A. Stavenhagen, and C. Reichard investigated the action of soln. of arsenic trioxide in water, soda-lye, and aq. ammonia, of an aq. soln. of potassium arsenite, and of sodium pyroarsenite on a number of metal salt soln.—*vide infra*, the arsenites. C. Reichard found that a soln. of arsenic trioxide in soda-lye does not act on **copper oxide**, but on **copper hydroxide**, a pale blue, fluorescent soln. is produced which in about 12 hrs. reacts: $4\text{Cu}(\text{OH})_2 + \text{As}_2\text{O}_3 = 2\text{Cu}_2\text{O} + \text{As}_2\text{O}_5 + 4\text{H}_2\text{O}$, while with the trioxide ammoniacal soln., copper hydroxide forms a blue soln. which gives no precipitate with potash-lye, but when heated, loses ammonia, and deposits copper arsenite. An aq. soln. of arsenic trioxide does not react with copper oxychloride; the ammoniacal soln. reacts as with copper hydroxide; and the soln. in soda-lye reacts: $2\text{Cu}_2\text{OCl}_2 + 4\text{NaOH} + \text{As}_2\text{O}_3 = \text{As}_2\text{O}_5 + 4\text{NaCl} + 2\text{Cu}_2\text{O} + 2\text{H}_2\text{O}$. A warm soln. of the trioxide in soda-lye reduces **silver oxide** to a silver mirror; and with a boiling, ammoniacal soln. the reduction is feeble; this soln. deposits normal silver arsenite when treated with acid. When the soln. of the trioxide in soda-lye acts on **mercuric oxide**, it becomes grey, and forms an arsenite and some arsenate; with an ammoniacal soln., the product is very unstable, but does not give a precipitate of mercurous chloride with hydrochloric acid. When **mercurous oxide** is treated with the alkaline soln. of the trioxide, the oxide becomes grey, mercury is deposited when the soln. is warmed, and a soluble arsenate is formed. The ammoniacal soln. of the trioxide reduces **mercuric amidochloride**, and partially reduces **mercurous amidochloride**. J. H. Yoe studied the adsorption of arsenic trioxide by hydrated **alumina**. The alkaline soln. of arsenic trioxide does not act on **stannic hydroxide**, but with stannous hydroxide the reaction: $3\text{Sn}(\text{OH})_2 + \text{As}_2\text{O}_3 + 6\text{KOH} = 3\text{K}_2\text{SnO}_3 + 2\text{As} + 6\text{H}_2\text{O}$ occurs, and some arsine is formed. The deposited arsenic contains some tin. **Lead monoxide** is not attacked by these soln. of arsenic trioxide; nor is **lead dioxide** attacked by the aq. or ammoniacal soln., but with the alkaline soln., $2\text{PbO}_2 + \text{As}_2\text{O}_3 = 2\text{PbO} + \text{As}_2\text{O}_5$. F. Feigl and F. Weiner pointed out that when the reaction is employed quantitatively for the volumetric determination of lead or manganese dioxide, the consumption of arsenite is too high owing to the catalytic action of lead and manganese hydroxides in promoting the oxidation of the arsenite by air. C. Reichard found that there is no reaction with **bismuth trioxide**, but with the soda-soln., alone, **bismuth pentoxide** reacts: $\text{Bi}_2\text{O}_5 + \text{As}_2\text{O}_3 = \text{Bi}_2\text{O}_3 + \text{As}_2\text{O}_5$. Aq. and ammoniacal soln. of the trioxide reduce **cobaltic hydroxide**; but with the boiling alkaline soln., a deep blue soln. of cobaltic acid is formed; **cobaltous hydroxide** is not changed; **nickelic hydroxide** is reduced to **nickelous hydroxide**; and the latter remains unchanged in the alkaline soln., but with the ammoniacal soln., it dissolves. When the soln. is boiled or treated with acids, $\text{Ni}_3\text{As}_4\text{O}_9$ is deposited. An alkaline soln. of the trioxide quickly reduces **manganese dioxide**, and an aq. soln. begins the reduction at 50° —*vide supra*. K. C. Sen studied the adsorption of arsenious acid by **chromic oxide**. According to F. Feigl and F. Weiner, the cold alkaline soln. slowly reduces **chromic acid**. An aq. soln. of arsenic trioxide slowly reduces **potassium dichromate**, but in the presence of acids, the reaction is much faster, and the reaction was employed by F. Kessler, and L. P. de St. Gilles for the volumetric determination of arsenic trioxide. The rate of oxidation of arsenic trioxide by a mixture of potassium dichromate and sulphuric acid was found by R. E. de Lury to be nearly proportional to the

first power of the conc. of the dichromate, the inexactness being probably ascribable to incomplete dissociation. It was proportional to the first power of the conc. of the arsenic trioxide, and to the $\frac{1}{4}$ th power of that of the sulphuric acid. The deviation from the second power is considered to be probably due to the influence of the hydrogen ion on the dissociation of the arsenic trioxide. The temp. coeff. is low; the rise from 0° to 10° only increased the rate of oxidation by 26 per cent. The induced reaction in which arsenic trioxide and potassium iodide are oxidized by acid soln. of potassium dichromate was studied by R. E. de Lury. The arsenic trioxide acts as the inductor and the potassium iodide as the acceptor of the oxidation. It was found that the rate of reduction of the chromic acid in soln. of arsenic trioxide and iodide is equal to the sum of the rates of reduction of the arsenic trioxide and iodide separately, the retardation of the former being equal to the acceleration of the latter. The temp. coeff. of the single actions and the joint action are equal. The ratio also of the rate of oxidation of the iodide alone and in presence of arsenic trioxide is independent of the conc. of dichromate and sulphuric acid. The results may be accounted for by the assumption of the formation of a higher oxide (most probably a complex oxide of chromium and arsenic), which is reduced instantaneously by arsenic trioxide or iodide, the quantity reduced by each in mixtures being dependent on their relative conc. An aq. soln. of arsenic trioxide slowly reduces **potassium permanganate**; the reaction is rapid in the presence of acids. M. Geloso obtained colloidal manganese dioxide by reducing permanganate soln. with one of arsenic trioxide. In alkaline soln., F. Feigl and F. Weiner found that the reaction: $3As_2O_3 + 4KMnO_4 = 3As_2O_5 + 2K_2O + 4MnO_2$ proceeds to a definite end-point only when there is a constant excess of permanganate. If the arsenite is in excess, the permanganate is reduced to manganous hydroxide in the complete absence of air; in the presence of air, oxidation of the manganous hydroxide takes place with the formation of an indefinite mixture of oxides intermediate between MnO and MnO_2 . An excess of arsenite also results in a considerable adsorption of arsenious and arsenic acids by the precipitated manganese hydroxide, and the amount of arsenic acid formed does not correspond with the oxygen consumed by reduction of the permanganate. According to A. Travers, permanganic acid is reduced by arsenic trioxide in presence of sulphuric or nitric acid to a manganic salt and manganese dioxide. In presence of hydrofluoric, phosphoric, or arsenic acid the whole of the manganese may be converted into the corresponding manganic salt. Reduction to manganous salts occurs in presence of a considerable excess of arsenic trioxide. W. Trautmann showed that arsenic trioxide is quantitatively oxidized by permanganate in the presence of an excess of sulphuric acid at a boiling heat. The reaction was studied by B. Brauner, A. Bose, A. Bussy, E. Deiss, F. Feigl and F. Weiner, M. Geloso, T. Oryng, W. T. Hall and C. E. Carlson, J. Holluta, F. Kessler, A. Klemenc, A. Travers, K. Swoboda, O. Kühling, R. Lang, E. Lenssen, L. Moser and F. Perjatel, L. P. de St. Gilles, L. Vanino, and E. Waitz. O. Cantoni showed that the reaction is considerably accelerated if a little potassium iodide be present. R. Lang studied the electrometric titration of arsenious acid with potassium permanganate soln. Arsenic trioxide forms complexes with **tungstic, molybdic, and vanadic acids** (*q.v.*).

According to W. Biltz,²⁵ the amount of arsenic trioxide absorbed from aq. soln. by **aluminium hydroxide** is very small, and is practically independent of the conc. The adsorption was also studied by G. Lockemann and M. Paucke, and K. C. Sen. The effect of **ferric hydroxide** in fixing arsenic trioxide so that it is no longer in a condition to dissolve was utilized by R. Bunsen and A. A. Berthold as an antidote for arsenic poisoning—*vide supra*. A. Stavenhagen was unable to prepare a definite compound by the action of ferric hydroxide on soln. of arsenic trioxide. According to G. Lockemann, the quantity of ferric hydroxide necessary for the complete adsorption of arsenic present in a soln. as arsenite or arsenate is in accordance with the formula $E = kA^2$, where E is the number of mgrms. of

ferric hydroxide in 100 c.c. ; A , the number of mgrms. of arsenic in 100 c.c. ; k , a constant which varies with the temp. ; and p has the value 0.57 for all temp. The value of A varied from 0.1 to 500, and the values of k were respectively 70, 90, and 130 at 0°, 25°, and 80°. With a rise of temp., the adsorption decreases considerably. At all temp., very small quantities of arsenic require relatively much more ferric hydroxide for complete adsorption than do larger quantities of arsenic. In preparing the ferric hydroxide, twice the theoretical quantity of ammonium hydroxide necessary for the precipitation of the iron was added ; if only the theoretical quantity is added, the adsorption of arsenic is considerably increased. R. Bunsen, N. J. B. G. Guibourt, T. Oryng, and A. Reychler attributed the action to the formation of a hydrolyzed ferric arsenite ; but W. Biltz showed that the antidotal action of ferric hydroxide is not due to the formation of a basic arsenate, or of a solid soln., but to reversible adsorption. The amount of arsenic trioxide adsorbed from soln. is diminished with the ageing of the ferric hydroxide. W. Biltz measured the distribution of arsenic trioxide between water and ferric hydroxide at different temp., and represented the results by the relation $C_1 = kC_2^n$, where k and n are constants ; C_1 , the conc. of the arsenic trioxide in the ferric hydroxide ; and C_2 , the conc. of the arsenic trioxide in soln. at equilibrium—*vide* 5. 39, 9. M. C. Boswell and J. V. Dickson found that the observed results deviate a little from this relation. W. Mecklenberg stated that the adsorption curves for different preparations of ferric hydroxide are each related by a particular factor to a unit curve, so that the ordinate corresponding to a given abscissa on one curve may be obtained by multiplying by the factor the ordinate for that abscissa on the unit curve. This means that if the adsorption follows the law $C_1 = kC_2^n$, n will be constant for the same adsorbent, and an adsorbent prepared under different conditions, or of different ages will vary only in the values of k . M. C. Boswell and J. V. Dickson found that while n varied only from 0.183 to 0.284 with differently prepared samples of ferric hydroxide, k varied from 33.3 to 200. G. Lockemann and co-workers, and M. C. Boswell and J. V. Dickson showed that the adsorption of arsenic trioxide by ferric hydroxide is diminished when sodium hydroxide is present ; and conversely, the adsorption of sodium hydroxide by ferric hydroxide is increased in the presence of arsenic trioxide. K. C. Sen studied the effect with different modes of preparation and of the ageing of the colloid, the effect of neutral salts and of variations in the conc. of the soln. on the adsorption of arsenious acid by ferric hydroxide ; L. Herboth, the adsorption of arsenic trioxide by saccharated iron ; and J. M. Clavera, by ferric hydroxide, and by ferric magnesium hydroxide.

The action of arsenic trioxide on the halides of the alkalies and alkaline earths is discussed in a special section below. The action on copper, silver, mercury, and lead salts is indicated in connection with the arsenites. It may be observed, however, that M. Kohn²⁶ found that when copper sulphate is heated with aq. ammonia and arsenic trioxide, in a sealed tube at 100°, it undergoes reduction to cuprous salt with formation of arsenic acid. After the resulting cuprous soln. has been oxidized to the cupric condition by atm. oxygen, estimation of the arsenic acid reveals more of the latter than corresponds with the eq., $2\text{Cu}^+ + \text{AsO}_3''' + 2\text{OH}' = \text{H}_2\text{O} + 2\text{Cu}^+ + \text{AsO}_4'''$. Evidently oxidation of the ammoniacal cuprous soln. to the cupric stage activates the atm. oxygen for the oxidation of the residual unchanged arsenious acid. Depression of the conc. of hydroxyl ions by addition of ammonium salts retards the reduction of cupric to cuprous salt. Again, he found that **silver nitrate** is completely reduced to metallic silver in ammoniacal soln. by arsenious acid, which is oxidized to arsenic acid. The reduction is not affected by the addition of neutral salts such as sodium nitrate or sulphate, but is hindered by ammonium sulphate, which causes a decrease in the conc. of hydroxyl-ions. The reduction of **cupric sulphate** by arsenious acid in presence of aq. ammonia is not influenced by neutral salts such as potassium chloride or nitrate. H. Rose found that soln. of **gold chloride** are reduced to the metal by soln. of arsenic trioxide or the arsenites. P. Woulfe

found that when a soln. of **stannous chloride** is digested for a long time with arsenic trioxide, tin is deposited; and if conc. hydrochloric acid be present, F. Kessler said that some arsine is formed. According to A. Bettendorff, aq. soln. of arsenic trioxide or pentoxide give no precipitate with stannous chloride unless conc. hydrochloric acid be present—*Bettendorff's reaction*. With an acid of sp. gr. between 1.135 and 1.185, a precipitate forms immediately; with an acid of sp. gr. 1.123, complete precipitation occurs in a few minutes; with an acid of sp. gr. 1.115, the precipitation is incomplete; and with an acid of sp. gr. less than 1.100, no precipitation occurs. The reaction was studied by C. O. Curtman, G. Frerichs, A. Ferraro and A. Carobbio, and O. Schlickum. K. Zwignagl observed that the reaction is exothermic, giving off about 20 Cals. per gram-atom of arsenic, depending on the conditions. The precipitate from a soln. in pure hydrochloric acid contained 98.18 per cent. of arsenic, and 1.82 per cent. of tin. R. Lang and J. Zwerina observed that arsenious acid induces the reaction between **chromic acid** and manganous salts. The reaction of an aq. soln. of arsenic trioxide and **ferric chloride** in 1.5N- to 4N-HCl in sealed tubes at 107° and 127° was studied by K. Jellinek and L. Winogradoff. They found the equilibrium constant of the reaction: $2\text{FeCl}_3 + \text{H}_3\text{AsO}_3 + \text{H}_2\text{O} \rightleftharpoons 2\text{FeCl}_2 + \text{H}_3\text{AsO}_4 + 2\text{HCl}$, namely, $k = \frac{[\text{H}_3\text{AsO}_3][\text{FeCl}_3]^2}{[\text{H}_3\text{AsO}_4][\text{FeCl}_2]^2[\text{HCl}]^2}$, is 0.0354 at 107°, and 0.117 at 127°. The thermal value of the reaction represented in the above equation from left to right is 18 Cals.; both reactions are termolecular, and are accelerated by hydrochloric acid. W. Manchot and F. Glaser found that a mixture of equimolar parts of arsenic trioxide, ferrous sulphate, and potassium hydroxide absorbed nearly twice as much oxygen as was required to produce ferric oxide, and assumed that a dioxide, FeO_2 , was formed. For G. Gire's observations on this subject, *vide supra*.

§ 12. The Arsenites

There are several reported¹ occurrences of sodium arsenite in natural waters. Thus, C. Morelli observed 6.2 mgrms. per litre in the water of Ceresole Reale of Piedmont; O. Henry and C. L. Lhéritier, traces in the waters of Plombières; and R. Pribram, 3.43 mgrms. per litre in the waters of Donna Sara, Roumania. In 1746, P. J. Macquer² prepared an impure alkali arsenite by treating white arsenic with alkali-lye; he called the product *foie d'arsenic—liver of arsenic*—apparently regarding arsenic as a compound of sulphur. In 1855, C. R. Fresenius³ said that no definite alkali arsenite had been prepared other than syrups and evaporation residues of variable composition. J. Thomsen's results for the heat of neutralization of an aq. soln. of arsenic trioxide with soda-lye, are indicated above. The action of indicators in the neutralization of alkali arsenites with acids was discussed by G. Favrel, R. T. Thomson, F. A. Flückiger, etc.—*vide supra*.

FIG. 17.—Equilibrium in the Ternary System: As_2O_3 — Li_2O — H_2O at 25° .

FIG. 18.—Equilibrium in the Ternary System: Na_2O — As_2O_3 — H_2O at 30° .

F. A. H. Schreinemaker and W. C. de Baat studied the ternary system: As_2O_3 — Li_2O — H_2O at 25° . The results are summarized in Fig. 17. The curve *ab* represents the solubility of arsenic trioxide in lithia-lye; *bc*, the solubility of

FIG. 19.—Equilibrium in the Ternary System: As_2O_3 — K_2O — H_2O at 25° .

lithium metarsenite, $LiAsO_2$; and *cd*, the solubility of hydrated lithium hydroxide, $LiOH.H_2O$. The shaded areas represent supersaturated soln. The conditions of stability of lithium metarsenite are shown in the diagram. The results of F. A. H. Schreinemaker and W. C. de Baat's study of the system Na_2O — As_2O_3 — H_2O at 30° are illustrated by Fig. 18. Here *A* denotes the solubility of arsenic trioxide in water; the region *abA*, the supersaturated soln. with arsenic trioxide as solid phase; *bcB*, of the solid phase $NaAsO_2$; *cdC*, of the solid $Na_4As_2O_5.9H_2O$; *deD*, of the solid $Na_{10}As_4O_{11}.26H_2O$; *efE*, of the solid $Na_4As_2O_5$; and *fgF*, of the hydrate $NaOH.H_2O$. The solubility curve *ab* shows the rapid increase in the

solubility of arsenic trioxide as the proportion of alkali in the soln. increases. The results of F. A. H. Schreinemaker and W. C. de Baat's study of the ternary

system $As_2O_3-K_2O-H_2O$ at 25° are shown in Fig. 19. *ab* represents the solubility curve of arsenic trioxide; *bc*, that of potassium paratetrarsenite, $K_2As_4O_7$; *de*, that of potassium metatetrarsenite, $K_8As_4O_9 \cdot 12H_2O$; *fg*, that of $KOH \cdot H_2O$; and *gh*, that of $KOH \cdot 2H_2O$. The dotted lines *cd* and *ef* represent unstable phases not yet recognized. The shaded areas represent supersaturated soln. The constitution of the tetrarsenites may be referred to that of the arsenic trioxide, As_2O_3 , which, with the *orthotetrarsenious acid*, $H_8As_4O_{10}$, can be represented graphically:

The derivatives of the ortho-acid are therefore:

Orthotetrarsenious acid	$H_8As_4O_{10}$ (or $H_4As_2O_5$)
Metatetrarsenious acid	$H_4As_4O_9$
Mesotetrarsenious acid	$H_4As_4O_8$ (or $H_2As_2O_2$)
Paratetrarsenious acid	$H_2As_4O_7$

A. Stavenhagen heated finely-powdered arsenic trioxide with an excess of an alcoholic soln. of sodium hydroxide in a reflux condenser, and after repeated extraction with alcohol, allowed the product to dry at 100° . The white powder has a composition approximating that of **sodium orthoarsenite**, Na_3AsO_3 . There is some doubt about the existence of the alkali orthoarsenites, and B. L. Vanzetti made sodium orthoarsenite by reacting on arsenic trioxide with sodium methoxide: $As_2O_3 + 6NaOCH_3 \rightarrow 2Na_3AsO_3 + 3(CH_3)_2O$. The arsenic trioxide easily dissolves in sodium methoxide, but not in sodium ethoxide, even after long boiling. The excess of methyl alcohol was distilled off on the water-bath. The remaining soln., when evaporated in vacuo, gives a white crystalline crust. The first fractions were nearly 80 per cent. Na_3AsO_3 , and the last fractions 20 per cent. The salt gives yellow silver orthoarsenite when treated with silver nitrate. The reaction with arsenic trioxide and sodium methoxide was not completed even after long boiling. B. L. Vanzetti prepared **potassium orthoarsenite**, K_3AsO_3 , in a similar manner, but the syrup could not be crystallized. A. Stavenhagen obtained a crystalline mass of potassium orthoarsenite by treating arsenic trioxide with an alcoholic soln. of potassium hydroxide. The potassium salt was also obtained by H. O. Schulze by exposing a soln. of arsenic trioxide and potassium iodide to air; and by A. Stavenhagen by treating the barium salt with potassium sulphate, and drying the clear liquid over conc. sulphuric acid at 100° in an atm. of hydrogen. The potassium salt forms a group of clear, transparent needles which become turbid when exposed to air; the sodium salt is a white powder. Both sodium and potassium arsenites dissolve freely in water. R. Robl observed no fluorescence with sodium arsenite in ultra-violet light. P. Walden gave for the eq. electrical conductivity of one-third of a mol of sodium orthoarsenite in *v* litres of water:

<i>v</i>	.	32	64	128	256	512	1024
λ	.	158.3	160.1	161.1	160.6	156.7	154.3

J. von Zawidzky discussed this subject, and concluded from his observations that the soln. contains $Na(H_2AsO_3)$, not Na_3AsO_3 —*vide supra*, aq. soln. of arsenic trioxide. E. Blanc estimated that in 0.0104*N*-aq. soln., sodium dihydrarsenite is 0.394 per cent. hydrolyzed. A. Miolati and E. Mascetti studied the sp. conductivity of arsenious acid during the progressive addition of a soln. of sodium hydroxide; and E. Cornec, the lowering of the f.p. According to R. Suchy and J. Michel, arsenic trioxide dissolved in a soln. of sodium carbonate is precipitated by carbon dioxide. A. W. Francis studied the speed of oxidation by bromine, and found the velocity constant of the reaction to be 4. K. H. Butler and D. McIntosh found sodium arsenite to be insoluble in liquid chlorine. According

to A. Gutmann, sodium thiosulphate reacts with a soln. of the tertiary sodium or potassium orthoarsenites: $\text{Na}_3\text{AsO}_3 + \text{Na}_2\text{S}_2\text{O}_3 = \text{Na}_3\text{AsSO}_3 + \text{Na}_2\text{SO}_3$, and with the secondary salt, sodium hydroarsenite, $\text{Na}_2\text{HASO}_3 + \text{Na}_2\text{S}_2\text{O}_3 = \text{NaHSO}_3 + \text{Na}_3\text{AsSO}_3$; and with the primary salt, a complex salt is formed, $\text{Na}_8\text{As}_{18}\text{O}_7\text{S}_{24} \cdot 3\text{H}_2\text{O}$; sodium tetrathionate reacts only slowly at ordinary temp., but when warmed, brown arsenic separates, and a soln. of sulphite, arsenate, and trioxysulpharsenate is produced; similar products are formed by the action of a warm soln. of sodium trithionate; while a cold or boiling soln. of sodium dithionate has no action on sodium orthoarsenite. According to A. Gutmann, the azides of sodium, barium, and lead do not react with normal sodium arsenite, which gives a silver mirror with ammoniacal soln. of silver azide, due solely to the reducing action of the arsenite on the silver salt. Chloroazoimide and sodium arsenite yield sodium azide, arsenate, and chloride; iodoazoimide behaves similarly. The permanence of the azido-groups in inorganic compounds appears most readily explicable on the basis of T. Curtius' formula. A. Gutmann found that sodium orthoarsenite reacts with quadrivalent oxygen in dioxides; with sulphur in polysulphides and disulphides; and with quinquevalent and tervalent nitrogen in organic compounds. The aq. soln. reacts alkaline, and slowly oxidizes to arsenate on exposure to air; W. Reinders and S. I. Vles said that the oxidation of alkali arsenite with free oxygen occurs only in the presence of a catalytic agent, and with silver nitrate furnishes a precipitate of normal silver arsenite. W. Clark studied the reversal of photographic plates by sodium arsenite. A. W. Francis measured the speed of oxidation of sodium arsenite; and J. D. Jenkins and E. F. Berger found that copper and copper salts act as catalysts. N. R. Dhar and co-workers, and W. P. Jorissen and co-workers found that the oxidation of phosphorus, sulphites, stannous salts, chloroform, benzaldehyde, and acrolein is retarded in presence of sodium arsenite; and A. N. Dey and N. R. Dhar showed that the oxidation of sodium arsenite at ordinary temp. is effected by passing air through a soln. in which finely divided copper, cuprous chloride or oxide, zinc, or yellow phosphorus is suspended; finely divided copper dissolves in cold soln. of sodium arsenite only in the presence of oxygen. The oxidation of sodium arsenite can be induced by the simultaneous oxidation of sodium sulphite, stannous chloride, manganous or cobaltous hydroxide, and various aldehydes. A. Gutmann found nitric oxide oxidizes sodium arsenite: $2\text{NO} + \text{Na}_3\text{AsO}_3 = \text{N}_2\text{O} + \text{Na}_3\text{AsO}_4$; and with hydroxylamine, there are concurrent reactions, $\text{NH}_2\text{OH} + \text{Na}_3\text{AsO}_3 = \text{Na}_3\text{AsO}_4 + \text{NH}_3$; and $3\text{NH}_2\text{OH} = \text{NH}_3 + \text{N}_2 + 3\text{H}_2\text{O}$. C. P. Jorissen and C. van den Pol said that sodium sulphite does not induce the oxidation of sodium arsenite soln. when the alkalinity is too great. F. E. Brown and J. E. Snyder found that sodium arsenite does not react with boiling vanadium oxytrichloride; J. H. C. Smith and H. A. Spoehr observed that sodium ferropyrrophosphate acts as a catalyst in the oxidation of potassium arsenite soln., and that an intermediate compound is formed with oxygen and the catalyst. A. Gutmann also studied the oxidation of the salt by organic compounds—sodium benzenediazoxide, azoxybenzene, etc. Sodium benzene-iso-diazoxide does not act; neither does sodium nitroprusside. M. C. Boswell and J. V. Dickson found that sodium arsenite is oxidized by fusion with the hydroxide.

A. Stavenhagen treated barium pyroarsenite with a soln. of potassium sulphate and evaporated the soln. The white powder so obtained was **hexahydrated potassium pyroarsenite**, $\text{K}_4\text{As}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$. L. Pasteur reported it to be formed by adding alcohol to a mixed soln. of potassium hydroxide and hexarsenite, but A. Stavenhagen said that the product so obtained is a mixture of variable composition. P. Walden gave for the eq. electrical conductivity of one-third of a mol. of sodium metarsenite in *v* litres of water:

<i>v</i>	.	.	.	32	64	128	256	512	1024
λ	.	.	.	73.2	77.3	80.9	84.4	87.6	9.6

J. K. Wood found the ionization constant to be 0.000214; and calculated that

in a decinormal soln., 1.4 per cent. of the salt is hydrolyzed at 25°. The salt is readily soluble in water, less so in alcohol; it is decomposed by carbon dioxide; and forms with silver nitrate the corresponding silver pyroarsenite. L. Pasteur could not prepare the corresponding **sodium pyroarsenite**, $\text{Na}_4\text{As}_2\text{O}_5$, in crystals, and A. Stavenhagen was not satisfied about the individuality of the product; but F. A. H. Schreinemaker and W. C. de Baat's diagram, Fig. 18, shows the condition of stability and also that of **enneahydrated sodium pyroarsenite**, $\text{Na}_4\text{As}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$.

According to C. L. Bloxam, if a soln. of sodium carbonate be boiled with an excess of arsenic trioxide, and the clear soln. evaporated to dryness, **sodium metarsenite**, NaAsO_2 , is formed; but if a mixture of dry sodium carbonate and arsenic trioxide be heated to redness, a mixture of arsenite and arsenate is formed. The conditions of stability are illustrated by Fig. 19. A. Stavenhagen found that if alcohol be poured over a soln. of arsenic trioxide in soda-lye, a yellow syrupy liquid is obtained, which, on evaporation, yields a white powder of variable composition and containing some crystals of arsenic trioxide. According to C. Reichard, salts of the type $\text{M}_3(\text{AsO}_3)_2$ are precipitated when sodium metarsenite is added to a soln. of stannous chloride, zinc sulphate, or lead or nickel nitrate; $\text{M}_2\text{As}_2\text{O}_5$, with soln. of cadmium sulphate, or cobalt nitrate; $\text{Cu}_4\text{As}_2\text{O}_7$, copper sulphate; $\text{Fe}_4\text{As}_2\text{O}_9$, with ferrous sulphate; $\text{M}_5(\text{AsO}_4)_2$, with manganese sulphate or mercuric chloride; $\text{Sn}_7\text{As}_2\text{O}_{17}$, with stannic chloride; and $\text{Ag}_6\text{As}_4\text{O}_9$, with silver nitrate. F. E. Brown and J. E. Snyder observed no reaction with vanadium oxytrichloride and anhydrous sodium arsenite. If potassium hexarsenite be boiled for some hours with a soln. of potassium carbonate, and the product washed with alcohol, L. Pasteur said that the syrupy mass is **potassium metarsenite**, KAsO_2 , but A. Stavenhagen could obtain only an impure salt in this way. E. Cornec showed that the measuring of the effect of the progressive neutralization of arsenious acid by potash-lye on the f.p. of aq. soln. shows the existence of the metarsenite. J. C. Ghosh and S. C. Bisvas measured the extinction coeff. of potassium arsenite in ultra-violet light. A. Bouchonnet prepared **rubidium metarsenite**, RbAsO_2 , by the action of arsenic trioxide on an aq. soln. of rubidium carbonate. The amorphous white powder, and the aq. soln. furnish the arsenate when heated. The aq. soln. is alkaline towards litmus, methyl-orange, and phenolphthalein. C. C. Palit and N. R. Dhar observed that metal salt soln. accelerate the oxidation of soln. of sodium arsenite by air—*vide* arsenic trioxide.

L. Pasteur, and A. Stavenhagen reported **potassium paratetrarsenite**, $\text{K}_2\text{As}_4\text{O}_7 \cdot 2\text{H}_2\text{O}$, to be formed as a syrupy liquid when an excess of arsenic trioxide is treated with a cold soln. of potassium hydroxide, and mixed with alcohol. The liquid crystallizes on standing some time. C. L. Bloxam also found it to be deposited on cooling a boiling conc. soln. of potassium carbonate and arsenic trioxide. The conditions of stability of the anhydrous salt are indicated in F. A. H. Schreinemaker and W. C. de Baat's diagram, Fig. 20. The prismatic crystals of the hydrated salt lose a mol. of water at 100°; and some water is lost at ordinary temp. over sulphuric acid. The salt melts a little over 100° in dry air, forming a yellow liquid which congeals to a glassy mass. Some arsenate, arsine, and arsenic are formed at the same time. Acids precipitate arsenic trioxide from conc. soln., but not from dil. soln.; and silver nitrate precipitates normal silver arsenite from the aq. soln. The conditions of stability of **potassium metatetrarsenite**, $\text{K}_6\text{As}_4\text{O}_9 \cdot 12\text{H}_2\text{O}$, are indicated in F. A. H. Schreinemaker and W. C. de Baat's diagram, Fig. 20; and those of **hexacosihydrated sodium tetrarsenite**, $\text{Na}_{10}\text{As}_4\text{O}_{11} \cdot 26\text{H}_2\text{O}$, are illustrated by Fig. 20. According to

FIG. 20.—Equilibrium in the Ternary System: As_2O_3 — NH_3 — H_2O .

C. L. Bloxam, if arsenic trioxide be boiled with an excess of a soln. of potassium carbonate, the filtrate, on evaporation, furnishes a crystalline mass approximating **potassium hexarsenite**, $K_4As_6O_{11} \cdot 3H_2O$; A. Stavenhagen could not verify this.

According to J. J. Berzelius,⁴ arsenic trioxide dissolves freely in hot aq. ammonia, and on cooling, or, according to J. M. F. de Lassone, on evaporating the soln., the original salt is deposited in octahedral crystals. Similar results were obtained by N. J. B. G. Guibourt, and N. W. Fischer. The results of F. A. H. Schreinemakers and W. C. de Baat's study of the ternary system $As_2O_3-NH_3-H_2O$ at 30° are summarized in Fig. 20. The point *a* represents the solubility of arsenic trioxide in water; the curve *ab*, the solubility of the trioxide in ammoniacal soln. The area *abA* represents supersaturated soln. with the trioxide as the solid phase; and the area *SdB*, unsaturated soln. with NH_4AsO_2 as the solid phase. Evidence of the formation of $NH_4(H_2AsO_3)$ was also obtained, but this region was not explored. E. Cornec observed no evidence of the formation of an ammonium arsenite by measuring the f.p. of soln. of arsenic trioxide progressively neutralized with aq. ammonia. A. Stavenhagen found that if arsenic trioxide be treated with an alcoholic soln. of ammonia, a pale yellow viscid mass is formed which does not become solid, and when dried in hydrogen at 40° , loses all its ammonia. A. Miolati and E. Mascetti studied the sp. conductivity of arsenious acid when progressively treated with additions of ammonia; and E. Cornec likewise measured the lowering of the f.p. of the soln. According to L. Pasteur, the crystalline mass, obtained by pouring conc. aq. ammonia on arsenic trioxide, consists of **ammonium pyroarsenite**, $(NH_4)_4As_2O_5$. A. Stavenhagen could not obtain L. Pasteur's salt, but W. Stein obtained the crystals which he washed with alcohol, then with ether, and finally pressed between bibulous paper. The salt furnishes oblique, rectangular, prismatic crystals, which look like hexagonal plates. They are permanent only in contact with the ammoniacal soln., for when taken out of the liquid or dissolved in water, ammonia is given off. The ammonia is rapidly given off when the salt is confined over sulphuric acid. According to N. W. Fischer, when conc. aq. ammonia is poured over pulverized arsenic trioxide, and the mixture is warmed so as to dissolve the viscid mass which is deposited, crystals of an acid salt—**ammonium metarsenite**, NH_4AsO_2 , separate out in rhombic prisms. C. L. Bloxam washed the crystals with alcohol, and dried them between folds of bibulous paper. V. de Luynes heated to 70° or 80° a mixture of arsenic trioxide and conc. aq. ammonia in a closed vessel, and, after the mixture has stood for some time, poured off the clear liquid, allowed the crystals to drain on porous tiles, and dried them between folds of bibulous paper. The analyses of C. L. Bloxam, F. A. H. Schreinemakers and W. C. de Baat, and V. de Luynes agreed with the formula NH_4AsO_2 , but A. Stavenhagen could not confirm this. The conditions of stability are indicated in Fig. 20. The salt rapidly loses ammonia when exposed to air; it is freely soluble in water, but sparingly soluble in aq. ammonia. If the aq. soln. be evaporated, arsenic trioxide is deposited. The aq. soln. gives precipitates with silver and copper salts. A little alcohol precipitates arsenic trioxide from the aq. soln., but much alcohol leaves the soln. transparent. The existence of **ammonium dihydroarsenite**, $NH_3(H_2AsO_3)$, was indicated by F. A. H. Schreinemakers and W. C. de Baat. H. Stamm measured the solubility of ammonium arsenite in aq. ammonia.

According to L. Gmelin,⁵ red-hot copper oxide does not absorb the vapour of arsenic trioxide. G. Tammann found that when a mixture of cupric oxide and arsenic trioxide is heated, there is an exothermal reaction at 400° , and the grey colour of the mass becomes reddish-violet. There is a terrace in the heating curve at 468° . The reaction $4CuO + As_2O_3 = 2Cu_2O + As_2O_5 - 12.5$ cal. is endothermal, but if a compound is formed, its heat of formation may make the reaction exothermal. J. L. Proust, H. Braconnot, C. L. Bloxam, and R. Fittig showed that when a soln. of a copper salt is treated with a soln. of arsenic trioxide and potassium hydroxide, a greenish precipitate containing copper arsenite is formed.

Owing to the hydrolysis of the salt, the product is more or less impure. J. J. Berzelius found that a soln. of copper carbonate in an excess of arsenious acid is not precipitated by acids or alkalis; and on evaporation it furnishes a yellowish-green mass which, according to A. Stavenhagen, does not have a constant composition. Analogous observations were made by S. P. Sharples, W. Hampe, and C. Reichard. A bluish-green mineral, found by A. Damour and G. vom Rath in druses in the massive cuprite of Copiapo, Chili, was named *trippkeite*—after P. Trippke. The qualitative analysis shows that it is a copper arsenite, $n\text{CuO} \cdot \text{As}_2\text{O}_3$. The tetragonal crystals have the axial ratio $a:c=1:0.9160$; the habit is octahedral; and the cleavage on the (100)-face is perfect, while that on the (110)-face is imperfect. J. A. Krenner supposes the mineral to be isomorphous with ferrous phosphite, $n\text{FeO} \cdot \text{P}_2\text{O}_3$, represented by the mineral schafarzikite (*q.v.*). E. S. Larsen gave for the refractive indices $\omega=1.900$, and $\epsilon=2.12$. The optical character is positive. The mineral is readily soluble in acids.

A. Stavenhagen made **copper orthoarsenite**, $\text{Cu}_3(\text{AsO}_3)_2$, by adding a soln. of normal potassium arsenite in 50 per cent. alcohol to an alcoholic soln. of cupric chloride, and drying the product at 100° . The dirty yellowish-green mass is decomposed by water. S. P. Sharples obtained **dihydrated copper orthoarsenite**, $\text{Cu}_3(\text{AsO}_3)_2 \cdot 2\text{H}_2\text{O}$, by mixing a boiling soln. of arsenic trioxide (2 parts) and decahydrated sodium carbonate (8 parts) in water (10 parts) with one of pentahydrated copper sulphate (6 parts) in water (40 parts). After boiling a few minutes, the precipitate is allowed to settle, washed with hot water, and dried at 100° . The salt is not freed from water at 150° ; it is not blackened by boiling water; it is soluble in dil. acids and alkalis. The soln. in alkali-lye is decomposed by an excess of the alkali hydroxide or carbonate. The boiling ammoniacal soln. is not decomposed, while the addition of potassium hydroxide decolorizes the soln. in consequence of the formation of cuprous salts. The reports of A. Stavenhagen, and S. P. Sharples of the behaviour of copper orthoarsenite towards water need revision. C. Reichard prepared a basic salt, **copper dioxyarsenite**, $5\text{CuO} \cdot \text{As}_2\text{O}_3$, or $2\text{CuO} \cdot \text{Cu}_3(\text{AsO}_3)_2$, by treating an excess of copper sulphate with a dil. soln. of arsenic trioxide. The pale green precipitate was washed by decantation, and dried at ordinary temp. The salt retains its colour at 100° ; at 120° – 130° , it loses 10 per cent. of water and becomes dark green. It is insoluble in water, but soluble in acids, and it forms a deep blue soln. with aq. ammonia. The ammoniacal soln. is not changed by boiling, and when neutralized or when the ammonia is volatilized, the dioxyarsenite is again precipitated. The salt is soluble in conc. potash-lye, forming a blue soln. which deposits cuprous hydroxide at 20° – 30° , and cuprous oxide at higher temp. Barium dioxide reacts with the salt at ordinary temp., giving off oxygen. When warmed with a soln. of arsenic trioxide in soda-lye, cuprous oxide is precipitated. L. Kahlenberg and J. V. Steinle observed that arsenic reacts with an aq. soln. of copper arsenite: $\text{Cu}_3(\text{AsO}_3)_2 + 2\text{As} = 3\text{Cu} + 2\text{As}_2\text{O}_3$.

C. W. Scheele gradually mixed, while constantly stirring, a hot filtered soln. of potassium carbonate (32 parts) and arsenic trioxide (11 parts) with an aq. soln. of copper sulphate (32 parts), and obtained a siskin-green precipitate which when washed and dried was used as a green pigment—*Scheele's green*—before the use of arsenical colours was prohibited. J. L. Proust, H. Braconnot, C. Reichard, C. L. Bloxam, W. Sattler, etc., obtained similar products by mixing potassium arsenite or the aq. acid with an aq. or ammoniacal soln. of copper salt. The Farbenindustrie A.G. treated basic cupric chloride with arsenites or arsenious acid. C. L. Bloxam represented the composition of the air-dried salt as that of **copper pyroarsenite**, $2\text{CuO} \cdot \text{As}_2\text{O}_3$, or $\text{Cu}_2\text{As}_2\text{O}_5$, with $2.89\text{H}_2\text{O}$; when dried at 100° , the composition is CuHAsO_3 , **copper hydroarsenite**. S. P. Sharples gave $\text{Cu}_3(\text{AsO}_3)_2 \cdot \text{H}_2\text{O}$. G. Bornemann said that Scheele's green is not really copper hydroarsenite, but approximates more closely to the normal arsenite, $\text{Cu}_3(\text{AsO}_3)_2 \cdot n\text{H}_2\text{O}$. Actually, the composition varies with the mode of preparation, and is

richer in cupric oxide, the greater the excess of alkali hydroxide or carbonate used in its preparation. A. Stavenhagen also said that the precipitate has a variable composition. J. L. Prout found that when the pale green, amorphous copper pyroarsenite is heated, it gives off water and arsenic trioxide, and leaves a residue of cupric oxide, which, according to J. F. Simon, is a mixture of copper arsenide and arsenate—the latter can be extracted by dil. nitric acid. L. N. Vauquelin, G. Bonnet, and C. Reichard found that the salt is soluble in cold potash-lye, and the deep blue soln. slowly decomposes into cuprous oxide on standing, rapidly when heated. J. J. Berzelius, and S. P. Sharples said that the soln. in aq. ammonia is colourless, and is not oxidized on standing or when boiled, and when the ammonia is evaporated, the original salt remains, provided, added A. Girard, the evaporation is conducted in an atm. of ammonia; if evaporated in air, an ammonioarsenate is formed. Soln. of ammonium salts were found by C. Reichard to act like aq. ammonia. S. P. Sharples showed that when potassium hydroxide is added to the ammoniacal soln., cuprous hydroxide is precipitated. E. C. Franklin and C. A. Kraus said that the pyroarsenite is insoluble in liquid ammonia, and J. Schröder, that it is insoluble in pyridine. W. Sattler showed that the fresh precipitate dissolves freely in acetic acid, but if the precipitate has stood a long time it dissolves less readily in acetic acid and crystals of arsenic trioxide are formed. He added that if acetic acid be present when the precipitate is formed, the so-called *Schweinfurt-green*, *Paris-green*, *mitis-green*, or *Vienna-green* is produced. According to E. Ehrmann, the composition is $\text{Cu}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 3\text{Cu}(\text{AsO}_2)_2$; and, according to H. Schiff and R. Sestini, $\text{Cu}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 3\text{Cu}_2\text{As}_2\text{O}_5$. S. Avery and H. T. Beans, T. B. Stillman, and E. W. Hilgard also found some free arsenic trioxide to be present. A. Vogel found that when copper pyroarsenite is heated with sulphurous acid, cuprous oxide is precipitated; while H. Baubigny and P. Rivals observed that iodine oxidizes it to copper hydroarsenate.

Various commercial preparations of Scheele's green, or Schweinfurt-green have been marketed—e.g. *parrot-green* is a mixture of copper arsenite and gelatinous starch; *Brunswick-green*, *Newwed-green*, *mountain-green*, *pickle-green*, and *mineral-green* are varieties prepared in different ways described by J. G. Gentele and others.

According to S. Avery, when Schweinfurt-green is repeatedly boiled with an excess of an aq. soln. of arsenic trioxide, **copper metarsenite**, $\text{Cu}(\text{AsO}_2)_2$, is formed as a grey, crystalline powder. The crystals are pseudomorphs after those of Schweinfurt-green. A. Stavenhagen treated a feebly acidic soln. of cupric chloride in alcohol with a soln. of arsenic trioxide in 50 per cent. alcohol. The pale green, amorphous precipitate when dried over sulphuric acid corresponded with **dihydrated copper metarsenite**, $\text{Cu}(\text{AsO}_2)_2 \cdot 2\text{H}_2\text{O}$. It loses one mol. of water at 100° , and the second at 200° —some arsenic trioxide is simultaneously sublimed.

When potassium or ammonium arsenite is added to an aq. soln. of silver nitrate, yellow **silver orthoarsenite**, Ag_3AsO_3 , or *normal silver arsenite*, is precipitated. Aq. soln. of arsenic trioxide were found by J. F. Simon⁶ to give a white turbidity which becomes yellow only in the presence of some alkali. The yellow product, said O. B. Kühn, is the normal arsenite; and if ammonia be the alkali used for the precipitation, some arsenite remains in soln. E. Filhol said that the normal arsenite is produced when an aq. soln. of arsenic trioxide is added to ammoniacal silver nitrate. J. R. Santos obtained this salt by mixing one mol of normal sodium arsenite with 3 mols of silver nitrate, and if one mol or two mols of silver nitrate be used, he said that *silver hydroarsenite* is formed. C. L. Bloxam found normal silver arsenite is precipitated by potassium metarsenite; and C. Reichard, by acidic potassium arsenite. J. A. Wanklyn obtained normal silver arsenite by the action of arsine (*q.v.*) on a soln. of silver nitrate. The preparation of this salt was also described by F. Wöhler, J. A. Wanklyn, and A. Stavenhagen. L. Meyer discussed the use of the reaction in quantitative analysis. A. Dexheimer prepared **colloidal silver arsenite** by mixing a soln. of a gram of sodium lysalbinat

in 10 grms. of water with a silver nitrate soln. until no more precipitate was formed. The precipitate is washed with water until the filtrate is free from silver. The pale yellowish-brown mass loses 6.71 per cent. of water at 100° in vacuo. It dissolves in water, forming a deep brownish-red soln. which has the usual characters of colloidal soln.

J. F. Simon said that silver arsenite is yellow or greenish-yellow, and that it becomes brown when exposed to light; and when dried at a gentle heat the colour remains yellow, but when heated more strongly it darkens, forming, according to A. Marcet, a brown basic salt with the evolution of a little arsenic trioxide. E. Filhol found that the salt melts at 140°–150° without loss of weight. When heated in air to redness, J. F. Simon, and A. Stavenhagen noted that arsenic trioxide sublimes, and the residue contains silver free from arsenic, and silver arsenate. According to A. Marcet, and J. Hume, silver arsenite is insoluble in water, but dissolves in acids; and when recently precipitated, it dissolves in aq. ammonia. J. R. Santos thought that silver arsenite is insoluble in aq. ammonia, but readily soluble in the presence of alkali nitrates. According to O. B. Kühn, if the ammoniacal soln. be boiled for a long time, replacing ammonia as it boils off, silver is deposited and an arsenate is formed. H. Reckleben and co-workers, and R. S. Bosworth said that the reaction: $(\text{NH}_4)_3\text{AsO}_3 + 2\text{AgNO}_3 \cdot \text{NH}_3 + \text{H}_2\text{O} = (\text{NH}_4)_3\text{AsO}_4 + 2\text{Ag} + 2\text{NH}_4\text{NO}_3$, is quantitative. O. B. Kühn found that silver arsenite is soluble in an excess of alkali or ammonium arsenite, and when the soln. is heated, silver is deposited. G. S. Whitby found that a litre of water at 20° dissolves 0.0115 gm. of the salt. G. C. Wittstein said that the salt is soluble in ammonium chloride soln. F. Bezold said that the arsenite is sparingly soluble in methyl acetate; and M. Hamers, insoluble in ethyl acetate, or in ethyl acetate sat. with water at 18°. A. Reynoso reported that silver arsenite is soluble in potash-lye, but F. Wöckler, O. B. Kühn, and A. Stavenhagen found that the salt is decomposed by this menstruum, forming soluble alkali arsenite and arsenate, and insoluble silver and silver arsenide. F. Wöhler said that some silver tetroxide is also formed. J. R. Santos found that silver arsenite is slightly soluble in acetic acid. O. B. Kühn, and A. Laugier and J. Pelletier observed that silver arsenite is oxidized to the arsenate by nitric acid.

According to L. Pasteur, and A. Girard, when a soln. of alkali pyroarsenite is added to one of silver nitrate, yellow **silver pyroarsenite**, $\text{Ag}_4\text{As}_2\text{O}_5$, is precipitated. L. Pasteur said that acid ammonium arsenite gives the same precipitate. Neither C. L. Bloxam, nor A. Stavenhagen could prepare this salt. According to C. Reichard, if alcohol be added to an ammoniacal soln. of silver arsenite, prismatic crystals of **silver tetramminopyroarsenite**, $\text{Ag}_4\text{As}_2\text{O}_5 \cdot 4\text{NH}_3$, are deposited. A. Girard reported **silver metatetrarsenite**, $\text{Ag}_6\text{As}_4\text{O}_9$, to be formed as a white precipitate by dropping a soln. of potassium pyroarsenite into one of silver nitrate containing much ammonium nitrate. The precipitate blackens in light; and dissolves in aq. ammonia, and potassium arsenite. A. Stavenhagen obtained only the normal arsenite when working under these conditions.

As indicated above, gold is precipitated when an aq. soln. of arsenic trioxide is added to a soln. of auric chloride. A. Stavenhagen reported **gold arsenite**, $\text{AuAsO}_3 \cdot \text{H}_2\text{O}$, to be formed when a soln. of auric chloride in 50 per cent. alcohol is treated with normal potassium arsenite. The pale brown solid slowly decomposes at 20°, rapidly at a higher temp., forming gold arsenide and gold. The arsenite is freely soluble in water, in an excess of the precipitating agents, in aq. ammonia, and in dil. acids.

A number of calcium arsenites have been reported. G. Tammann⁷ heated mixtures of calcium oxide and arsenic trioxide, and observed that a chemical reaction occurs near the m.p. of the trioxide. Some calcium orthoarsenite is formed at 465°, and there is then a strong exothermal reaction. L. G. Story and E. Anderson investigated the ternary system: $\text{As}_2\text{O}_3\text{--CaO--H}_2\text{O}$, at 0°, 25°, and 99°, by the method indicated in connection with the basic mercurous sulphates—

4. 31, 29. The results at 0° are illustrated by Fig. 21. Only two salts appear to be formed under these conditions—calcium hydroarsenite, $\text{Ca}(\text{OH})\text{AsO}_2$, or $\text{Ca}(\text{HAsO}_3)$, and calcium metarsenite, $\text{Ca}(\text{AsO}_2)_2$. A. Stavenhagen, and O. B. Kühn reported normal calcium arsenite, or **calcium orthoarsenite**, $\text{Ca}_3(\text{AsO}_3)_2$, to be formed by treating a boiling soln. of arsenic trioxide with an excess of lime-water; and, added O. B. Kühn, if the arsenic trioxide be in excess, no precipitate appears.

FIG. 21.—Equilibrium Curves for the System: $\text{As}_2\text{O}_3\text{-CaO-H}_2\text{O}$ at 0°.

calcium chloride with potassium orthoarsenite. The white powder is sparingly soluble in water, and freely soluble in acids. At a red-heat, it passes into calcium arsenate. J. Altwegg converted the arsenite to arsenate by heating it in a current of oxygen. G. F. Wach mentioned the formation of acid calcium arsenites by dissolving one of the other calcium arsenites in a conc. soln. of ammonium chloride, and then evaporating the filtrate; but the products were not further examined. Both the primary and secondary derivatives are known. The existence of **calcium hydroarsenite**, $\text{Ca}(\text{OH})\text{AsO}_2$, or CaHAsO_3 , was established by the observations of L. G. Story and E. Anderson, illustrated by Fig. 21. J. Perper reported **calcium dihydroarsenite**, $\text{Ca}(\text{H}_2\text{AsO}_3)_2 \cdot 5$ to $11\text{H}_2\text{O}$, to be produced when an ammoniacal soln. of arsenic trioxide is mixed with an excess of lime-water; or when an excess of ammonium metarsenite is mixed with lime-water. A soln. of calcium chloride can be used in place of lime-water. The proportion of water varied from 5 to $11\text{H}_2\text{O}$. The white powder, or gelatinous mass is fairly soluble in water, and insoluble in absolute alcohol. The aq. soln. has an alkaline reaction, and is decomposed by carbon dioxide.

J. F. Simon prepared **calcium pyroarsenite**, $\text{Ca}_2\text{As}_2\text{O}_5$, by mixing a soln. of arsenic trioxide with an excess of lime-water, or ammonium arsenite with a soln. of calcium sulphate or chloride. J. Stein regarded the product obtained by the former process as impure normal arsenite. A. Stavenhagen used this process, and added that when dried in hydrogen at 105° , the salt is anhydrous; J. F. Simon found that the air-dried product contained a mol. of water. The salt attracts carbon dioxide from the air. The white, heavy, coherent powder is decomposed at a red-heat, forming, according to J. F. Simon, calcium arsenate. The salt is sparingly soluble in water—100 parts of water dissolving 0.025–0.030 part of salt; if alkali chlorides be present, more pyroarsenite dissolves. The salt is readily soluble in dil. acids. According to C. Giesecke, G. C. Wittstein, and G. F. Wach, the salt is soluble in soln. of ammonium salts—chloride, sulphate, nitrate, arsenite, acetate, and succinate; according to G. C. Wittstein, the soln. in ammonium carbonate soon becomes turbid; and C. Giesecke found that alkali carbonates and phosphates precipitate the corresponding calcium salt. G. F. Wach said that the soln. of the salt in ammonium arsenite does not give a precipitate with alcohol, but yields an acid salt on evaporation. L. G. Story and E. Anderson established the existence of **calcium metarsenite**, $\text{Ca}(\text{AsO}_2)_2$. It was prepared by J. F. Simon, and A. Stavenhagen by mixing a boiling soln. of calcium chloride with a hot, sat. soln. of arsenic trioxide in aq. ammonia. The precipitate is washed with aq. ammonia. The white, amorphous powder contains half a mol. of water when dried in air, but it is anhydrous after being dried at 100° . It is readily dissolved by water. According to J. Stein, **calcium metatetrarsenite**, $\text{Ca}_3\text{As}_4\text{O}_9 \cdot n\text{H}_2\text{O}$, remains when the pyroarsenite is digested with a smaller quantity of a soln. of arsenic trioxide than is necessary to dissolve it; and, according to C. Reichard, it is formed by mixing conc. soln. of calcium chloride and potassium tetrarsenite, and washing the precipitate with alcohol. The white, air-dried powder loses a mol. of water at 100° ; it is fairly soluble in water.

A. Stavenhagen obtained what was regarded as impure **strontium orthoarsenite**, $\text{Sr}_3(\text{AsO}_3)_2$, as a white precipitate on mixing a soln. of strontium chloride with potassium orthoarsenite; the composition varied a little, and had rather more strontium than was required for the normal salt. He also made **strontium pyroarsenite**, $\text{Sr}_2\text{As}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, by adding an aq. soln. of arsenic trioxide to an alcoholic soln. of strontium chloride, and washing the precipitate with alcohol. If ammonia be present, the precipitate has a variable composition. It retains 2 mols. of water when dried at 100° . The salt is readily soluble in water, and acids. J. Stein reported **strontium metarsenite**, $\text{Sr}(\text{AsO}_2)_2 \cdot 4\text{H}_2\text{O}$, to be precipitated when ammonium arsenite is added to a soln. of a strontium salt; more of the precipitate is formed if alcohol be added to the soln. The evaporation of the aq. soln. yields a crystalline powder which retains 4 mols. of water when dried over sulphuric acid. It loses a mol. of water at 100° , and at a higher temp. it is decomposed into arsenate and arsenic. A. Stavenhagen could not prepare the salt. C. Reichard reported **strontium tetraarsenite**, $\text{Sr}_3\text{As}_4\text{O}_9$, to be formed when potassium tetraarsenite is added to a conc. soln. of strontium nitrate. The salt is washed with alcohol. The white powder is fairly soluble in water; it is only slightly affected by potash-lye, and aq. ammonia; and it is decomposed when heated, forming an arsenate and arsenic.

L. G. Story and E. Anderson found, in their study of the ternary system: As_2O_3 - BaO - H_2O at 25° and 50° , that only two salts are formed, barium metarsenite, and barium hexarsenite, Fig. 22. A. Stavenhagen prepared **barium orthoarsenite**, $\text{Ba}_3(\text{AsO}_3)_2$, by the method employed for the strontium salt. The white precipitate was washed with cold water. The salt is sparingly soluble in cold water, but freely soluble in hot water and in dil. acids. When digested with a soln. of potassium sulphate, it forms potassium orthoarsenite. As just indicated, L. G. Story and E. Anderson obtained **barium hydroarsenite**, $\text{Ba}(\text{OH})\text{AsO}_2 \cdot 2\text{H}_2\text{O}$, or $\text{Ba}(\text{HAsO}_3) \cdot 2\text{H}_2\text{O}$. The conditions of equilibrium are indicated in Fig. 22.

J. Perper reported **barium dihydroarsenite**, $\text{Ba}(\text{H}_2\text{AsO}_3)_2 \cdot 34\text{H}_2\text{O}$, to be formed by adding an excess of baryta-water to an aq. soln. of arsenic trioxide; and by treating an ammoniacal soln. of arsenic trioxide with barium chloride in excess. The white powder is fairly soluble in cold water, and more so in hot water. It is insoluble in alcohol. It loses water when exposed to air, and is decomposed by the carbon dioxide in the air. The aq. soln. reacts feebly alkaline. When dried at 100° , the white powder is insoluble in water; when dried at 150° , it is yellow; and at a higher temp., the colour is darker.

J. Stein, and A. Stavenhagen obtained **barium pyroarsenite**, $\text{Ba}_2\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, by the action of an excess of conc. baryta-water on a sat. aq. soln. of arsenic trioxide; and E. Filhol, by treating a soln. of barium chloride with potassium pyroarsenite. J. Perper obtained the dihydroarsenite by both these processes. J. Stein said that when the white product is dried over sulphuric acid it retains 4 mols. of water; and A. Stavenhagen, 8 mols.; when dried at 100° , it retains 2 mols. of water. At a higher temp., it forms arsenate and arsenic. It is slightly soluble in water, and in dil. alcohol. C. L. Bloxam reported **barium metarsenite**, $\text{Ba}(\text{AsO}_2)_2 \cdot 2\text{H}_2\text{O}$, to be formed by precipitation from a soln. of barium chloride and ammonium arsenite—A. Stavenhagen could not prepare the salt in this way, and J. Perper obtained the dihydroarsenite by this process. A. Stavenhagen precipitated barium metarsenite, $\text{Ba}(\text{AsO}_2)_2$, from a warm soln. of barium chloride by an ammoniacal soln. of arsenic trioxide, washed the product with water, and dried it at 100° . E. Filhol mixed soln. of potassium metarsenite and barium chloride and obtained this salt as a gelatinous precipitate, which became pulverulent when boiled with its mother-liquid.

FIG. 22.—Equilibrium Curves for the System: As_2O_3 - BaO - H_2O at 25° .

C. Reichard obtained **barium tetrarsenite**, BaAs_4O_7 , by the method employed for the strontium salt; and L. G. Story and E. Anderson's diagram, Fig. 22, shows the conditions of equilibrium of **barium hexarsenite**, $\text{Ba}_2\text{As}_6\text{O}_{11}\cdot 4\text{H}_2\text{O}$.

B. Bleyer and B. Müller found it impossible to prepare definite **beryllium arsenites**. What were obtained can be regarded only as adsorption products. They examined the behaviour of the hydrogel of beryllium hydroxide, with aq. soln. of arsenic trioxide, and found that only very small amounts of the arsenic trioxide were adsorbed, due probably to the rapidity with which the precipitated hydroxide loses its colloidal character. With beryllium hydroxide precipitated by ammonia and ammonium chloride in the arsenic soln., larger quantities of the trioxide were adsorbed at the ordinary temp., and these were adsorbed in accordance with the adsorption law. At the temp. of boiling water the quantities adsorbed were less than at the ordinary temp., and followed Henry's law, that is, the ratio between the quantity of arsenic trioxide absorbed and that remaining in the soln. was constant.

G. Tammann observed that when a mixture of magnesium oxide and arsenic trioxide is heated, some magnesium metarsenite is formed at the m.p. of the trioxide, and at a higher temp., a basic arsenite is formed, **magnesium trioxyorthoarsenite**, $3\text{MgO}\cdot\text{Mg}_3(\text{AsO}_3)_3$. L. G. Story and E. Anderson observed no sign of the formation of a magnesium arsenite in their study of the ternary system: $\text{As}_2\text{O}_3\text{--MgO--H}_2\text{O}$ at 25° . The magnesium hydroxide adsorbs the arsenic trioxide; a similar phenomenon was observed by E. Filhol, and on this property magnesia, like ferric hydroxide, has been recommended as an antidote for poisoning. J. F. Simon said an arsenite is formed when the vap. of arsenic trioxide is passed over red-hot magnesia. According to A. Stavenhagen, when a soln. of magnesium chloride in 50 per cent. alcohol is treated with a soln. of potassium orthoarsenite just neutralized with acetic acid, white pulverulent **magnesium orthoarsenite**, $\text{Mg}_3(\text{AsO}_3)_2\cdot n\text{H}_2\text{O}$, is precipitated. If the alkali arsenite be not neutral, the precipitate will be contaminated with magnesium hydroxide. C. Reichard added a soln. of potassium tetrarsenite gradually to a soln. of magnesium sulphate, and obtained the same product; and, added E. Filhol, if the soln. be boiled, the precipitate will not have a constant composition. J. Stein reported the formation of this salt by adding a soln. of ammonium arsenite in aq. ammonia to a soln. of magnesium sulphate mixed with so much ammonium chloride that it gives no precipitate with aq. ammonia. A. Stavenhagen found that the precipitate is always contaminated with magnesium hydroxide, and J. Perper used this process for making the tetrarsenite—*vide infra*. C. L. Bloxam said that J. Stein's salt has the composition $\text{Mg}_2\text{As}_2\text{O}_5\cdot 2\text{H}_2\text{O}$ when dried at 100° ; $\text{Mg}_2\text{As}_2\text{O}_5\cdot \text{H}_2\text{O}$, *i.e.* MgHAsO_3 , when dried at 205° ; and at a higher temp., $\text{Mg}_2\text{As}_2\text{O}_5$. J. F. Simon found that at a red-heat, arsenate and arsenic are formed. C. Reichard showed that the salt is freely soluble in boiling water and in dil. acid; while potash-lye, and aq. ammonia have very little action. J. Stein observed that the salt is soluble in a soln. of ammonium chloride. A. Stavenhagen could not make **magnesium pyroarsenite**, $\text{Mg}_2\text{As}_2\text{O}_5\cdot 4\text{H}_2\text{O}$, by C. L. Bloxam's method just indicated; but he obtained it as a white, hygroscopic, amorphous powder from the calculated quantities of magnesium sulphate and barium pyroarsenite. The salt is freely soluble in water and acids. J. Perper reported **magnesium metatetrarsenite**, $\text{Mg}_3\text{As}_4\text{O}_9\cdot n\text{H}_2\text{O}$, to be formed by treating an aq. soln. of arsenic trioxide with magnesia mixture; or by using a soln. of magnesium sulphate in place of magnesia mixture.

C. L. Bloxam prepared a salt regarded as **zinc orthoarsenite**, $\text{Zn}_3(\text{AsO}_3)_2$, by mixing a soln. of zinc sulphate with much ammonium chloride and ammonia, and adding it to an aq. soln. of arsenic trioxide; C. Reichard obtained the same salt by adding sodium metarsenite or acid potassium arsenite to an excess of a soln. of zinc sulphate; and by A. Stavenhagen, by adding potassium orthoarsenite to a soln. of zinc chloride in 50 per cent. alcohol. S. Avery obtained an impure

product by adding a butyric acid soln. of zinc butyrate to an aq. soln. of arsenic trioxide. The white, crystalline powder is decomposed by heat. G. Tammann found that when a mixture of zinc oxide and arsenic trioxide is heated to 250° , some zinc metarsenite is formed; and at about 420° , zinc orthoarsenite, $Zn_3(AsO_3)_3$, is formed; and at 535° , the basic arsenite, possibly **zinc trioxyorthoarsenite**, $3ZnO \cdot Zn_2(AsO_3)_3$, is formed; and at 535° , the basic arsenite, possibly zinc trioxyorthoarsenite, $3ZnO \cdot Zn_2(AsO_3)_3$, is formed. A. Stavenhagen prepared **cadmium orthoarsenite**, $Cd_3(AsO_3)_2$, in a similar manner. S. Avery prepared **zinc metarsenite**, $Zn(AsO_2)_2$, by neutralizing with sulphuric acid and phenolphthalein a soln. of arsenic trioxide in soda-lye, and added the liquid to a hot soln. of zinc sulphate. A similar product was obtained by mixing a soln. of zinc acetate in dil. acetic acid with an aq. soln. of arsenic trioxide. The product is a white crystalline powder. C. Reichard reported **cadmium pyroarsenite**, $Cd_2As_2O_5$, to be formed by adding acid potassium arsenite to a soln. of cadmium sulphate; dissolving the precipitate, dried at 120° , in hydrochloric acid, and reprecipitating with sodium metarsenite. The white powder is decomposed by heat; it is soluble in acids; and not changed by alkali-lye. If sodium orthoarsenite is added to a soln. of a cadmium salt, **cadmium diarsenite**, $3CdO \cdot Cd_2As_2O_5 \cdot 2H_2O$, is precipitated as a gelatinous mass which dries at ordinary temp. to a hard mass. The water can be expelled by heat; and at a higher temp., the compound is decomposed. It absorbs carbon dioxide from air; it is freely soluble in dil. or conc. sulphuric acid; it is not attacked by potassium hydroxide, barium hydroxide or dioxide, or alkali carbonates; and it is insoluble in a soln. of potassium cyanide. M. Henglein and W. Meigen described a grass-green, crystalline mineral from Guchab, Otavi Valley, which they named **barthite**. The analysis corresponds with **copper zinc dihydroxyhexametarsenite**, $3Zn(AsO_3)_2 \cdot Cu(OH)_2 \cdot H_2O$. The crystals are optically biaxial, and probably monoclinic. E. S. Larsen found that the optic axial angle $2V=c. 90^{\circ}$; the optical character is positive. The core has the indices of refraction $\alpha=1.770$, $\gamma=1.783$; and the outer portion, $\alpha=1.780$, $\beta=1.795$, and $\gamma=1.815$. The outer zone is feebly pleochroic. The sp. gr. is 4.19 at 14° ; and the hardness 3.

J. J. Berzelius observed that a mercurous arsenite is formed by digesting mercury with an aq. soln. of arsenic trioxide; and J. F. Simon obtained a white precipitate of mercury arsenite by treating mercurous nitrate with a soln. of arsenic trioxide or potassium arsenite. These salts were not analyzed. A. Stavenhagen obtained a white precipitate of **mercurous orthoarsenite**, Hg_3AsO_3 , by adding a soln. of arsenic trioxide in 50 per cent. alcohol to an aq. soln. of mercurous nitrate, acidified with a few drops of nitric acid, and mixed with alcohol until it just begins to appear turbid. The product is dried at 100° . C. Reichard obtained a pale yellow precipitate of this salt by adding a soln. of sodium orthoarsenite to one of mercurous nitrate. This salt becomes reddish-brown when exposed to light and air; it is sparingly soluble in water; and is not blackened by boiling water; although it is gradually decomposed by water with the separation of mercury. The salt is slowly reduced by ammonia. The salt is decomposed by potassium and barium oxides, barium dioxide, and by sodium carbonate and hydrocarbonate. It is easily soluble in acids—dil. sulphuric acid slowly forms a basic sulphate; and hydrochloric acid, a brown precipitate. C. Reichard obtained a yellowish precipitate of **mercurous metarsenite**, $HgAsO_2$, by gradually adding a soln. of acid potassium arsenite to mercurous nitrate, and drying the product at 125° . An excess of the alkali arsenite decomposes the salt with the separation of mercurous oxide and mercury. The salt is also decomposed by potash-lye and aq. ammonia.

According to J. J. Berzelius, a mercuric arsenite is formed when an aq. soln. of arsenic trioxide is added to one of mercuric nitrate. A. Dexheimer could not prepare *colloidal mercuric arsenite* on account of its ready decomposition into mercury, etc. J. F. Simon obtained a white unstable precipitate by adding potassium arsenite to a soln. of mercurous nitrate. A. Stavenhagen reported white **mercuric orthoarsenite**, $Hg_3(AsO_3)_2$, by using a soln. of mercuric chloride in place of mercurous

nitrate as described in his process for preparing mercurous orthoarsenite. C. Reichard obtained the salt by a similar modification of his mode of preparing the mercurous salt. The colour darkens when the salt is exposed to light, or heat; and at 150° , the arsenic trioxide sublimes. The salt is sparingly soluble in water, and it is slowly reduced to mercurous hydroxide and mercury in the cold, rapidly when boiled. The salt is also reduced by aq. ammonia, potassium hydroxide, and by barium hydroxide, and dioxide. It is easily soluble in acids—with sulphuric acid, a basic sulphate is formed. An excess of a soln. of sodium arsenite reduces it to mercury. G. Dessner obtained complex salts, **mercurous nitratoarsenite**, $2\text{Hg}_3\text{AsO}_3 \cdot \text{HgNO}_3$; and **mercurous sulphatoarsenite**, $2\text{Hg}_3\text{AsO}_3 \cdot \text{Hg}_2\text{SO}_4$. C. Reichard obtained **mercuric pyroarsenite**, HgAs_2O_5 , by treating a mercuric salt with a soln. of acid potassium arsenite, and drying the product at 125° . G. Dessner could not verify this, he obtained a mixture of arsenite and arsenate. C. Reichard said that the yellowish-white pyroarsenite is darkened by exposing the salt to light. It is not decomposed by water, but is so by aq. ammonia, potassium hydroxide or carbonate, and with an excess of a soln. of alkali arsenite. It is decomposed when heated. The salt dissolves in acids without decomposition. According to C. Reichard, **mercuric diarsenite**, $\text{Hg}_5\text{As}_2\text{O}_8$, is formed by treating sodium metarsenite with an excess of a conc. soln. of mercuric chloride. The white precipitate is partly decomposed by light, and by heat. The salt is decomposed by water, aq. ammonia, alkali hydroxide and carbonate, and by a soln. of sodium metarsenite. It is sparingly soluble in sulphuric and hydrochloric acids.

C. Reichard prepared **aluminium arsenite**, AlAsO_3 , by adding potassium tetraarsenite to a cold sat. soln. of aluminium sulphate. The gelatinous precipitate is dried. It decomposes when heated; is slightly soluble in boiling water; and easily soluble in acids, and soda-lye. E. Thorey evaporated at a gentle heat the filtered soln. from a mixture of barium arsenite and aluminium sulphate, and finally over sulphuric acid. Rhombic pyramids of aluminium arsenite were formed. A. Stavenhagen prepared **thallous orthoarsenite**, Tl_3AsO_3 , as a yellowish-red precipitate by adding an aq. soln. of arsenic trioxide to the liquid prepared by boiling thallous sulphate with alkali-lye, diluting with water, and again boiling with water until all dissolves. It is also formed when a soln. of thallous sulphate is boiled with one of potassium orthoarsenite, and potash-lye gradually added; or when a soln. of thallous chloride in alkali-lye is treated with potassium orthoarsenite. The crystals resemble those of potassium dichromate; they are sparingly soluble in water, and alcohol; but freely soluble in acids—particularly sulphuric acid.

F. Frerichs and F. Smith prepared **didymium hydroarsenite**, $\text{Di}(\text{HASO}_3)_3$, by boiling didymium hydroxide with an aq. soln. of arsenic trioxide. It is a white, granular powder which is insoluble in water. They prepared **lanthanum hydroarsenite**, $\text{La}(\text{HASO}_3)_3$, in an analogous manner. P. T. Cleve doubted the existence of these salts. G. Tammann heated mixtures of cerium dioxide and arsenic trioxide and found that oxidation occurs; and at 600° the mixture contains CeO_2 , Ce_2O_3 , As_2O_3 , and As_2O_5 .

S. J. Thugutt reported **arsenito-sodalite**, $6\text{Na}_2\text{Al}_2\text{Si}_2\text{O}_4 \cdot 12\text{NaAlSiO}_4 \cdot \text{Na}_2\text{As}_2\text{O}_6 \cdot 6\text{H}_2\text{O}$, by boiling in a sealed tube, at 207° – 208° , for 54 hrs., a mixture of 6 grms. china-clay, 6.5 grms. of arsenic trioxide, 12 grms. of sodium hydroxide, and 45 c.c. of water—*vide* the *arsenitosilicates*, 6. 40, 47. C. Reichard mixed a nearly neutral soln. of titanyl sulphate with an excess of potassium tetraarsenite and obtained a gelatinous precipitate of **titanyl tetraarsenite**, $(\text{TiO})_5\text{As}_4\text{O}_{11}$, which gradually crystallized. It is decomposed by heat; acids dissolve it without decomposition; and it is scarcely attacked by aq. ammonia or potassium hydroxide. E. Wedekind and H. Wilke observed that the hydrogel of zirconium dioxide forms true adsorption complexes with arsenic trioxide, but there is no evidence of the formation of a *zirconium arsenite*.

According to C. Reichard, **stannous orthoarsenite**, $\text{Sn}_3(\text{AsO}_3)_2 \cdot 2\text{H}_2\text{O}$, is formed

as a white precipitate when acid potassium arsenite is poured into a soln. of stannous chloride; by the action of a warm soln. of sodium arsenite on stannous hydroxide—some arsenical tin, arsine, and sodium stannate are formed at the same time; and by the action of sodium metarsenite on a soln. of stannous chloride. A. Stavenhagen obtained it by adding a soln. of arsenic trioxide to a soln. of potassium chlorostannite and potassium chloride. J. J. Berzelius first obtained this salt, but did not analyze it. The white, amorphous powder is decomposed by heat; it is sparingly soluble in water, but soluble in dil. acids and alkali-lye, and in an excess of arsenious acid. A. Stavenhagen obtained **stannic orthoarsenite**, $\text{Sn}_3(\text{AsO}_3)_4 \cdot 5\frac{1}{2}\text{H}_2\text{O}$, by adding an aq. soln. of arsenic trioxide to an aq. soln. of stannic and sodium chlorides. According to C. Reichard, stannic hydroxide is not changed by treatment with a warm soln. of arsenic trioxide in soda-lye. He also obtained **stannic tetroxy-orthoarsenite**, $2\text{SnO}_2 \cdot \text{Sn}_3(\text{AsO}_3)_4$, by mixing aq. soln. of stannic chloride and potassium arsenite. He also made **stannic diarsenite**, $\text{Sn}_7\text{As}_2\text{O}_{17}$, by treating an excess of a soln. of stannic chloride with sodium arsenite. The white precipitate has a yellow colour when dried. It is decomposed by heat.

G. Tammann heated mixtures of lead oxide and arsenic trioxide, and found that at the m.p., a yellow glass is produced; the heating curve shows an acceleration at 590° . J. J. Berzelius, and A. Reynoso examined the white precipitates produced when lead salt soln. are treated with an aq. soln. of arsenic trioxide, or of a soluble arsenite. Plumbiferous iron pyrites was found by E. Masing to yield crystals of **lead arsenite** when immersed in a soln. of arsenic trichloride. L. G. Story and

E. Anderson studied the conditions of equilibrium in the ternary system: $\text{As}_2\text{O}_3\text{-PbO-H}_2\text{O}$ at 25° . The results are summarized in Fig. 23. Only one compound was produced, namely, lead meta-arsenite. B. Ormont prepared lead arsenite by an electrolytic process, using as catholyte a 15 per cent. soln. of sodium hydroxide or other sodium salt, or 30 per cent. potassium hydroxide soln., and a cathode of nickel, and as the anolyte, a soln. of an alkali arsenite neutralized towards phenolphthalein by means of acetic acid, and an anode of lead. The cathode space was separated by a diaphragm of vegetable parchment. A current yield of 97 per cent. was obtained and the energy yield amounted on the average to 1 kg. per kilowatt-hour. F. Herrmann recommended a 2 per cent. soln. of lead arsenite for killing insects, since, at this concentration, the liquid is harmless to man and domestic animals. A. Dexheimer made **colloidal lead arsenite**, by the following process:

FIG. 23.—Equilibrium Curves of the System: $\text{As}_2\text{O}_3\text{-PbO-H}_2\text{O}$ at 25° .

A soln. of 2 grms. of sodium lysalbinat in 20 c.c. of water is mixed with a soln. of lead acetate so long as a precipitate forms. The precipitate is washed with hot water. It dissolves in dil. sodium hydroxide, mixed with sodium dihydroarsenite. The turbid liquid is allowed to stand for some hours, filtered, and dialyzed until the exterior liquid is free from arsenic. The filtrate is concentrated on a water-bath, mixed with absolute alcohol and ether, filtered, and the yellow, horny mass dried over sulphuric acid *in vacuo*. The pale yellow colloid is readily soluble in water; and the soln. exhibits the characteristic reactions of sol colloids.

O. B. Kühn prepared **lead orthoarsenite**, $\text{Pb}_3(\text{AsO}_3)_2$, by mixing a soln. of basic lead acetate with a boiling aq. soln. of arsenic trioxide; C. Reichard, and E. Filhol used acid potassium arsenite and basic lead acetate; C. Reichard, soln. of lead nitrate and sodium metarsenite; and A. Streng, soln. of an alkali plumbite, and alkali arsenite. G. Dessner also prepared this salt. A. Stavenhagen added that the alkali cannot be all removed by washing. The white powder slowly darkens when exposed to light. When heated, its colour darkens, and when incipient fusion occurs the colour is reddish-brown; and when cold, greenish-yellow; the salt

decomposes at a red-heat. It is only slightly soluble in water; boiling water extracts some arsenic trioxide from the salt; it dissolves very sparingly in potash-lye, but is more soluble in soda-lye; and it is readily soluble in nitric and acetic acids. G. C. Wittstein said lead arsenite is insoluble in aq. ammonia and ammonium salts, but the orthoarsenite was found by C. Reichard to expel ammonia from ammonium salts even in the cold. A. Stavenhagen reported **monohydrated lead orthoarsenite**, $Pb_3(AsO_3)_2 \cdot H_2O$, to be formed by drying in air the precipitate from a mixture of potassium orthoarsenite and a dil. soln. of lead nitrate. According to J. J. Berzelius, **lead pyroarsenite**, $Pb_2As_2O_5$, is formed when basic lead acetate is mixed with an ammoniacal soln. of arsenic trioxide; C. Reichard used lead acetate and potassium tetrarsenite; E. Filhol, and A. Stavenhagen, a normal lead salt and potassium pyroarsenite; and C. L. Bloxam, normal lead acetate and an ammoniacal soln. of arsenic trioxide. The precipitate was dried at 100° .

J. F. Simon said that the vapour of arsenic trioxide is rapidly absorbed when it is passed over heated lead oxide; the oxide fuses, and becomes red-hot; the mass solidifies to a yellow enamel or glass on cooling. It is not decomposed at a bright red-heat. No reduction to arsenic or lead occurs unless one of the oxides is in excess; when the proper proportions are used, J. F. Simon said that lead pyroarsenite is formed, but A. Stavenhagen said that the product is really a mixture of lead oxide, and arsenic tri- and penta-oxides.

When the white, pulverulent lead pyroarsenite is heated it loses water, and melts to a yellow glass. It drives ammonia from ammonium salts even in the cold, and forms a basic lead salt. A. Reynoso found the salt is soluble in soda-lye, and insoluble in potash-lye. A. Stavenhagen obtained **lead metarsenite**, $Pb(AsO_2)_2$, by mixing normal lead acetate with a boiling ammoniacal soln. of arsenic trioxide. A. Schafarik recommended using dil. soln.; E. Filhol worked with potassium metarsenite and a normal lead salt; and O. B. Kühn, normal lead acetate and a boiling, sat., aq. soln. of arsenic trioxide. The white crystalline powder, said A. Schafarik, has a sp. gr. of 5.85 at 23° . J. J. Berzelius said that it melts when heated, and decomposes; it is more triboelectric than sulphur. The salt is sparingly soluble in water. G. Dessner obtained a mixture of lead meta-arsenite with basic lead nitrate from a mixture of an excess of an aq. soln. of arsenic trioxide and lead nitrate— $Pb(AsO_2)_2 + 3PbO \cdot Pb(NO_3)_2$. The precipitates with lead chloride, bromide, or iodide were likewise contaminated with basic salts. C. L. Bloxam reported **lead metatetrarsenite**, $Pb_3As_4O_9 \cdot 3H_2O$, or $Pb_3(AsO_3)_2 \cdot 2H_3AsO_3$, to be formed by mixing soln. of lead nitrate and potassium tetrarsenite, or sodium hexarsenite; but A. Stavenhagen could not verify this. G. Aminoff described a **lead chloroarsenite**, $Pb_5Cl(AsO_3)_3$, or $3Pb_3(AsO_3)_2 \cdot PbCl_2$, occurring as a dark grey or black mineral which he named *finnemanite*—after K. J. Finneman. The prismatic crystals belong to the hexagonal system, and have the axial ratio: $a : c = 1 : 0.6880$. The sp. gr. is 7.08–7.265; the hardness 2–3; and the indices of refraction for light of wave-length λ :

λ	.	.	486	527	540	589	656	687
ω	.	.	2.3634	2.3333	2.3242	2.2949	2.2725	2.2651
ϵ	.	.	2.3449	2.3170	2.3077	2.2847	2.2634	2.2594

J. J. Berzelius⁸ reported the formation of a soln. of *antimony arsenite* to be formed when an aq. soln. of arsenic acid is digested with antimony; and the soln. diluted with water. It is also obtained as a vitreous mass on heating a mixture of arsenic and antimonic acid. A. Stavenhagen reported **bismuth arsenite**, possibly $BiAsO_3 \cdot 5H_2O$, to be precipitated when an aq. soln. of arsenic trioxide is added to one of bismuth and sodium chlorides. C. Reichard found that an alkaline soln. of sodium arsenite does not change bismuth trioxide, or bismuthyl chloride, and it reduces bismuth pentoxide to bismuthyl hydroxide. L. Vanino and F. Hartl reported bismuth arsenite to be formed by the action of an aq. soln. of arsenic trioxide on a soln. of bismuth nitrate and mannite. R. Schneider said that the salt is soluble in nitric acid; and L. Jassoy, that it is not decomposed when boiled for a short time with a soln. of sodium hydroxide or carbonate.

According to G. Bonnet,⁹ a soln. of chromic chloride does not give a precipitate with an aq. or an ammoniacal soln. of ammonium arsenite. R. H. C. Neville reported that **chromic arsenite**, CrAsO_3 , is formed when a conc. soln. of chromic acid and arsenic trioxide is heated for a long time; but A. Stavenhagen could not verify this. C. Reichard found that dil. soln. of chromic sulphate and potassium tetrarsenite can be mixed and warmed without perceptible change, but when conc. soln. are heated to 100° for some time a dark green mixture of chromic arsenite and arsenic trioxide is precipitated; to remove the arsenic trioxide, the mixture is dissolved in hydrochloric acid, and reprecipitated by ammonia. The dark green arsenite decomposes when heated. It dissolves in dil. acids and in alkali-lye; it is insoluble in aq. ammonia. E. Weidenbach added hydrochloric acid of sp. gr. 1.12 to a soln. of a molybdate and alkali arsenite, and obtained white microscopic needles of **hydrodiarsenitodimolybdic acid**, $\text{H}_6[\text{As}_2\text{O}_4(\text{MoO}_4)_2]\cdot 3\text{H}_2\text{O}$. The neutralization curve shows that the acid is tribasic; and the equivalent conductivity of one-sixth of a mol in v litres of water:

v . . .	32	64	128	256	512	1024
λ . . .	51.7	55.8	59.3	65.1	71.2	83.9 mhos

shows that the acid is but feebly ionized, and that it is rather stronger than arsenic acid. F. Ephraim and H. Feidel obtained **sodium diarsenitodimolybdate**, $\text{Na}_2\text{H}_4[\text{As}_2\text{O}_4(\text{MoO}_4)_2]\cdot 4\text{H}_2\text{O}$, in rectangular crystals of sp. gr. 3.43 at 16° , crystallized ammonium salts could not be made, but they prepared octahedral crystals of **copper ammonium octahydrodiarsenitodimolybdate**, $\text{Cu}(\text{NH}_4)_2\text{H}_8[\text{As}_2\text{O}_4(\text{MoO}_4)_2]_2$, of sp. gr. 2.50 at 16° ; and **copper ammonium hexahydrotrisdiarsenitodimolybdate**, $\text{Cu}(\text{NH}_4)_4\text{H}_6[\text{As}_2\text{O}_4(\text{MoO}_4)_2]_3\cdot 10\text{H}_2\text{O}$, in hexagonal prisms of sp. gr. 3.17 at 16° ; and **ammonium barium icosi-hydroquinusdiarsenitodimolybdate**, $\text{Ba}_2(\text{NH}_4)_6\text{H}_{20}[\text{As}_2\text{O}_4(\text{MoO}_4)_2]_5\cdot 40\text{H}_2\text{O}$.

O. W. Gibbs found that **arsenitomolybdates** are obtained by boiling arsenic trioxide with a conc. soln. of an acid molybdate. The general formula is $x\text{R}_2\text{O}\cdot y\text{As}_2\text{O}_3\cdot z\text{MoO}_3$, where y is generally greater than unity. He thus prepared **ammonium arsenitomolybdate**, $3(\text{NH}_4)_2\text{O}\cdot 5\text{As}_2\text{O}_3\cdot 12\text{MoO}_3\cdot 24\text{H}_2\text{O}$, in colourless crystals; **copper arsenitomolybdate**, $2\text{CuO}\cdot 3\text{As}_2\text{O}_3\cdot 6\text{MoO}_3\cdot 6\text{H}_2\text{O}$, in green octahedral crystals; **zinc arsenitomolybdate**, $2\text{ZnO}\cdot 3\text{As}_2\text{O}_3\cdot 6\text{MoO}_3\cdot 6\text{H}_2\text{O}$, in colourless octahedral crystals; and **manganous arsenitomolybdate**, $2\text{MnO}\cdot 3\text{As}_2\text{O}_3\cdot 6\text{MoO}_3\cdot 6\text{H}_2\text{O}$, in pale, orange octahedral crystals; and **nickel arsenitomolybdate**, $2\text{NiO}\cdot 3\text{As}_2\text{O}_3\cdot 6\text{MoO}_3\cdot 6\text{H}_2\text{O}$. F. Ephraim and H. Feidel prepared **sodium hexahydrodiarsenitetetramolybdate**, $\text{Na}_4\text{H}_6[\text{As}_2\text{O}_4(\text{MoO}_4)_4]\cdot 10\text{H}_2\text{O}$; and O. W. Gibbs obtained **barium arsenitomolybdate**, $3\text{BaO}\cdot 2\text{As}_2\text{O}_3\cdot 8\text{MoO}_3\cdot 13\text{H}_2\text{O}$, in very pale green crystals. F. Ephraim and H. Feidel mixed a soln. of 3 mols of potassium carbonate, 6 mols of molybdic acid, and one mol of arsenic trioxide; a crop of crystals of potassium molybdate was followed by a crop of white crystals of **potassium diarsenitopentamolybdate**, $3\text{K}_2\text{O}\cdot \text{As}_2\text{O}_3\cdot 5\text{MoO}_3\cdot 3\text{H}_2\text{O}$. E. Weidenbach prepared **potassium dihydroarsenitopentamolybdate**, $\text{K}_4\text{H}_2[\text{AsO}(\text{MoO}_4)_5]\cdot 7\text{H}_2\text{O}$; and F. Ephraim and H. Feidel made white crystals of **potassium diarsenitooctomolybdate**, $3\text{K}_2\text{O}\cdot \text{As}_2\text{O}_3\cdot 8\text{MoO}_3\cdot 18\text{H}_2\text{O}$, of sp. gr. 3.15 at 16° . E. Weidenbach reported the formation of **silver tetrahydrodiarsenitotetradecamolybdate**, $\text{Ag}_{12}\text{H}_4[\text{As}_2\text{O}_2(\text{Mo}_2\text{O}_7)_9]\cdot 36\text{H}_2\text{O}$; of **barium hexahydrotetraarsenitetracontimolybdate**, $\text{Ba}_{12}\text{H}_6[\text{As}_4\text{O}_4(\text{Mo}_2\text{O}_7)_{17}]\cdot 58\text{H}_2\text{O}$; as well as of some *guanidine arsenitomolybdates*. A series of **alkyl molybdatoarsenites** has been prepared by A. Miolati, and A. Rosenheim and R. Bilecki—e.g. $\text{R}_2[\text{As}(\text{CH}_3)(\text{Mo}_2\text{O}_7)_3]$; $\text{R}_2[\text{HAS}(\text{C}_6\text{H}_5)_2(\text{Mo}_2\text{O}_7)_2]$; etc. O. W. Gibbs reported **platinous tetramminoarsenitomolybdate**, $2\text{Pt}(\text{NH}_3)_4\text{O}\cdot 2(\text{PtO}\cdot \text{As}_2\text{O}_3)\cdot 12\text{MoO}_3\cdot \text{As}_2\text{O}_3\cdot 27\text{H}_2\text{O}$, by digesting platinous tetramminochloride with an arsenitomolybdate or an acid and molybdate. O. W. Gibbs also obtained a **platinum arsenitophosphatomolybdate** by the action of a phosphatoarsenitomolybdate on platinous tetramminochloride, or ammonium platinous arsenite with platinous chloride.

O. W. Gibbs also prepared a series of **arsenitotungstates** by a process similar to that employed for the arsenitomolybdates. The general formula is $xR_2O.yAs_2O_3.zWO_3$, where y is usually greater than unity. He thus prepared **ammonium arsenitotungstate**, $7(NH_4)_2O.2As_2O_3.18WO_3.18H_2O$, in pale yellow, almost colourless, crystals; **sodium arsenitotungstate**, $9Na_2O.8As_2O_3.16WO_3.55H_2O$, in colourless, prismatic crystals; **barium arsenitotungstate**, $4BaO.As_2O_3.9WO_3.2H_2O$, as a white, crystalline powder. O. W. Gibbs also made pale yellow **mercurous arsenitotungstate** by adding mercurous nitrate to a soln. of the sodium salt. O. W. Gibbs reported **platinous tetramminoarsenitotungstate**, $6Pt(NH_3)_4O.3(2PtO.As_2O_3).22WO_3.3As_2O_3.40H_2O$, by digesting ammonium platinous arsenite with an acid molybdate or platinous tetramminochloride with an arsenitotungstate. Likewise, by boiling a soln. of potassium platinous chloroarsenite with an acid tungstate, he obtained **platinous tetramminohexachloroarsenitotungstate**, $12Pt(NH_3)_4O.3(2PtCl_2As_2O_3).24WO_3.As_2O_3.6H_2O$. He also reported a series of **arsenitophosphatotungstates** to be formed by boiling arsenic trioxide with a phosphatotungstate, or by adding an orthophosphate to an arsenitotungstate. He thus obtained **potassium arsenitotetraphosphatotungstate**, $7K_2O.As_2O_3.4P_2O_5.60WO_3.55H_2O$, in pale yellow crystals; **potassium tetradecarsenitotriphosphatotungstate**, $10K_2O.14As_2O_3.3P_2O_5.32WO_3.28H_2O$, in minute greenish-yellow crystals; **sodium potassium arsenitophosphatotungstate**, $5K_2O.Na_2O.2As_2O_3.2P_2O_5.12WO_3.15H_2O$, as a yellow oil, which dries to a pale yellow, gummy, transparent mass; and **platinum arsenitophosphatotungstate**, as in the case of the molybdate. A. Rogers obtained **ammonium arsenitovanaditotungstate**, $16(NH_4)_2O.15V_2O_3.5As_2O_3.20WO_3.101H_2O$, by boiling a mixture of arsenic and vanadium trioxides, ammonium tungstate, and aq. ammonia. Black, octahedral crystals are obtained on evaporating the soln. The salt is sparingly soluble in cold water, and freely soluble in hot water. Dil. nitric acid changes the colour of the soln.; conc. nitric acid and conc. hydrochloric acid give yellow precipitates; silver nitrate, a greenish-black precipitate; and barium chloride, a grey precipitate.

C. Reichard reported **uranyl metarsenite**, $UO_2(AsO_2)_2$, to be precipitated when uranyl nitrate is treated with potassium tetrarsenite. It dries at 110° to a pale yellow powder. It first darkens in colour, and then decomposes when heated. It does not dissolve in aq. ammonia; is only slightly soluble in potash-lye; and is readily dissolved by acids.

C. Reichard reported what may not be a chemical individual, or may be a basic manganese arsenite, **manganese dioxyarsenite**, $2MnO.Mn_3(AsO_3)_2$, or **manganese diarsenite**, $Mn_5As_2O_8$, which he prepared by adding sodium metarsenite to a soln. of manganese sulphate in slight excess. The white gummy precipitate soon becomes rose-red, and brown. It is decomposed by heat. A. Stavenhagen obtained **manganese orthoarsenite**, $Mn_3(AsO_3)_2.3H_2O$, by treating manganese acetate with a soln. of potassium orthoarsenite almost neutralized with acetic acid. The pale reddish-brown precipitate was washed with 50 per cent. alcohol, dried over sulphuric acid in an atm. of hydrogen. It oxidizes at 50° , and in a moist atm. at ordinary temp. The black mineral *armangite* described by G. Aminoff and R. Mauzelius is an orthoarsenite, $Mn_3(AsO_3)_2$, and the name is supposed to be compounded from arsenic and manganese. The trigonal crystals have the axial ratio $a : c = 1 : 1.3116$; the hardness is 4. J. Stein mixed soln. of ammonium arsenite and a manganese salt, and obtained a pale red precipitate of **manganese metatetrarsenite**, $Mn_3As_4O_9.5H_2O$; C. Reichard also obtained it by mixing soln. of potassium tetrarsenite and manganese sulphate, washing the precipitate with air-free water, and drying in an atm. of an inert gas. The compound is white, but quickly turns rose-red, brown, and black on exposure to air. It loses a mol. of water at 100° , and the rest at 130° . It is decomposed at a higher temp. Aq. ammonia, potash-lye, and a soln. of potassium cyanide are without action. The mineral *trigonite* named from $\tau\rho\acute{\iota}\gamma\eta\omicron\varsigma$, triangular, in allusion to the shape of the crystals, was described by

G. Flink. It appears to be a **manganese lead arsenite**, $6\text{PbO}\cdot 2\text{MnO}\cdot 3\text{As}_2\text{O}_3\cdot \text{H}_2\text{O}$, or $\text{HMnPb}_3(\text{AsO}_3)_3$; and it occurs in pale sulphur-yellow or brownish, monoclinic crystals with the axial ratios $a : b : c = 1.07395 : 1 : 1.65897$, and $\beta = 91^\circ 31'$. The sp. gr. is 8.28, the hardness 2-3; and the indices of refraction $\alpha = 2.08$, and $\gamma = 2.16$.

According to G. C. Wittstein,¹⁰ a greenish-white precipitate is produced when ammonium arsenite is added to a soln. of ferrous sulphate. The precipitate then changes to a yellow colour; it is supposed to be **ferrous arsenite**; and is soluble in aq. ammonia, but not in ammonium arsenite or other ammoniacal salts. N. J. B. G. Guibourt also reported that he had formed the same salt in soln. by digesting freshly precipitated ferrous hydroxide with an aq. soln. of arsenic trioxide. Some of the hydroxide dissolves. C. Reichard found that potassium tetrarsenite precipitates **ferrous metarsenite**, $\text{Fe}(\text{AsO}_3)_2$, from a soln. of ferrous sulphate. The salt is decomposed when heated.

According to R. Bunsen and A. A. Berthold, when ferric acetate is treated with a soln. of arsenic trioxide, or an alkali arsenite, a basic salt, **ferric enneoxyarsenite**, $\text{Fe}_3\text{As}_2\text{O}_{15}\cdot 5\text{H}_2\text{O}$, or $3\text{Fe}_2\text{O}_3\cdot \text{Fe}_2(\text{AsO}_3)_2\cdot 5\text{H}_2\text{O}$, is precipitated. If ferric sulphate, chloride, or nitrate be employed, all the ferric salt will not be precipitated. J. F. Simon added that it is difficult to wash the precipitate free from ammonium acetate. R. Bunsen and A. A. Berthold said that the same salt is formed when freshly precipitated ferric hydroxide is agitated with an aq. soln. of arsenic trioxide. N. J. B. G. Guibourt said that 6.67 parts of dry ferric oxide are not quite enough to precipitate one part of arsenic trioxide from soln., and 10 parts are not quite enough. R. Bunsen and A. A. Berthold obtained an analogous result with the moist hydroxide. The product decomposes when heated, and N. J. B. G. Guibourt said that the arsenic trioxide is not all expelled by ignition, while J. F. Simon removed all the arsenic in this way. Acetic acid has no action on the product, but the mineral acids dissolve it with the separation of arsenic trioxide. As indicated in connection with the action of ferric hydroxide on arsenic trioxide—*vide supra*—there are reasons for supposing that the product obtained by the action of ferric oxide on the soln. of arsenic trioxide is not a chemical individual, but rather an adsorption product. N. J. B. G. Guibourt found that when ferric hydroxide is mixed with a sat. soln. of arsenic trioxide, in soda-lye, freed from excess of the trioxide, by cooling, and allowed to stand 24 hrs., a yellow substance is obtained with the composition of **ferric pyroarsenite**, $\text{Fe}_4(\text{As}_2\text{O}_5)_3\cdot 7\text{H}_2\text{O}$, when dried in air; 11.6 per cent. of water is lost at 100° . The product forms a deep red soln. with soda-lye. A. Reyhler, and T. Oryng also believed that hydrated ferric oxides adsorb arsenious acid from soln. to form complex arsenites, but *vide supra*, arsenic trioxide. A. Arzruni and E. Schütz obtained three crystalline substances from a factory making chlorine by Deacon's process. The arsenical hydrogen chloride acts on the porous bricks soaked in a copper salt. Monoclinic prisms of ferric orthoarsenite, FeAsO_3 , with the axial ratios $a : b : c = 0.9405 : 1 : 0.6234$, and $\beta = 105^\circ 10\frac{1}{2}'$; and rhombic crystals of the *pentahydrate* were found. V. Ipatieff observed that ferric arsenite is reduced by hydrogen under press., forming colloidal iron oxide, iron arsenide, and arsenic trioxide.

A. Stavenhagen reported **cobalt orthoarsenite**, $\text{Co}_3(\text{AsO}_3)_2\cdot 4\text{H}_2\text{O}$, to be formed by adding a soln. of potassium orthoarsenite, neutralized with acetic acid, to a soln. of cobaltous chloride in 50 per cent. alcohol. The pale red precipitate blackens when heated; it is sparingly soluble in water, readily soluble in acids. According to C. Reichard, when an excess of a soln. of cobalt nitrate is treated with sodium orthoarsenite, a voluminous, amethyst coloured mass is formed which, when dried in air, retains 20 per cent. of water which it loses at 150° , and has then the empirical composition $\text{Co}_3(\text{AsO}_3)_2\cdot 4\text{CoO}$, or **cobalt tetroxyorthoarsenite**. It is easily soluble in dil. sulphuric acid, and less soluble in the conc. acid; it is soluble in soda-lye, and aq. ammonia; it is oxidized by barium dioxide when suspended in water, and cobaltic oxide is formed. It is soluble in a soln. of potassium cyanide. J. L. Proust mixed a soln. of a cobalt salt with potassium arsenite and obtained a

rose-red precipitate which darkened in colour when dried. A. Girard, and A. Stavenhagen said that if potassium pyroarsenite be used, **cobalt pyroarsenite**, $\text{Co}_2\text{As}_2\text{O}_5$, is produced; and this salt was obtained by C. Reichard by adding sodium metarsenite to a soln. of cobalt nitrate. J. L. Proust said that the inner portion of cobalt-bloom or erythrite contains this salt. When heated in a glass vessel, the salt gives off arsenic trioxide and colours the glass blue; when heated with potassium hydroxide, it forms cobalt oxide and a blue liquid which deposits the oxide when diluted with water. It dissolves in nitric and hydrochloric acids; and forms a red soln. with aq. ammonia. A. Reynoso found that the pyroarsenite dissolves in alkali-lye only when it is produced in that menstruum. A. Girard obtained **cobalt metatetrarsenite**, $\text{Co}_3\text{As}_4\text{O}_9 \cdot 4\text{H}_2\text{O}$, by adding potassium arsenite to a soln. of cobalt chloride mixed with an excess of ammonium chloride. C. Reichard obtained it by treating a dil. soln. of a cobalt salt with potassium tetrarsenite. A. Stavenhagen could not prepare this salt by the action of potassium diarsenite on a soln. of cobaltous chloride. According to A. Girard, the rose-red precipitate loses its water at 100° , and at a higher temp. it darkens in colour, then loses water, arsenic trioxide, and melts to a blue mass. The metatetrarsenite is decomposed when heated with potassium hydroxide; it is also dissolved by hydrochloric and nitric acids; with aq. ammonia it gives a reddish-brown soln., and with aq. potassium cyanide, a yellowish-red soln.

G. Tammann observed that when mixtures of nickel oxide and arsenic trioxide are heated, some **nickel orthoarsenite**, $\text{Ni}_3(\text{AsO}_3)_3$, is formed at about 465° . J. L. Proust, and A. Girard obtained an apple-green precipitate by adding potassium arsenite to a soln. of a nickel salt; and C. Reichard showed that the precipitate obtained by the action of sodium metarsenite on a soln. of nickel nitrate in excess, is nickel orthoarsenite. As shown by J. J. Berzelius, and A. Reynoso, the compound is decomposed when heated, and arsenic trioxide is given off. J. L. Proust said that the salt is insoluble in water, but easily soluble in aq. ammonia. A. Reynoso found that it dissolves in alkali-lye at the moment of its formation. A. Girard also reported **nickel metatetrarsenite**, $\text{Ni}_3\text{As}_4\text{O}_9$, to be formed as in the case of the analogous cobalt salt. The greenish-white product is decomposed by heat, forming the arsenate, and arsenic trioxide. It is transformed by nitric acid into an arsenate; by hydrochloric acid into a chloride; and with aq. ammonia, it forms a yellow soln.

A. Stavenhagen reported **platonic orthoarsenite**, $3\text{PtO}_2 \cdot 2\text{As}_2\text{O}_3$, or $\text{Pt}_3(\text{AsO}_3)_4$, to be formed by adding alcohol to a mixture of an aq. soln. of arsenic trioxide and an alcoholic soln. of platinum tetrachloride. The pale yellow precipitate decomposes even at ordinary temp. into arsenical platinum and arsenic pentoxide. C. Reichard reported **platonic pyroarsenite**, $\text{PtO}_2 \cdot \text{As}_2\text{O}_3$, or PtAs_2O_5 , to be formed as a pale yellow precipitate on mixing eq. soln. of potassium tetrarsenite and platonic chloride. The product is dried at 100° . It decomposes when heated; it is not attacked by potash-lye; and it forms a colourless soln. with potassium cyanide. This salt was also prepared by J. F. Simon. O. W. Gibbs mentioned **ammonium platinous arsenite**, $5(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_3 \cdot 3(2\text{PtO} \cdot \text{As}_2\text{O}_3) \cdot 7\text{H}_2\text{O}$; and J. F. Simon obtained **ammonium platonic arsenite** by the action of hydrochloroplatinic acid on an ammoniacal soln. of arsenic trioxide, but A. Stavenhagen could not obtain a salt of constant composition by this procedure. Both J. F. Simon, and C. Reichard obtained **palladium pyroarsenite**, PdAs_2O_5 , by treating a soln. of palladic chloride with potassium tetrarsenite in a manner similar to that employed for the platinum salt.

§ 13. Arsenic Tetroxide; Arsenosic Oxide

According to C. L. Bloxam,¹ if chlorine be passed over arsenic trioxide as long as arsenic trichloride is formed, and the residue melted to a clear glass, the product has a composition corresponding with *arsenosic oxide*, or *arsenoarsenic oxide*, $2As_2O_3 \cdot As_2O_5$. He also obtained the same product by fusing together a mixture of arsenic acid with two molar proportions of arsenic trioxide. The clear glass becomes turbid in a few days, and when in contact with water, a soln. containing arsenic trioxide, arsenic acid, and about 0.5 per cent. of chlorine appears. There is here no evidence of chemical combination. C. Matignon and J. A. Lecanu

obtained the tetroxide as an intermediate stage in the oxidation of arsenic trioxide. E. Bacalogio said that a boiling aq. soln. of arsenic acid dissolves arsenic trioxide, and rejects it as the soln. cools; only 1.8-1.9 parts of the trioxide remain in soln. A. Joly reported a hydrated complex of arsenic tri- and penta-oxides by allowing a mixture of 100 grms. of powdered arsenic trioxide and 25-30 c.c. of conc. nitric acid to stand for some time. Red vapours are evolved and a solid mass of needle-like crystals remains. The composition is $3\text{As}_2\text{O}_3 \cdot 2\text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$. If an excess of arsenic acid be present, tabular crystals of $\text{As}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ are formed; and if arsenic trioxide be in excess, $2\text{As}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ is formed. These complexes are decomposed by water with the separation of the trioxide. O. W. Gibbs prepared *potassium arsenitoarsenatotungstate*, $10\text{K}_2\text{O} \cdot \text{As}_2\text{O}_3 \cdot 4\text{As}_2\text{O}_5 \cdot 21\text{WO}_3 \cdot 26\text{H}_2\text{O}$, in white crystals.

The so-called **arsenic tetroxide**, or **arsenosic oxide**, As_2O_4 , can be regarded as a combination of a mol. each of arsenic trioxide and pentoxide; H. Herbst supposed it to be a mixed anhydride of metarsenious acid, HAsO_2 , or $\text{HO} \cdot \text{AsO}$, and metarsenic acid, HAsO_3 , or $\text{HO} \cdot \text{AsO}_2$:

H. Herbst said that when a mixture of equimolar parts of arsenic tri- and penta-oxides is heated to 350° no trioxide volatilized, although that oxide alone sublimes at 200° ; if an excess of the trioxide be present, the excess over the molar ratio 1:1 sublimes; and if an excess of the pentoxide be present, that excess loses oxygen until the 1:1 ratio is formed. When arsenic pentoxide alone is heated, oxygen is given off and arsenic tetroxide is formed. E. Weidenbach showed that between 800° and 1200° the product has the composition As_6O_{11} corresponding with the compound $\text{As}_4\text{O}_6 \cdot \text{As}_2\text{O}_5$. He obtained no evidence of the formation of the compound $\text{As}_4\text{O}_6 \cdot 2\text{As}_2\text{O}_5 = 4\text{As}_2\text{O}_4$. The fused mass freezes to a transparent glass which becomes opaque when it has stood some hours in a desiccator—*vide infra*, arsenic pentoxide. The tetroxide is slightly soluble in water, and is precipitated from the aq. soln. by alcohol; it is easily soluble in a soln. of an alkali carbonate or hydroxide, or in hydrochloric acid.

§ 14. Arsenic Pentoxide; Arsenic Acid

A manuscript entitled: *Experiments on arsenic* by H. Cavendish, written in 1765, shows that he anticipated by sixteen years the discovery of the acid of arsenic, its relation to the oxide and regulus, and the complete examination of its salts.¹ It is also true that a number of early workers investigated the action of nitric acid on arsenic trioxide. J. R. Glauber confined his attention to the red fumes which are evolved during the reaction; but T. Paracelsus obtained a solid product which he called *arsenicum fixum*; A. Libavius called it *butyrum arsenici*; J. B. van Helmont said that a fiery salt is produced; N. Lemery called the product *arsenic caustique*; and P. J. Macquer, *sel neutre arsenical*. But so far as the development of chemistry is concerned, the discovery of this compound must be attributed to C. W. Scheele in 1775. Analyses and the composition of the product, **arsenic pentoxide**, As_2O_5 , were worked out by J. L. Proust,² C. F. Bucholz, J. J. Berzelius, L. J. Thénard, T. Thomson, and E. Mitscherlich.

M. Berthelot found that the pentoxide can be formed by the direct action

of oxygen on arsenic, or arsenic trioxide. In the oxidation of arsenic trioxide, suspended in nitric acid of sp. gr. 1.4 at 90°, by oxygen: $\text{As}_2\text{O}_3\text{aq.} + \text{O}_2 = \text{As}_2\text{O}_5\text{aq.}$ H. Zieler showed that the finer the particles the faster the reaction; the more vigorously the soln. is agitated, the faster the oxidation; the more conc. the acid the faster the oxidation, thus:

Conc. of HNO_3 . . .	47.7	55.9	59.0	65.4	73.3 per cent.
As_2O_3 oxidized . . .	1.6	72.0	75.7	82.3	100 „
HNO_3 reduced . . .	26	34	36	40	60 „

The higher the temp. the faster the oxidation, thus:

	60°	70	80°	90°	100°
As_2O_3 oxidized . . .	9.0	16.2	33.1	82.3	100 per cent.
HNO_3 reduced . . .	120	89	73	40	23.5 „

and the greater the press. of the oxygen, the faster the oxidation, thus:

Press. of oxygen . . .	0	5	10	20	25 atm.
As_2O_3 oxidized . . .	12.4	30.0	49.5	80.2	88.8
HNO_3 reduced . . .	—	99	68	36	33

No oxidation occurs in neutral soln., but the reaction is quantitative in the presence of nitric acid if the arsenic trioxide is finely divided. R. Weber obtained it by the action of dry chlorine on arsenic trioxide. C. Ellis and V. T. Stewart also oxidized the trioxide with chlorine. P. Askenasy and E. Elöd heated 150 parts of arsenious oxide (or sulphide) and 150 parts of 60 per cent. nitric acid in a closed vessel with a stirrer. A little arsenic pentoxide or other catalyst is added; and oxygen at 20 atm. press. is forced in and the mixture stirred for 12–18 hrs. at 70°–80°. The nitric acid is nearly always unchanged and can be distilled off. Arsenic pentoxide is obtained by heating the hydrated oxide or arsenic acid—*vide infra*. V. Augur showed that the water can be all driven off at 180°, and the pentoxide is stable below 400°; hence, 180°–200° is a convenient temp. for the dehydration of arsenic acid. According to A. W. C. Menzies and P. D. Potter, arsenic pentoxide retains a small quantity of water at a high temp., and its removal can be best and most rapidly effected by heating it in air containing water vapour.

Arsenic pentoxide is a white pulverulent solid, or when it has been fused it may form a transparent or opaque glass. T. Bergman gave for the sp. gr. 3.391; L. Playfair and J. P. Joule, 3.985–4.023; W. Herapath, 3.729; E. Filhol, 4.25; and V. Auger, 4.3. C. J. B. Karsten gave 3.7342 for the oxide which had been heated to dull redness. D. Balareff, and C. del Fresno studied the mol. vol. According to C. F. Bucholz, when arsenic pentoxide is heated somewhat above its m.p., it is resolved into oxygen and volatile arsenic trioxide. The residue is a mixture of arsenic tri- and penta-oxides. V. Auger, H. Kopp, and E. C. Szarvasy and C. Messinger found that the decomposition occurs at a red-heat before the pentoxide melts; and H. Kopp added that partial sintering may occur if the temp. be rapidly raised. C. F. Bucholz's product may have contained a little alkali. V. Auger said that the pentoxide begins to decompose above 400°: $2\text{As}_2\text{O}_5 = \text{As}_4\text{O}_6 + 2\text{O}_2$. E. Weidenbach showed that between 800° and 1000°, the product has the composition As_6O_{11} , a substance also obtained by C. L. Bloxam. This is considered by E. Weidenbach to be a compound $\text{As}_4\text{O}_6 \cdot \text{As}_2\text{O}_5$, and not $\text{As}_4\text{O}_6 \cdot 2\text{As}_2\text{O}_5 = 4\text{As}_2\text{O}_4$. A. W. C. Menzies and P. D. Potter measured the amount of water lost when the hydrated pentoxide is heated for different lengths of time at different temp. J. Thomsen found the heat of formation ($2\text{As}_2\text{O}_5$) = 219.38 Cals., and ($\text{As}_2\text{O}_3, \text{O}_2$) = 32.355 Cals., while M. Berthelot gave 32.4 Cals.; and C. Matignon and J. A. Lecanu, $\text{As}_2\text{O}_3 + \text{O}_2 = \text{As}_2\text{O}_5 + 62.2$ Cals.

Arsenic pentoxide appears at first to be tasteless, but it quickly appears to have a sharp, acidic taste; and, according to E. Filhol, it is more poisonous than arsenic trioxide towards plants. On the other hand, G. Joachimoglu said that with

intravenous injections in rabbits the relative toxicity of sodium arsenites and arsenates is as 6 : 10, but arsenious acid is more toxic towards an isolated frog's heart; and an isolated small intestine of a rabbit. He added: "Arsenic acid acts toxically only after reduction to arsenious acid." When arsenic pentoxide is heated in an atm. of **hydrogen** it is reduced to the trioxide, and finally to arsenic; **oxygen** has no action; **water** converts it into the hydrate or into arsenic acid, H_3AsO_4 —*vide infra*. Arsenic pentoxide attracts moisture from the air and is transformed into arsenic acid. Many of the reactions furnish products like those obtained with arsenic trioxide (*q.v.*), or with arsenic acid (*q.v.*). Thus, the pentoxide is reduced by **sulphur**, and this forms arsenic sulphide. H. A. von Vogel found that the pentoxide absorbs **hydrogen sulphide**, forming arsenic pentasulphide and water. J. Mayrhofer found that **hydrogen chloride** is vigorously absorbed by the pentoxide, forming water and arsenic trichloride. No arsenic trichloride is formed at -20° . C. F. Schönbein observed that when triturated with **potassium iodide**, the mixture becomes brown, and when the mixture is heated, the reaction is symbolized: $3As_2O_5 + 4KI = 4KAsO_3 + As_2O_3 + 2I_2$; **potassium bromide** acts similarly, likewise also **alkaline earth chlorides** but not the **alkali chlorides**. H. O. Schulze found that a mixture of alkali chloride and the pentoxide is rapidly decomposed when heated in oxygen gas. E. Berl studied the oxidation of **sulphur dioxide** in the presence of the pentoxide. F. Faktor found that when the trioxide is melted with **sodium thiosulphate** arsenic di- and tri-sulphides are formed. The reaction between alkali arsenate and sodium thiosulphate in acid soln. results in the precipitation of arsenic trisulphide as indicated by G. Vortmann. G. S. Forbes and co-workers showed that there is a definite period of induction so that the appearance of the trisulphide furnishes a so-called clock reaction—*vide* arsenic trioxide. According to A. Rosenheim and F. Jacobsohn, when arsenic pentoxide is treated with liquid **ammonia** in a sealed tube at ordinary temp., **arsenic triamminopentoxide**, $As_2O_5 \cdot 3NH_3$, is formed. Its constitution has not been determined. It may be **ammonium imidodimetarsenate**, $(NH_4)_2As_2O_5(NH)$, because when treated with lead iodide, in ammoniacal soln., a heavy white precipitate with the composition **lead imidodimetarsenate**, $Pb\{(NH_4)As_2O_4(NH)\}_2$, is formed. Arsenic pentoxide is reduced by **phosphorus** to the trioxide, etc. A. Michaelis said that **phosphorus trichloride** does not act on the pentoxide at 200° , but, according to L. Hurtzig and A. Geuther, **phosphorus pentachloride** reacts: $As_2O_5 + 5PCl_5 = 2AsCl_3 + 5POCl_3 + 2Cl_2$. The pentoxide is reduced by **carbon**, as in the case of the trioxide. J. J. Berzelius said that the pentoxide is more soluble than the trioxide in **alcohol**; that it is very slightly soluble in **fatty oils**, for 100 parts of oil dissolve only 0.2 part of the trioxide in the cold, and one part, with partial decomposition, on boiling. J. J. Heimpel, and K. von Grundner found that 100 parts of boiling **poppy oil** dissolve 2.7 parts of arsenic pentoxide; and 100 parts of **castor oil**, 3.4 parts of the pentoxide. O. Aschan found that 100 grms. of 95 per cent. **formic acid** dissolve 7.6 grms. of the pentoxide at 19° . Arsenic pentoxide is reduced by **arsenic** to the trioxide; **antimony**, and **bismuth** act similarly. L. Kahlenberg and W. J. Trautmann said that when heated with **silicon**, arsenic oxide is volatilized. According to J. L. Gay Lussac and L. J. Thénard, the pentoxide is vigorously reduced by heated **potassium** or **sodium**; J. J. Berzelius found that it is reduced when heated with **zinc**; and C. W. Scheele, when heated with **iron**. Similar results have been obtained with other metals—*e.g.* **copper**, **tin**, **lead**, **manganese**, and **cobalt**—**silver**, and **mercury** act only at a high temp., **gold** and **platinum** not at all.

Arsenic pentoxide is slowly dissolved by cold water and rapidly by hot water. The aq. soln. is usually designated *arsenic acid*. When the aq. soln. is evaporated C. F. Bucholz said that a syrupy liquid is obtained which ultimately furnishes crystals of arsenic acid, presumably $H_3AsO_4 \cdot nH_2O$. H. A. von Vogel found that 100 parts of water at 12.5° dissolve 244.8 parts of As_2O_5 or 302.3 parts of H_3AsO_4 . E. Mitscherlich reported that at 15° , crystals of the hydrate, $2HAsO_4 \cdot H_2O$, are formed; and T. Graham found that the products obtained by the successive loss

of water are analogous in composition to those obtained with phosphorus pentoxide, namely :

Arsenic acid,
 H_3AsO_4

Pyroarsenic acid,
 $\text{H}_4\text{As}_2\text{O}_7$

Metaarsenic acid,
 HAsO_3

but he said that the products of the dehydration do not furnish distinctive salts as in the case of the condensation products of phosphoric acid, and accordingly should not be designated pyro- and meta-arsenic acids. J. J. Berzelius and E. Mitscherlich emphasized the similarity of the arsenates to the phosphates in their constitution, properties, and crystalline form. After T. Clark had converted sodium orthophosphate into the pyrophosphate by driving off one-third of the constitutional water, he investigated whether sodium arsenate would exhibit a similar change, and found that "the appearances were the same, but the effects were different." Both phosphates and arsenates when heated to redness lose one proportion of water, but aq. soln. of the arsenate alone gave the same precipitates with other salts as it did before the thermal change, and the soln. of the arsenate alone on crystallization gave the old salt back again. Hence, said T. Clark, "this looks as though the phosphate and the arsenate alike lose a mol. of water, but with the phosphate an additional change occurs not produced with the arsenate."

H. E. Armstrong and F. P. Worley made some observations on the constitution of arsenic acid—*vide* sulphuric acid. A. Joly reported the *hemitrihydrate*, $2\text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, to be formed by drying arsenic acid, *i.e.* the trihydrate, or the tetrahydrate at 110° , or in vacuo. D. Balareff, A. W. C. Menzies and P. D. Potter could not make this hydrate. H. Kopp prepared the *monohydrate*, $\text{As}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or **metaarsenic acid**, HAsO_3 , by heating a very conc. soln. of arsenic acid at 200° and then raising the temp. slowly to 206° . The product dissolves slowly in cold water, with the evolution of heat, and it dissolves rapidly in hot water. V. Auger, D. Balareff, and A. W. C. Menzies and P. D. Potter could not make this hydrate. The last-named observed that when the tetrahydrate is left to stand in a superfused state, a hard, white crystalline scale is produced of the *pentatritahydrate*, $3\text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, which can be satisfactorily obtained by evaporating a soln. of arsenic acid to dryness at 100° . A supersaturated soln. of this hydrate at $9 \cdot 2^\circ$ was well inoculated with crystals and stirred continuously. Supersaturation was not entirely removed until after 27 days. D. Balareff said that crystals of this hydrate are always formed when a soln. of arsenic acid is evaporated in an open vessel at 50° , or under increased press. at 150° . H. Kopp evaporated an aq. soln. between 140° and 180° , and obtained a hard mass with the composition of the *dihydrate*, $\text{As}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, or **pyroarsenic acid**, $\text{H}_4\text{As}_2\text{O}_7$. D. Balareff, V. Auger, A. W. C. Menzies and P. D. Potter could not make this hydrate, and similar remarks apply to the *trihydrate*, $\text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or **orthoarsenic acid**, H_3AsO_4 , reported by H. Kopp to be formed by heating the tetrahydrate at 100° , and allowing the fused mass to cool; and by heating the aq. soln. for a long time on a water-bath. The needle-like crystals lost half their water at 110° ; and were said to be readily soluble in water without a perceptible rise of temp. D. Balareff, V. Auger, and A. W. C. Menzies and P. D. Potter could not make this hydrate. H. Kopp obtained the *tetrahydrate*, $\text{As}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, or *hemihydrated arsenic acid*, $\text{H}_3\text{AsO}_4 \cdot \text{H}_2\text{O}$, by crystallizing the conc. aq. soln. at 15° . According to A. W. C. Menzies and P. D. Potter, the tetrahydrate can be prepared by concentrating an aq. soln. of arsenic acid until it has a b.p. of 150° ; and, after cooling, inoculating a small portion of the soln. with crystals of the corresponding hydrate of phosphoric acid, $\text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, and using the crystals so obtained to inoculate the remainder of the

liquid. A. Joly said that the crystals of the tetrahydrates of arsenic and phosphorus pentoxides must be isomorphous because crystals of the one can be used for inducing the crystallization of sat. soln. of the other. The crystals, said H. Kopp, are rhombic prisms or plates, which are deliquescent, and dissolve freely in water with the development of heat. The crystals melt and freeze between 35.5° and 36° . A. W. C. Menzies and P. D. Potter gave 36.14° for the m.p. A. Joly found the crystals lose water in vacuo, forming the hemitrihydrate; and V. Auger said that complete dehydration occurs at 180° – 200° . D. Balareff said that when fused the tetrahydrate forms the pentatritahydrate. J. Kendall and co-workers, and D. I. Mendeléeff discussed the hydrate formation with this and related acids; and H. Remy, the structure of arsenic acid. A. W. C. Menzies and P. D. Potter's solubility curve of the pentoxide, expressed in percentage amounts of arsenic acid, H_3AsO_4 , between 0° and 60° , the so-called ice-line, where ice is the solid phase:

FIG. 24.—Solubility Curves of Arsenic Pentoxide in Water.

H_3AsO_4	0°	-10°	-20°	-30°	-40°	-50°	(-60°)
	0.0	23.0	46.2	54.5	60.5	65.1	(89.0) per cent.

After passing the eutectic region extrapolated in Fig. 24, the solid phase is the tetrahydrate, $As_2O_5.4H_2O$, or $H_3AsO_4.H_2O$, for which the solubility is:

H_3AsO_4	-55°	-50°	-30°	-10°	0°	20°	30°
	-69.9	70.9	74.9	78.9	81.0	86.3	90 per cent.

The unstable tetrahydrate phase at 35° has a 92.8 per cent. solubility. There is a transition point near 36.1° , and the solid phase at higher temp. is the pentatritahydrate, $3As_2O_5.5H_2O$, unstable at 10° and 20° with 88.4 and 89.1 per cent. respectively of H_3AsO_4 , and the stable at

H_3AsO_4	40°	50°	60°	80°	100°	120°	140°
	90.5	91.2	91.9	93.2	94.4	95.6	96.8 per cent.

A. Simon and E. Thaler cooled to -20° to -30° a soln. of arsenic acid which had been evaporated at 130° , and obtained the *heptahydrate*, $As_2O_5.7H_2O$. The time-composition curve of the decomposition of the tetrahydrate, $As_2O_5.4H_2O$, shows no indication of any hydrate other than $3As_2O_5.5H_2O$; and no signs of solid soln. were observed. The three hydrates are represented:

According to M. Berthelot,³ arsenic acid is not formed when dry arsenic trioxide is heated in an atm. of oxygen in a sealed tube for 48 hrs.; nor does an aq. soln. of arsenic trioxide absorb any oxygen in the presence of hydrochloric acid when exposed in air for 2 months; but at 100° , oxygen is slowly absorbed, and arsenic acid is formed. The reaction is accelerated in the presence of platinum foil. For oxidation of arsenic trioxide by hydrogen dioxide, and by ozone, *vide supra*. Arsenic acid is formed when arsenic or arsenic trioxide is treated with oxidizing agents. T. Thomson used hot nitric acid with arsenic or arsenic trioxide (*q.v.*). L. Gmelin added that if boiling dil. nitric acid is used, a mixture of arsenic acid and arsenic trioxide is formed. Nitric acid is employed on a large scale when about 4 parts of arsenic trioxide are gradually added to 3 parts of nitric acid of sp. gr. not less than 1.35. About 65.70 kilograms of the trioxide are treated at a time.

Much heat is evolved, and the nitrous fumes evolved are passed over coke moistened with water, whereby up to two-thirds of the nitric acid can be recovered. In 24 hrs. a syrupy liquid is formed; this is treated with a little more nitric acid to ensure the oxidation of all the trioxide. The liquid is evaporated to a syrup which deposits crystals of the tetrahydrate when cooled. O. C. Behse used hydrochloric acid as catalyst. The arsenic acid was formerly made in earthenware pots; but it is now made in nitrating kettles made of a ferrosilicon alloy—duriron. C. M. Smith and G. E. Miller showed that in the oxidation of arsenic trioxide by nitric acid in the manufacture of calcium arsenate, the rate of oxidation progresses very differently with different raw materials. The sluggish action is due to the presence of small quantities of mercury in the arsenic trioxide, 0.1 per cent. being a powerful negative catalyst. Reactivity may be restored in such cases by the addition of small quantities of hydrochloric, hydrobromic, or hydriodic acids. These compounds, even in the low concentrations necessary, may, however, be corrosive to the metallic vessels in which the oxidation is frequently accomplished. The acceleration of the reaction by the haloid acids is the subject of a patent by O. C. Behse. The manufacture was discussed by C. W. Drury and C. W. Simmons, W. C. Piver, and E. A. Suverkrop. C. G. Richardson treated a soluble arsenate with ferric sulphate, forming an insoluble arsenate which was then converted to arsenic acid by sulphuric acid. C. W. Scheele, and C. F. Bucholz employed aqua regia as the oxidizing agent; N. A. E. Millon said that if the acid is so dil. that no chlorine is evolved, it does not attack arsenic until heat is applied, or nitrous acid added. The oxidation was found by T. Bergman, C. Ellis and V. T. Stewart, and J. Girardin, to occur with chlorine or chlorine-water; by A. J. Balard, and R. Wagner, with bromine; by J. F. Simon, with iodine; by A. J. Balard, with hypochlorous acid; by H. Rose, with a mixture of potassium chlorate and hydrochloric acid; by F. C. Schneider, with gold trichloride, or sodium chloroaurate; and by F. Kessler, with chromic acid, or permanganic acid. J. A. Kaiser found that arsenic acid is formed when arsenic trichloride is decomposed by chlorine-water; and W. Wallace, by chromic acid. L. L. de Koninck said that bromine-water converts arsenic trisulphide into arsenic acid; and L. N. Vauquelin, that some metal oxides—*e.g.* cupric oxide—convert the trioxide into arsenic acid when in the presence of alkali-lye. The oxidation of arsenic trioxide in the presence of alkalies or alkaline earths was observed by J. L. Gay Lussac, W. H. Wollaston, A. F. Gehlen, E. Soubeiran, etc.—*vide supra*, the arsenites.

H. A. von Vogel⁴ said that the **specific gravity** of a sat. aq. soln. of arsenic pentoxide is 2.550; the soln. remains liquid at -26° ; and it attracts moisture from the air until its sp. gr. is 1.935. G. T. Gerlach calculated the results indicated in Table VIII, from H. Kopp's data. H. Schiff also obtained a short table of

TABLE VIII.—SPECIFIC GRAVITIES OF AQUEOUS SOLUTIONS OF ARSENIC ACID AT 15.

Per cent. H_3AsO_4	0	2	4	6	8
0	1.000	1.013	1.026	1.039	1.052
1	1.066	1.081	1.096	1.111	1.126
2	1.142	1.158	1.175	1.192	1.210
3	1.228	1.248	1.267	1.288	1.309
4	1.331	1.353	1.376	1.400	1.425
5	1.450	1.478	1.505	1.534	1.564
6	1.594	1.626	1.659	1.693	1.730
7	1.767	1.809	1.851	1.897	1.946
8	1.995	2.045	2.095	2.149	2.207
9	2.265	2.295	—	—	—

results—for soln. with 7.5, 30, and 67.4 per cent. of arsenic acid, the sp. gr. were respectively 1.0495, 1.2350, and 1.7346. H. A. von Vogel's result does not agree

with those indicated in Table VIII. D. I. Mendeléeff represented the sp. gr. of the aq. soln. containing p per cent. H_3AsO_4 at $15^\circ/4^\circ$ by $S=0.9992+0.0060p+0.0000576p^2$. R. Reyher found the **viscosity** of $N-H_3AsO_4$ to be 1.2707 (water unity), and for $\frac{1}{2}N$ -soln., 1.1291; $\frac{1}{4}N$ -, 1.0595; and $\frac{1}{8}N$ -, 1.0309 at 25° . L. J. Simon made some measurements of the **viscosity** during the progressive neutralization of the soln. with sodium hydroxide. G. Tammann found that the lowering of the **vapour pressure** of water by arsenic acid to be about half as great as is the case with sulphuric acid, being 13.1 mm. for 12.68 grms. of H_3AsO_3 in 100 grms. of water, 36.7 mm. for 34.07 grms. of acid, and 62.88 mm. for 72.5 grms. of acid. J. Thomsen gave for the **heat of neutralization** of H_3AsO_4 aq. with an aq. soln. of 1, 2, and 3 mols of NaOH to be respectively 14.994, 27.580, and 35.916 Cals. This agrees with the assumption that arsenic acid in aq. soln. is tribasic. E. Baud and A. Astruc calculated for the three heats of neutralization $H_4AsO_4(\text{solid})+Na(\text{solid})=H_{\text{gas}}+NaH_2AsO_4(\text{solid})+57.15$ Cals.; similarly, for (NaH_2AsO_4, Na) , 45.87 Cals.; and for (Na_2HASO_4, Na) , 60.76 Cals. T. Graham made some observations on this subject.

J. C. Ghosh and S. C. Bisvas measured the extinction coeff. of arsenic acid for light. W. J. Pope gave 27.72 for the refraction equivalent of the H_2AsO_4 -radicle. J. B. Richter, and C. F. Bucholz found that arsenic is deposited and arsine evolved at the negative pole during the electrolysis of the aq. soln. of arsenic acid. P. Walden found the **electrical conductivity**, μ , of aq. soln. of a mol of arsenic acid in v litres of water, at 25° , to be :

v	8	16	32	64	128	256	512	1024
μ	68.4	89.4	117.4	150.2	188.4	228.0	264.2	290.3

He also gave for potassium dihydroarsenate, and for the three sodium arsenates :

v		32	64	128	256	512	1024
μ	$\left\{ \begin{array}{l} KN_2AsO_4 \\ NaH_2AsO_4 \\ Na_2HASO_4 \\ Na_3AsO_4 \end{array} \right.$	87.8 67.6 79.0 94.7	91.3 70.6 84.7 105.5	93.8 73.2 88.8 113.7	96.0 75.4 92.0 118.5	97.9 77.4 94.4 119.3	99.4 78.6 95.6 118.4

He added that the dihydroarsenates behave like salts of a monobasic acid, $H(H_2AsO)_4$; that sodium hydroarsenate behaves like a salt of a dibasic acid, $H_2(HAsO_4)$; while normal sodium arsenate is quickly decomposed with progressive dilution. The three salts behave like the corresponding salts of phosphoric acid. It is inferred that two of the three replaceable hydrogen atoms are similarly oriented in the molecule of arsenic acid, but the third hydrogen atom is not similarly disposed, for it is not so readily displaced by a metal. This is taken to be in agreement with J. Thomsen's thermochemical data; and with the behaviour of arsenic acid towards alkalis in the presence of different indicators. Arsenic acid in aq. soln. strongly reddens blue litmus. A. Joly, C. Blarez, and A. Astruc and J. Tarbouriech found that with lacmoid, and methyl-orange as indicators, arsenic acid behaves as if it were monobasic towards potassium or barium hydroxide; and with phenolphthalein, as a dibasic acid. R. Engel showed that with Porrier's blue as indicator, arsenic acid behaves as if it were tribasic. R. T. Thomson made observations on this subject—*vide infra*. The conductivity of aq. soln. of the potassium metarsenate, obtained by calcining the dihydroarsenate; and for sodium pyroarsenate obtained by calcining the hydroarsenate, were found by P. Walden to be :

v		32	64	128	256	512	1024
μ	$\left\{ \begin{array}{l} KAsO_3 \\ Na_4As_2O_7 \end{array} \right.$	87.8 79.0	91.3 84.6	93.8 88.8	96.0 92.0	97.6 94.4	99.4 95.5

The values for the metarsenate agree with those of the dihydroarsenate, and it is therefore inferred that the salt is hydrated in aq. soln. : $KAsO_3+H_2O=KH_2AsO_4$. Similarly, the numbers for the pyroarsenate agree with those for the hydroarsenate, hence, in aq. soln., $Na_4As_2O_7+H_2O=2Na_2HASO_4$. This means that neither

the metarsenate nor the pyroarsenate can exist in aq. soln. R. Luther found the first **ionization constant** of arsenic acid: $\text{H}_3\text{AsO}_4 \rightleftharpoons \text{H}^+ + \text{H}_2\text{AsO}_4'$, that is, $K = [\text{H}_2\text{AsO}_4'] [\text{H}^+] / [\text{H}_3\text{AsO}_4]$, to be 0.005. E. W. Washburn calculated the ionization constant of the first hydrogen-ion of arsenic acid to be 0.0048; and added that the constants for the second and third hydrogen-ions are probably lower than 2.1×10^{-7} and 5.6×10^{-13} , the respective values for those of phosphoric acid. E. Blanc calculated $K_2 = 4 \times 10^{-5}$, and $K_3 = 6 \times 10^{-10}$; and he found that in the neutralization of 0.002*N*-arsenic and with 0.595*N*-NaOH, there is a break corresponding with NaH_2AsO_4 when $C_4 = 0.9 \times 10^{-4}$; and with Na_2HASO_4 , when $C_4 = 5 \times 10^{-11}$. For the affinity constant, *vide* sulphuric acid. According to G. Bischof, when an aq. soln. of arsenic acid is electrolyzed, arsenic is deposited at the **cathode**, and hydrogen or arsine is evolved while oxygen is given off at the anode.

A. C. Chapman and H. D. Law, and W. Thomson studied the **electrolytic reduction** of arsenic acid. L. Ramberg found that the nature of the cathode as well as of the cathodic surface has a great influence on the reduction of arsenic to arsine. The process generally occurs far more rapidly at spongy surfaces than at polished ones. The reduction is rapid and complete only at mercury cathodes. F. Förster and H. Pressprich found the reduction potential in soln. at least 0.1*N*-HCl to be $E = E_0 + 0.029 \log [\text{H}_2\text{AsO}_4] / [\text{H}_2\text{AsO}_3]$, when E_0 at 18° is 0.574 volt, in agreement with R. Luther's value 0.575 volt for $\text{H}_3\text{AsO}_4 + 2\text{H}^+ + 3\text{I}^- \rightleftharpoons \text{H}_3\text{AsO}_3 + \text{I}_3 + \text{H}_2\text{O}$. Increasing the acidity of the soln. raises the potential. The subject was studied by L. Loimaranta, J. R. Roebuck, and K. Jellinek and L. Winogradoff. A. Brochet and J. Petit found that alternating currents exert a specific action on the reduction of arsenic acid by lead electrodes; the evolution of gas varies with the current density but not the temp. L. Ramberg studied the effect of different cathodes on the reduction of arsenic acid.

The chemical properties of arsenic acid.—Arsenic acid is reduced by nascent **hydrogen** in acid soln. as in the case of aq. soln. of arsenic trioxide; but E. Covelli⁵ said that in alkaline soln. it resists reduction under conditions where arsenious acid forms arsine. Hence it is possible to detect arsenites in the presence of an arsenate. For the effect of **water**, *vide supra*, Fig. 24. According to S. Aschkenasy, if **alkaline earth peroxides** be dissolved in arsenic acid, and the soln. be evaporated under reduced press., at a low temp., a **perarsenate** of the alkaline earth is produced. The liquid before evaporation can be converted into a soln. of the alkali perarsenate by treatment with alkali sulphate. An alkali perarsenate is produced by evaporating, under reduced press., a soln. of the arsenate in dil. **hydrogen dioxide**.

According to H. Rose, when a soln. of arsenic acid and fuming **hydrochloric acid** is heated in the presence of conc. sulphuric acid, no arsenic trichloride is at first formed, but after a prolonged boiling a small quantity along with free chlorine appears in the distillate. C. R. Fresenius and A. Souchay found that on distilling a mixture of arsenic acid with hydrochloric acid of sp. gr. 1.12 mixed with more than its own vol. of water, no arsenic appears in the distillate, but if a more conc. acid be used some arsenic passes over as volatile chloride; J. Mayrhofer found that with fuming acid much arsenic trichloride is formed in the receiver, while with an acid of sp. gr. 1.10, only traces pass over. O. Hehner found that the presence of organic matter favours the reduction of the pentoxide and the formation of the volatile trichloride. The presence of other reducing agents also results in the production of the volatile chloride. F. L. Usher and M. W. Travers represent the reaction $\text{As}_2\text{O}_5 + 10\text{HCl} \rightleftharpoons 2\text{AsCl}_3 + 2\text{Cl}_2 + 5\text{H}_2\text{O}$; they added that increasing the conc. of the hydrochloric acid, favours the production of the volatile chloride. J. Clark found that in the presence of cuprous chloride—H. Hagen used ferrous sulphate; and E. Fischer ferrous chloride—arsenic acid is readily converted into the volatile chloride, and this reaction has been employed in analytical work—by C. W. Zenger, F. Hufschmidt, F. A. Gooch and E. W. Danner, C. Field and E. F. Smith, J. B. Moyer, M. Rohmer, C. R. Fresenius and E. Hintze—for separating arsenic

from elements which do not form volatile chlorides under these conditions—*vide infra*, arsenic trichloride. W. Manchot and F. Oberhauser studied the reducing action of **hydrobromic acid**: $\text{As}_2\text{O}_5 + 4\text{HBr} \rightleftharpoons \text{As}_2\text{O}_3 + 4\text{Br} + 2\text{H}_2\text{O}$ —*vide supra*, arsenic trioxide. J. R. Roebuck, and W. C. Bray studied the rate of reduction of arsenic acid by **hydriodic acid**, a reaction previously considered in connection with the reverse change, namely, the oxidation of arsenic trioxide by iodine: $\text{As}_2\text{O}_3 + 2\text{I}_2 + 5\text{H}_2\text{O} \rightleftharpoons 2\text{H}_3\text{AsO}_4 + 4\text{HI}$. W. A. H. Naylor applied the reducing action of hydriodic acid on arsenic acid to the volumetric determination of arsenates. C. F. Schönbein found that when arsenic acid is warmed with **potassium iodide**, iodine is set free; but R. Bunsen said that the reduction of arsenic acid to the trioxide, by warming with potassium iodide and hydrochloric acid, is not complete. F. A. Gooch and P. E. Browning based a method for the determination of iodine in the halide salts upon the action of arsenic acid in the presence of dil. sulphuric acid: $\text{H}_3\text{AsO}_4 + 2\text{HI} = \text{H}_3\text{AsO}_3 + \text{H}_2\text{O} + \text{I}_2$. The iodine is completely volatilized, leaving behind in the amount of arsenic trioxide present, the record of the amount of iodine originally present. The reduction of arsenates by means of ammonium iodide is a common laboratory process. If **potassium bromide** be present, there is a trifling reduction of the arsenic acid, but no arsenic is lost by volatilization; and if **potassium chloride** be present, no reduction occurs, but a proportional amount of arsenic is volatilized as trichloride.

G. Vortmann and C. Padberg found that the aq. soln. of arsenic acid is not affected by **sulphur**. J. J. Berzelius showed qualitatively that when **hydrogen sulphide** acts on a moderately conc. soln. of arsenic acid, **arsenic pentasulphide** is precipitated: $\text{As}_2\text{O}_5 + 5\text{H}_2\text{S} = \text{As}_2\text{S}_5 + 5\text{H}_2\text{O}$; on the other hand, H. W. F. Wackenroder said that the arsenic is first reduced by hydrogen sulphide to the trioxide even in the presence of hydrochloric acid, and that a mixture of sulphur and arsenic trisulphide is precipitated; and H. Ludwig represented the reaction: $\text{As}_2\text{O}_5 + 5\text{H}_2\text{S} = \text{As}_2\text{S}_3 + 5\text{H}_2\text{O} + 2\text{S}$. E. W. Parnell also supposed the arsenic to be precipitated as trisulphide. H. Rose found that after the hydrogen sulphide has been passed through the liquid, both arsenic and arsenious acids are present, showing that a partial reduction of the arsenic acid occurs. R. Bunsen, and L. M. McCay confirmed the observation of J. J. Berzelius, for they proved that when a rapid current of hydrogen sulphide is passed into a soln. of an alkali arsenate, acidified with hydrochloric acid, and heated by a water-bath, arsenic pentasulphide is formed, and this reaction may be employed to determine arsenic quantitatively. These facts stimulated B. Brauner and F. Tomicek to examine the conditions under which the two arsenic sulphides are produced. The conditions which favour the formation of arsenic pentasulphide are (i) a high conc. of the hydrochloric acid; (ii) a rapid passage of gas through the soln.; and (iii) a temp. between 0° and 100° . The conditions which favour the production of a mixture of arsenic trisulphide and sulphur are (i) a low conc. of hydrochloric acid; (ii) a slow passage of gas through the liquid; and (iii) a high temp. in the range 0° – 100° . It was also found that arsenic acid, especially in presence of ammonium chloride, is reduced more easily than an acidified soln. of an arsenate. The second limit, namely, complete formation of trisulphide, is reached, if at all, with greater difficulty than the first limit, that is, formation of pure pentasulphide. F. L. Usher and M. W. Travers added the observations that working at 15° under constant conditions with an aq. soln. of arsenic pentoxide, and varying proportions of hydrochloric acid:

HCl	.	1.8	7.9–14.34	25.10	32.27 per cent.
As_2S_5	.	91	100	58	0
As_2S_3	.	7	0	42	100

According to F. Neher, if hydrogen sulphide be passed into a soln. of an arsenate, mixed with sufficient conc. hydrochloric acid, the pentasulphide is alone precipitated in the cold. He said that the liquid should not contain less than 29 per cent. hydrogen chloride. The reaction was also examined by J. Thiele. According to

L. W. McCay, when a soln. of an alkali arsenate, strongly acidified with hydrochloric acid, and sat. with hydrogen sulphide, is heated in a closed vessel at 100° for one hour, the arsenic is completely converted into pentasulphide; no trisulphide and no free sulphur are formed if air be excluded. He also found that when a slow stream of hydrogen sulphide is passed through an acidified soln. of an arsenate at 70°, besides arsenic pentasulphide there is also formed some free thioxyarsenic acid, H_3AsO_3S . This, under the influence of mineral acids and heat, decomposes into free sulphur and arsenious acid, the latter of which then yields arsenic trisulphide with the hydrogen sulphide. Like L. W. McCay, and unlike F. L. Usher and M. W. Travers, W. Foster found that the reduction of arsenic acid to arsenic trioxide and sulphur by hydrogen sulphide is never direct; monosulphoxyarsenic acid, H_3AsO_3S , is first formed. This is quickly decomposed by acids, and this the more rapidly, the greater the conc. of the acid. A low conc. of hydrogen sulphide also favours the decomposition. When soln. of arsenic acid are treated with a rapid stream of hydrogen sulphide no reduction occurs even if no mineral acid be present, and arsenic pentasulphide is formed. No reduction occurs at 15° when a rapid stream of hydrogen sulphide is passed through a soln. of arsenic acid containing 0.9–32.0 per cent. of hydrochloric acid.

According to F. Wöhler, **sulphur dioxide** reduces arsenic acid in the cold, and more rapidly when heated, and the resulting arsenic trioxide separates from the sat. soln. in octahedral crystals. R. Bunsen said that the reduction of a conc. hydrochloric acid soln. of arsenic acid is complete only with a prolonged boiling, and this results in the loss of much arsenic as volatile chloride. B. Brauner and F. Tomicek found that in the absence of hydrochloric acid, the aq. soln. of arsenic acid is completely reduced to the trioxide when kept for 20 hrs. at 60°; and with a soln. of arsenic acid acidified with sulphuric acid, and sat. with sulphur dioxide, L. W. McCay found that the reduction is completed in an hour when heated in a closed vessel on a water-bath. F. L. Usher and M. W. Travers showed that the progress of the reduction depends on the acidity of the soln. P. E. Browning, P. E. Browning and R. J. Goodman, W. Trautmann, G. Edgar, and V. Auger and L. Odinet observed that when sulphur dioxide is passed into a boiling soln. of arsenic and vanadic acids in 10 per cent. aq. sulphuric acid, very little reduction of arsenic occurs, the result being scarcely affected by the presence or absence of vanadium. If, as recommended by F. A. Gooch, the soln. sat. in the cold with sulphur dioxide, is heated in a closed vessel for an hour on the water-bath, complete reduction to arsenious acid and vanadyl salt takes place. If a trace of potassium iodide is added to a warm soln. containing arsenic, vanadic, and sulphuric acids, reduction by sulphur dioxide may be effected in fifteen minutes in an open vessel. According to C. Himly, **sodium thiosulphate** precipitates arsenic pentasulphide from an aq. soln. of arsenic acid—slowly in the cold, rapidly when heated. Arsenates acidified with hydrochloric acid and boiled with sodium thiosulphate also form the pentasulphide. G. Vortmann said that the precipitation is complete, and that pentathionic acid is formed and little or no sulphuric acid. R. M. Chapin found that the speed of the reaction depends largely on the conc. of the acid, and the course of the reduction by the conc. of the reagents and by the order in which they are mixed—*vide supra*, action of sodium thiosulphate on arsenic trioxide.

G. Gore found that crystals of arsenic acid are very slightly soluble in liquid **ammonia**; and E. Knövenagel and E. Ebler showed that arsenic acid is only slightly reduced to the trioxide after many hours' boiling with **hydrazine salts**. L. Rosenstein said that red **phosphorus** does not reduce arsenic salts. J. Thiele found that **hypophosphorous acid** readily reduces arsenic acid to brown arsenic; and T. Graham observed that with **phosphine**, a soln. of arsenic acid yields a copper-coloured product, possibly arsenic phosphide. For the action of **phosphorus trihalides**, *vide* N. N. Sen's observations with arsenic trioxide. According to H. Hager, **formic acid**, and **oxalic acid** reduce arsenic acid in the presence of sulphuric acid; and C. Patrouillard found that in a boiling soln. arsenic acid and the arsenates

are reduced by oxalic acid. W. A. H. Naylor and J. O. Braithwaite hold that oxalic acid alone exerts no reducing action on arsenates; and any reduction which occurs when oxalic acid and hydrogen sulphide act simultaneously on sodium arsenate is due to the formation of a powerful reducing agent, probably formic acid, when hydrogen sulphide acts on oxalic acid. E. Wedekind and H. Wilke studied the adsorption of arsenic acid by **zirconium hydroxide**. The adsorption of arsenic acid by metal oxides was studied by P. P. Kozakevitch.

The development of arsine by the reducing action of **metals** on soln. of arsenic acid has been indicated in connection with that gas. The deposition of arsenic on **copper** immersed in acidified soln. of arsenic acid is used as a test for the qualitative detection of arsenic. This reaction was discussed by G. Werther, H. Reinsch, C. R. Fresenius and C. H. L. von Babo, J. L. Howe and P. S. Mertins, and E. B. Kenrick. According to A. Colorianu, when an aq. soln. of arsenic acid is heated with copper in a sealed tube for 18 hrs. at 180° – 200° , arsenic trioxide and copper arsenate are formed. According to C. A. Maack, **magnesium** immediately precipitates arsenic from aq. soln. of arsenic acid, gas is evolved at the same time. N. W. Fischer, and F. Mohr found that **zinc, tin, and iron** precipitate metal arsenates, arsine, and arsenic from soln. of arsenic acid. C. A. Maack observed that **aluminium** acts like magnesium, but more slowly. O. C. Johnson found that an alkaline soln. of arsenic acid, and aluminium react: $3\text{As}_2\text{O}_5 + 16\text{Al} + 48\text{KOH} = 6\text{AsH}_3 + 15\text{H}_2\text{O} + 16\text{Al}(\text{OK})_3$. O. Schlickum found that **stannous chloride** behaves towards arsenic acid much as it does with arsenic trioxide. Arsenic acid forms complexes with **molybdic, tungstic, and vanadic acids (g.v.)**. The reaction with magnesia mixture was studied by F. L. Sonnenschein, and H. Struve, and is indicated in connection with some analytical reactions of arsenic. K. Jellinek and W. Kühn studied the reaction between sodium arsenate and **lead nitrate**: $2\text{Na}_3\text{AsO}_4 + 3\text{Pb}(\text{NO}_3)_2 = \text{Pb}_3(\text{AsO}_4)_2 + 6\text{NaNO}_3$; and K. Jellinek and J. Czerwinsky, $\text{Pb}(\text{NO}_3)_2 + \text{Na}_2\text{HASO}_4 = \text{Pb}(\text{HASO}_4) + 2\text{NaNO}_3$ in their application to analytical work.

S. Aschkenasy⁶ prepared **alkali perarsenates**, analogous to the perphosphates and perborates, by the addition of the necessary quantity of alkali to a soln. of barium dioxide in aq. arsenic acid, barium arsenate is precipitated, and the filtrate containing the per-salt is then evaporated with slight warming and under reduced pressure; an aq. soln. of a mixture of sodium dioxide with the primary or secondary alkali salts can also be submitted to evaporation. If a soln. of an arsenate, in dil. hydrogen dioxide, is evaporated to dryness with gentle warming and under reduced press., the corresponding per-salt, for example, sodium perarsenate, can be obtained with scarcely any loss of oxygen.

§ 15. The Ammonium and Alkali Arsenates

P. J. Macquer¹ found that the residue obtained after distilling nitric acid from a mixture of potassium nitrate and arsenic trioxide furnished a crystallizable salt which he called *sel neutre arsenical*. Paracelsus had previously applied the term *arsenicum fixum* to the product obtained by heating a mixture of arsenic trioxide and potassium nitrate; and A. Libavius called it *butyrum arsenici—butter of arsenic*—although this term was used for arsenic trichloride (*q.v.*). These preparations were all impure **alkali arsenates**. C. W. Scheele then prepared a number of arsenates by the action of arsenic acid on the alkalis, etc. C. P. Linville prepared alkali arsenates by roasting speiss with sodium carbonate; and extracting the soluble arsenate from the cold mass.

According to C. F. Rammelsberg,² when arsenic acid is sat. with lithium carbonate, and the clear soln. evaporated for crystals, or treated with ammonia, **lithium orthoarsenate**, Li_3AsO_4 , or $\text{Li}_3\text{AsO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, is formed. A. de Schulten obtained the salt in crystals by fusing the precipitated arsenate in molten lithium chloride, and dissolving out the alkali chloride. The crystals resemble those of lithium orthophosphate, being tabular and rhombic. The sp. gr. is 3.07 at 15°; and they do not fuse at a white heat. The salt is soluble in dil. acids—*e.g.* acetic acid. If a soln. of lithium orthophosphate be mixed with arsenic acid, rhombic prisms of **lithium dihydroarsenate**, $\text{LiH}_2\text{AsO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ can be obtained. The salt is deliquescent, and is decomposed by water into the orthoarsenate and arsenic acids.

The occurrence of sodium arsenate in natural water has been reported by many.

Thus, J. Bouquet³ found traces in the water of Château-neuf, 3 mgrms. per litre in the water of Lusset, 3 mgrms. per litre in the water of Saint Yorre; and also in the water of Vaisse, and of Vichy; E. Willm, 17.2 mgrms. per litre in the water of La Bourboule; A. Moitessier, 0.4 mgrm. per litre in the waters of Montpellier; A. Terreil, 0.4 mgrm. per litre in the waters of Montrond; and T. Husemann, 1.71–1.99 mgrms. per litre in the waters of Val Sinistra.

Many observers have noted the formation of alkali arsenates during the oxidation of arsenical compounds in the presence of potassium salts. Thus, J. W. Slater⁴ oxidized arsenic with potassium permanganate; and F. Jones similarly oxidized arsine. H. O. Schulze oxidized arsenic trioxide by heating it with potassium chlorate, or with an alkali halide in the presence of air or oxygen. D. Tommasi observed the oxidation of the alkali arsenite by electrolytic gas. C. Brame heated arsenic trioxide with alkali hydroxide—arsenic is separated at the same time. H. O. Schulze observed the formation of alkali arsenate by heating the alkali iodide with arsenic pentoxide—some trioxide is formed at the same time; J. Brode and K. Klein oxidized a boiling soln. of arsenic trioxide or an arsenite by air or oxygen under press.

Anhydrous **sodium orthoarsenate**, Na_3AsO_4 , was obtained by E. Mitscherlich by calcining a mixture of the hydroarsenate with an excess of sodium carbonate. An eq. amount of carbon dioxide is given off. S. J. Lloyd and A. M. Kennedy have discussed the electrolytic preparation of sodium arsenate—*vide infra*, calcium arsenate. F. W. Clarke, and H. Stallo gave 2.8128 to 2.8577 for the sp. gr. at 21°. The following are the sp. gr. of the aq. soln. containing the following proportions of the orthoarsenate per 100 parts of soln.:

Na_3AsO_4	0.981	1.962	2.944	4.906	6.868	8.831	9.812
Sp. gr.	1.0167	1.0215	1.0325	1.0547	1.0773	1.1003	1.1120

L. J. Simon studied the viscosity of soln. of arsenic acid progressively treated with soda-lye; and A. Miolati and E. Mascetti, the sp. conductivity. J. Thomsen's, T. Graham's, and E. Baud and A. Astruc's observations on the heats of formation, and P. Walden's experiments on the electrical conductivities of these soln. were discussed in connection with arsenic acid. E. Blanc estimated that of a 0.002N- Na_3AsO_4 soln., 8 per cent. is hydrolyzed. W. G. Mixer gave $3\text{Na}_2\text{O} + \text{As}_2\text{O}_5 = 2\text{Na}_3\text{AsO}_4 + 202.8$ Cals. J. C. Ghosh and S. C. Bisvas measured the extinction coeff. of soln. of sodium arsenate. L. W. McCay, and E. F. Smith and L. K. Frankel were able to deposit copper electrolytically from a soln. containing alkali arsenates without contamination with arsenic; and T. Graham showed that the aq. soln. reacts alkaline; that it attracts carbon dioxide from the air and thereby forms the hydroarsenate; and that other dil. acids, as well as chlorine, iodine, and ammonium nitrate produce a similar result. Ammonia is liberated from ammonium nitrate by the aq. soln. W. Farmer and J. B. Firth found that in the reduction of sodium arsenate by sodium hyposulphite in cold, aq. soln., **sodium arsenohyposulphite**, $\text{Na}_3\text{As}(\text{S}_2\text{O}_4)_3$, is formed; and as this decomposes to form arsenic trisulphide, **sodium arsenothiosulphate** is formed as an intermediate product.

According to G. I. Petrenko, the interaction of hydrogen dioxide and sodium orthoarsenate furnishes a salt with the composition $3\text{Na}_3\text{AsO}_4 \cdot 5\text{H}_2\text{O}_2 \cdot 16\text{H}_2\text{O}$, possibly *decahexahydrate sodium pentahydroperoxytriorthoarsenate*, in which part of the water of crystallization is replaced by hydrogen dioxide. E. P. Alvarez reported **sodium perarsenate**, NaAsO_4 , to be formed by dissolving 100 grms. of sodium hydroarsenate in a mixture of 2000 grms. of water and 2000 grms. of alcohol at 98°, then cooling the vessel containing soln. with ice and salt; finally, 100 grms. sodium dioxide are added by degrees, part of the salt produced is precipitated by the action of 2000 grms. absolute alcohol, the liquid is rapidly filtered on the pump, carefully washed with anhydrous alcohol, the product recovered from the filter, and finally dried in a vacuum and in presence of phosphorus anhydride.

E. P. Alvarez found that the perarsenates react with soln. of lead acetate (white precipitate), silver nitrate (white precipitate), mercurous nitrate (white precipitate with rapid decomposition), mercuric chloride (red precipitate), copper sulphate (blue precipitate), zinc and cadmium sulphates (white precipitate), bismuth nitrate (white precipitate), gold chloride (slight effervescence and escape of oxygen), manganous chloride (pink precipitate), nickelous chloride or sulphate (greenish-white precipitate), cobaltous nitrate and chloride (pink precipitate), ferrous sulphate (green or bluish-green precipitate), ferric chloride (red ferric hydroxide), and alkaline earth chlorides (white precipitates). The precipitates are all per-salts of the bases in question.

J. A. Hall said that an aq. soln. of 25 grms. of sodium hydroarsenate in 10 c.c. of 50 per cent. sodium hydroxide at 80° deposits crystals of the *hemihydrate*, $\text{Na}_3\text{AsO}_4 \cdot 4\frac{1}{2}\text{H}_2\text{O}$; and that a soln. of 100 grms. of the hydroarsenate in 150 c.c. of 50 per cent. soda-lye deposits crystals of the *decahydrate*, $\text{Na}_3\text{AsO}_4 \cdot 10\text{H}_2\text{O}$, when kept a long time at 77°. O. Schairer treated a sat. soln. of arsenic trioxide—cooled by ice—with an excess of sodium dioxide; evaporated the filtered soln. to about half its bulk on a water-bath, and crystallized by cooling the soln. The cubic crystals resemble those of the corresponding vanadate. J. A. Hall said that they effloresce in dry air; and melt at 85°. T. Graham prepared the *dodecahydrate*, $\text{Na}_3\text{AsO}_4 \cdot 12\text{H}_2\text{O}$, by evaporating a conc. soln. of sodium hydroarsenate, mixed with one and a half times as much sodium hydroxide as it already contains, and recrystallizing the product from hot water. K. Preis observed its formation when a soln. of arsenic trioxide acts on calcium sulphide. The prismatic crystals were shown by H. Dufet, and H. B. Baker to belong to the hexagonal system, and they are isomorphous with the corresponding phosphate. H. Schiff gave 1.762 for the sp. gr.; L. Playfair and J. P. Joule, 1.804 at 3.9°; and H. Dufet, 1.7593. H. Schiff found that the aq. soln. sat. at 17° has a sp. gr. 1.1186. T. Graham gave 85.5° for the m.p. H. Dufet found the refractive indices for sodium light to be $\omega = 1.4567$, and $\epsilon = 1.4662$; and for Li-, Na-, and Tl-light, H. B. Baker gave respectively $\omega = 1.4553$, 1.4589, and 1.4624; and $\epsilon = 1.4630$, 1.4669, and 1.4704. E. Doumer gave for the mol. refraction 61.4. T. Graham said that the crystals are stable in dry air, and at 15.5°, 100 grms. of water dissolve 38.9 grms. of the salt. H. Schiff said that 100 parts of water at 17° dissolve 16.7 parts of salt; and C. F. Wenzel, that 100 parts of alcohol dissolve 1.67 parts of sodium arsenate. For the action of many reagents—permanganates, etc.—*vide* arsenic trioxide. L. Kahlenberg and W. J. Trautmann observed no-reaction with silicon at comparatively low temp., but in the arc, a black slag is formed.

According to E. Mitscherlich, C. R. Fresenius, and R. Wagner, hydrated **sodium hydroarsenate**, Na_2HAsO_4 , is produced when a soln. of arsenic acid is mixed with a large excess of sodium carbonate, and allowed to crystallize. C. de Freycinet, J. Higgin, and A. Streng made the salt on a manufacturing scale by mixing a soln. of arsenic trioxide in soda-lye with sodium nitrate, evaporating to dryness, and calcining in a reverberatory furnace. The residue was extracted with dil. soda-lye, and allowed to crystallize. H. Lescoeur found that at temp. above 23° the soln. deposits crystals of the *heptahydrate*, $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$. L. Gmelin found the heptahydrate is produced by exposing the dodecahydrate in air; and G. C. Fleury, by leaving the commercial salt exposed to moist air. This salt was also made by H. Salkowsky, F. C. B. Schiefer, O. Hörmann, and T. Clark. G. P. Baxter and F. B. Coffin prepared the alkali hydroarsenate of a high degree of purity for their determination of the at. wt. of arsenic. According to A. Rosenheim and S. Thon, in the ternary system: $\text{As}_2\text{O}_5 - \text{Na}_2\text{O} - \text{H}_2\text{O}$ at 0°, there is no evidence of the existence of polyarsenates. The solid phase with the percentage proportions $\text{As}_2\text{O}_5 : \text{Na}_2\text{O}$ above 54.16 : 5.36 is the hemihydrate, $2\text{H}_2\text{AsO}_4 \cdot \text{H}_2\text{O}$; from this to the proportions 38.03 : 10.25, the monohydrate, $\text{NaH}_2\text{AsO}_4 \cdot \text{H}_2\text{O}$, is the solid phase; and from this stage to 3.35 : 1.81, the solid phase is the *dodecahydrate*, $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$. The solubility curves show that the dodecahydrate

has a transition temp. at 22° above which the heptahydrate is formed. The percentage solubility, *S*, of sodium hydroarsenate, is :

<i>S</i>	0°	8·6°	11·8°	16·0°	21·0°	22·5°	28°	30·1°	34·0°	
	5·46	9·66	12·53	17·30	25·75	26·75	30·48	32·34	35·09	per cent.
	$\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$					$\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$				

The prismatic or tabular crystals, said W. Haidinger, J. J. Bernhardt, C. M. Marx, E. Mitscherlich, and C. F. Rammelsberg, belong to the monoclinic system, and H. Dufet gave for the axial ratios : $a : b : c = 1.2294 : 1 : 1.3526$, and $\beta = 97^\circ 14'$; the cleavage on the (100)-face is well-developed. The optic axial angles for Li-, Na-, and Tl-light were found by H. Dufet to be respectively $2V = 57^\circ 32'$, $57^\circ 7'$, and $56^\circ 43'$; and $2E = 89^\circ 28'$, $88^\circ 59'$, and $38^\circ 29'$. These angles are greater at higher temp. The sp. gr. is 1.8825—H. Schiff gave 1.87. According to O. Hörmann, the crystals melt at 120°–130°, they lose their combined water at 180°, and form a colourless liquid which solidifies to a radiating mass of crystals. H. Lescoeur gave for the dissociation press., *p* mm. :

<i>p</i>	0°	5°	10°	20°	30°	40°	60°	80°	100°
	1	1.2	2.1	4.6	15	29	77	188	424

and if the hydroarsenate has more than 7 mols. of water, the dissociation press. at 20° is greater, being 16 mm. with 7.07 mols. of water; 15.8 mm. with 7.26 mols.; and 16 mm. with 12 mols. H. Dufet found the double refraction to be positive; and the indices of refraction for Li-, Na-, and Tl-light to be respectively $\alpha = 1.4587$, 1.4622, and 1.4654; $\beta = 1.4623$, 1.4658, and 1.4689; and $\gamma = 1.4746$, 1.4782, and 1.4814. The dispersion is small. P. Walden gave for the eq. conductivity of soln. with $\frac{1}{2}\text{Na}_2\text{HAsO}_4$ mols. per *v* litres :

<i>v</i>			32	64	128	256	512	1024	∞
μ			79.0	84.7	88.8	92.0	94.4	95.9	103.8

T. Clark said that the salt does not effloresce in warm air; and H. Lescoeur, that it absorbs water vapour at a low temp. without becoming moist. F. E. Brown and J. E. Snyder observed a reaction with the hydroarsenate and vanadium oxytrichloride.

According to E. Mitscherlich, R. F. Marchand, and C. R. Fresenius, the aq. soln. of sodium hydroarsenate in the cold deposits crystals of the *dodecahydrate*, $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$ —while J. Setterberg, and P. von Kotschoubey said 13 mols. C. Tomlinson found that the aq. soln. is easily obtained supersaturated. E. Mitscherlich found the monoclinic prismatic crystals to be isomorphous with those of the corresponding phosphate, and H. Dufet gave for the axial ratios $a : b : c = 1.7499 : 1 : 1.4121$, and $\beta = 121^\circ 49'$. H. Dufet found the optic axial angle $2V = 65^\circ 13'$, $65^\circ 13'$, and $65^\circ 12'$ respectively for Li-, Na-, and Tl-light. T. Thomson gave 1.759 for the sp. gr.; L. Playfair and J. P. Joule, 1.736 at 3.9°; H. Schiff, 1.670; and H. Dufet, 1.6675. H. Schiff found the sp. gr. of soln. containing the following number of grams per 100 c.c. at 14° :

Na_2HAsO_4	5	10	15	20	25	30	35	40
Sp. gr.	1.0212	1.0434	1.0665	1.0904	1.1153	1.1410	1.1677	1.1952

As indicated above, H. Lescoeur measured the dissociation press. W. A. Tilden gave 28° for the m.p. H. Dufet found that the bi-refringence is negative and the indices of refraction for Li-, Na-, and Tl-light to be respectively $\alpha = 1.4420$, 1.4453, and 1.4482; $\beta = 1.4462$, 1.4496, and 1.4513; and $\gamma = 1.4480$, 1.4513, and 1.4545. H. de Sénarmont made some observations on this subject. R. Robl observed no fluorescence occurs when the salt is exposed to ultra-violet light. The observations of P. Walden on the electrical conductivity of the soln. have been discussed in connection with arsenic acid. E. Blanc estimated that in 0.002*N*- Na_2HAsO_4 soln., 0.0455 per cent. is hydrolyzed. A. Borel gave for

the dielectric constants k , 7.26; k_2 , 5.91; and k_3 , 5.28. T. Clark found that the crystals effloresce in dry air and form the heptahydrate. W. A. Tilden said that 100 parts of water at 0° dissolve 17.2 parts of the dodecahydrate, and at 30°, 140.7 parts. H. Schiff gave 56 parts at 14°; and T. Thomson, 22.268 parts at 7.2°. B. E. Curry and T. O. Smith studied the solubility of the salt in soln. of lead nitrate—*vide infra*, lead hydroarsenate. P. von Kotschoubey said that the conc. aq. soln. becomes turbid when warmed, and deposits the heptahydrate. K. H. Butler and D. McIntosh found sodium arsenate to be insoluble in liquid chlorine. When the hydroarsenate is calcined it forms what has been regarded as **sodium pyroarsenate**, $\text{Na}_4\text{As}_2\text{O}_7$. O. Hörmann said that this change occurs at 250°. C. M. Marx described this product as a fibrous mass with a silky lustre. T. Clark, F. C. B. Schiefer, and P. Walden said that when the pyroarsenate is dissolved in water it behaves like the orthophosphate; and they questioned the existence of the pyroarsenate. E. Soubeiran said that when heated in hydrogen gas, arsenic is given off and sodium hydroxide formed.

According to E. Mitscherlich, hydrated **sodium dihydroarsenate**, NaH_2AsO_4 , is formed by adding arsenic acid to an aq. soln. of sodium carbonate until the liquid no longer gives a precipitate with barium chloride, evaporating, and leaving the soln. to stand for some time in a cold place. O. Hörmann made this salt by fusing arsenic trioxide with sodium nitrate, in eq. proportions, and crystallizing the salt from the aq. soln. P. Walden's values for the electrical conductivity of the aq. soln. have been discussed in connection with arsenic acid. The *monohydrate*, NaH_2AsO_4 , crystallizes normally from the cold aq. soln. E. Mitscherlich said that the well-defined, rhombic crystals are isomorphous with those of the corresponding phosphate. A. Joly and H. Dufet said that the rhombic, bisphenoidal crystals have the axial ratios $a:b:c=0.9177:1:1.6039$. The optic axial angles for Li-, Na-, and Tl-light are respectively $2V=67^\circ 15'$, $67^\circ 57'$, and $68^\circ 33'$, and $2E=118^\circ 11'$, $120^\circ 28'$, and $122^\circ 33'$. The monohydrate is dimorphous. H. Dufet said that if the crystals are deposited from warm soln., monoclinic crystals are formed with the axial ratios $a:b:c=1.087:1:1.1588$, and $\beta=92^\circ 22'$. The monoclinic crystals rapidly become turbid, without change in weight, forming the rhombic crystals. H. Dufet gave 2.6700 for the sp. gr. of the monoclinic form; and for the ordinary, rhombic, monohydrated crystals 2.6700; and H. Schiff gave 2.535. H. Dufet found the indices of refraction for Li-, Na-, and Tl-light are respectively $\alpha=1.5341$, 1.5382, and 1.5418; $\beta=1.5494$, 1.5535, and 1.5573; and $\gamma=1.5563$, 1.5607, and 1.5647. O. Hörmann said that the salt loses its water of crystallization at 100°–130°; and at 200°–280°, passes into **sodium metarsenate**, NaAsO_3 . The product obtained by J. Higgin, and A. Streng—*vide supra*—was supposed to have been the metarsenate. According to C. Lefèvre, if the salt be heated to redness in a stream of hydrogen or carbon monoxide, nearly all the arsenic is expelled. T. Graham, and P. Walden said that the metarsenate forms the dihydroarsenate when dissolved in water. According to A. Joly and H. Dufet, if the aq. soln. of the dihydroarsenate be conc. to a sp. gr. 1.7, crystals of the *dihydrate*, $\text{NaH}_2\text{AsO}_4 \cdot 2\text{H}_2\text{O}$, are formed in rhombic octahedra, isomorphous with those of the corresponding phosphate. The rhombic crystals have the axial ratios $a:b:c=0.9177:1:1.6039$; the optic axial angles are for Na-light $2V=89^\circ 11'$; for Li-light, $88^\circ 40'$; and for Tl-light, $88^\circ 57'$. The sp. gr. is 2.309; the indices of refraction for Na-light, $\alpha=1.4794$, $\beta=1.5021$, and $\gamma=1.5265$. The crystals effloresce in air.

E. Filhol and J. B. Senderens reported that when a soln. of arsenic acid is neutralized by sodium hydroxide, with litmus as indicator, and evaporated to a syrupy liquid, it furnishes monoclinic crystals of a complex acid salt, $\text{Na}_3\text{AsO}_4 \cdot \text{H}_3\text{AsO}_4 \cdot 3\text{H}_2\text{O}$, **sodium trihydrodiorthoarsenate**, $\text{Na}_3\text{H}_3(\text{AsO}_4)_3 \cdot 3\text{H}_2\text{O}$. When heated, the salt loses its water of crystallization, without melting; it melts at a higher temp. They also obtained monoclinic pyramids of **sodium potassium trihydrodiorthoarsenate**, $\text{K}_3\text{Na}_3\text{H}_6(\text{AsO}_4)_4 \cdot 9\text{H}_2\text{O}$; and of **sodium ammonium trihydrodiorthoarsenate**, $\text{Na}_3(\text{NH}_4)_3\text{H}_6(\text{AsO}_4)_4 \cdot 6\text{H}_2\text{O}$.

E. Mitscherlich prepared anhydrous **potassium orthoarsenate**, K_3AsO_4 , by heating a mixture of the hydroarsenate with potassium carbonate as in the case of the sodium salt. T. Graham also found that this salt crystallizes in deliquescent needles from a soln. of arsenic acid in an excess of potash-lye. L. J. Simon studied the viscosity of soln. of arsenic acid progressively treated with potash-lye. According to A. Naumann, the salt is insoluble in ethyl acetate. C. W. Scheele obtained **potassium hydroarsenate**, $K_2HASO_4 \cdot H_2O$, by adding potassium carbonate to a soln. of arsenic acid so long as effervescence continues. He was unable to make the soln. crystallize, and obtained the solid by evaporating the soln. to dryness, and fusing the product to form a white glass. O. Hörmann obtained the salt in triclinic prisms with the composition just indicated. The crystals lose their water of crystallization at 110° – 125° , and, at a higher temp., form a white glass alleged to be *potassium pyroarsenate*, $K_4As_2O_7$ —*vide supra*, sodium pyroarsenate. C. W. Scheele said that the aq. soln. of this salt colours the juice of violets green; R. T. Thomson found that the salt is neutral towards litmus, rosolic acid, methyl-orange, and phenacetolin; and alkaline towards phenolphthalein, and lacmoid—*vide supra*, arsenic acid. E. Mitscherlich prepared **potassium sodium hydroarsenate**, $KNaHASO_4 \cdot 7H_2O$, by neutralizing potassium dihydroarsenate with sodium carbonate. The crystals were said to be isomorphous with the corresponding sodium salt. P. von Kotschoubey considered the salt had 9 mols. of water of crystallization; E. Mitscherlich, 8 mols.; and H. Schiff, 7 mols. H. Schiff gave 1-884 for the sp. gr., and he found the crystals do not effloresce in air.

P. J. Macquer, L. Glaser, and O. Hörmann melted together equal parts of arsenic trioxide and potassium nitrate, and found that **potassium dihydroarsenate**, KH_2AsO_4 , crystallized from the aq. soln. E. Mitscherlich obtained it by crystallization from a mixture of arsenic acid with an aq. soln. of potassium carbonate so long as the soln. reddens litmus; and from a soln. of potash-lye and arsenic acid, neutral to vegetable colours. The crystals are stable in air, and they are isomorphous with the corresponding potassium and ammonium dihydrophosphates, and with ammonium dihydroarsenate. W. Muthmann said that the potassium dihydrophosphate and dihydroarsenate form mixed crystals in all proportions. H. Töpsöe gave for the axial ratio of the tetragonal crystals $a : c = 1 : 0.9380$; H. Braumhauer found the corrosion figures to correspond with those of the corresponding phosphate. O. Hassel found the tetragonal crystals isomorphous with those of the ammonium salt, and with those of the corresponding phosphates. T. Thomson gave 2.638 for the sp. gr.; H. Schiff, 2.832; and H. Töpsöe, 2.862; H. G. F. Schröder, 2.851 at 4° ; W. Muthmann, 2.868; and B. Gossner, 2.879. T. Thomson found that the sat. aq. soln. at 6° has a sp. gr. 1.1134. V. von Lang observed that the ratio of the thermal conductivities $a : c = 1 : 0.88$. H. Kopp gave 0.175 for the sp. ht., and H. V. Regnault for the fused salt, $KAsO_3$, 0.156. J. C. G. de Marignac found the sp. ht. of soln. of sodium dihydroarsenate, NaH_2AsO_4 , with 200, 100, and 50 mols. of water to be respectively 0.9595, 0.9264, and 0.8107; and sodium hydroarsenate, Na_2HASO_4 , with 200, 100, and 50 mols. of water 0.9500, 0.9112, and 0.8550 respectively. N. de Kolossowsky discussed this subject. F. M. Raoult measured the lowering of the f.p. of water and found for the sp. lowering of the f.p. 0.168, and for the mol. lowering of the f.p., 30.2. T. Graham gave -4.9 Cals. for the heat of dissolution in water. H. Töpsöe and C. Christiansen gave for the indices of refraction with the *C*-, and *F*-, and *D*-lines respectively $\omega = 1.5632$, 1.5674, and 1.5762; and $\epsilon = 1.5146$, 1.5179, and 1.5252. P. Walden's observation on the electrical conductivity of aq. soln. of this salt were discussed in connection with arsenic acid. V. von Lang found the ratio of the diamagnetic induction for $a : c$ to be $1 : 0.715$. T. Thomson said that the salt loses only a little water at 288° ; and O. Hörmann showed that no water is lost at 140° , and one mol. at 240° – 290° . T. Thomson stated that the salt passes into *potassium metarsenate* at a dull red-heat; and at a higher temp. C. Friedheim found that oxygen is given off. The fused masses obtained by P. J. Macquer, T. Thomson,

L. Glaser, and O. Hörmann are sometimes supposed to be the metarsenate; but F. C. B. Schiefer, O. Hörmann, and P. Walden showed that when dissolved in water, the dihydroarsenate is formed. T. Thomson found that 100 parts of water at 6° dissolve 18.87 parts of the dihydroarsenate; that the salt is freely soluble in hot water, and insoluble in alcohol. C. F. Wenzel said that 100 parts of boiling alcohol dissolve 0.0037 part of the salt. The aq. soln. tastes like nitre. E. Mitscherlich found that the alkaline earth salts do not give precipitates with aq. soln. of this salt. The aq. soln. of the dihydroarsenate reddens blue litmus; and, according to R. T. Thomson, it is neutral towards lacmoid and phenolphthalein—*vide supra*, arsenic acid. C. Friedheim reported that fine, feathery crystals of the *monohydrate*, $\text{KH}_2\text{AsO}_4 \cdot \text{H}_2\text{O}$, can be formed by crystallizing a soln. of a mol of the dihydrophosphate and a mol of arsenic acid, over conc. sulphuric acid. C. Neuberg and M. Kobel said that potassium arsenate inhibits the combination of sucrose and phosphoric acid.

According to A. Bouchonnet, **rubidium orthoarsenate**, Rb_3AsO_4 , is obtained by neutralizing a soln. of rubidium hydroxide with arsenic acid using Porrier's blue as an indicator. The soln. deposits hygroscopic lamellæ of the *dihydrate*, $\text{Rb}_3\text{AsO}_4 \cdot 2\text{H}_2\text{O}$, which become anhydrous at 100°. The salt absorbs carbon dioxide from the air, and the soln. is alkaline to litmus, methyl-orange, and phenolphthalein. He also made **rubidium hydroarsenate**, Rb_2HAsO_4 , by mixing aq. soln. of rubidium hydroxide and the dihydroarsenate in molar proportions. It deposits hygroscopic lamellæ of the *monohydrate*, $\text{Rb}_2\text{HAsO}_4 \cdot \text{H}_2\text{O}$, which become anhydrous at 100°. At 150°, **rubidium pyroarsenate**, $\text{Rb}_4\text{As}_2\text{O}_7$, is formed. Rubidium hydroarsenate absorbs carbon dioxide from the air, and more rapidly when in aq. soln. The soln. is neutral to litmus, and methyl-orange, and alkaline to phenolphthalein. A. Bouchonnet also obtained **rubidium dihydroarsenate**, RbH_2AsO_4 , by melting together equal parts of arsenic trioxide and rubidium nitrate. It forms tabular crystals, or, when prepared by neutralizing rubidium carbonate soln. with arsenic acid, using methyl-orange as indicator, it forms silky needles. Both forms are anhydrous, and the aq. soln. is acid to litmus, neutral to methyl-orange, and phenolphthalein. The arsenate, when heated to dull redness, loses water and forms **rubidium metarsenate**, RbAsO_3 , a milky-white, crystalline mass which decomposes at a bright red-heat. F. Ephraim and H. Herschfinkel reported white, well-developed crystals of **cæsium paratetrarsenate**, $\text{Cs}_2\text{As}_4\text{O}_{11} \cdot 5\text{H}_2\text{O}$, by the action of an excess of arsenic on a nitric acid soln. of cæsium hydroxide in the presence of molybdic acid.

E. Mitscherlich, and H. Uelsmann found that if a conc. soln. of ammonium hydroarsenate is mixed with aq. ammonia, it solidifies to a magma of crystals of **ammonium orthoarsenate**, $(\text{NH}_4)_3\text{AsO}_4 \cdot 3\text{H}_2\text{O}$, which can be washed with aq. ammonia, and dried by press. between bibulous paper. E. Mitscherlich, and H. Salkowsky obtained the same salt by cooling a conc. soln. of arsenic acid in warm aq. ammonia, and he found that the crystals belong to the rhombic system. They can be recrystallized from hot, aq. ammonia. E. Mitscherlich said that on exposure to air ammonia is given off, and the hydroarsenate remains; and H. Uelsmann, that when the ammoniacal soln. is boiled ammonia is lost and the dihydroarsenate is formed. H. Stamm measured the solubility of the salt in aq. ammonia. H. Uelsmann also reported **diammonium sodium orthoarsenate**, $(\text{NH}_4)_2\text{NaAsO}_4 \cdot 4\text{H}_2\text{O}$, to be formed from a sat. soln. of ammonium sodium hydroarsenate in conc. ammonia. The tabular crystals lose half their ammonia when confined over 5 per cent. sulphuric acid. A. Miolati and E. Mascetti studied the sp. electrical conductivity when arsenic acid is progressively neutralized with ammonia.

C. W. Scheele, E. Mitscherlich, and H. Salkowsky prepared **ammonium hydroarsenate**, $(\text{NH}_4)_2\text{HAsO}_4$, by adding ammonia to a conc. aq. soln. of arsenic acid until a precipitate is formed, warming the liquid until the precipitate dissolves, and allowing the soln. to crystallize. A crop of the normal salt may be first

deposited, but this soon forms the hydroarsenate on exposure to air. From time to time, ammonia should be added to the exposed liquid or crystals of the dihydroarsenate will be formed. The monoclinic, prismatic crystals are isomorphous with those of the corresponding phosphate. E. Mitscherlich, and C. F. Rammelsberg gave for the axial ratios $a : b : c = 0.918 : 1 : 1.1715$, and $\beta = 91^\circ 13'$. H. Schiff found the sp. gr. to be 1.99. C. W. Scheele observed that when the salt is heated it decomposes into ammonia, water, arsenic, and nitrogen; and E. Mitscherlich, that on exposure to air it yields the dihydroarsenate. C. W. Scheele said that the aq. soln. colours violet-juice green. E. Mitscherlich obtained **ammonium sodium hydroarsenate**, $(\text{NH}_4)\text{NaHASO}_4 \cdot 4\text{H}_2\text{O}$, by crystallization from equal parts of sodium and ammonium hydroarsenates; and H. Uelsmann, by evaporating a soln. of six parts of sodium dihydroarsenate, and one part of ammonium chloride in aq. ammonia. The monoclinic crystals are like those of the corresponding phosphate. J. M. Thomson and W. P. Bloxam found that neither of the component salts will induce the crystallization of the complex salt. H. Schiff gave 1.838 for the sp. gr. when the salt is calcined, E. Mitscherlich said that sodium metarsenate remains.

The salt prepared by P. J. Macquer by heating a mixture of arsenic trioxide and ammonium nitrate, and crystallizing the aq. soln. of the product, was probably **ammonium dihydroarsenate**, $\text{NH}_4\text{H}_2\text{AsO}_4$. This salt was obtained by E. Mitscherlich by evaporating a soln. of arsenic acid saturated with ammonia; and by exposing the hydroarsenate to air. The tetragonal crystals are isomorphous with the corresponding phosphate. H. Töpsöe gave for the axial ratio $a : c = 1 : 1.0035$. No marked cleavage was observed; and H. Baunhauer found the corrosion figures resembled those of the corresponding phosphate. O. Hassel found the tetragonal crystals isomorphous with those of the corresponding potassium salt, and with those of the corresponding phosphates. H. Schiff gave 2.259 for the sp. gr.; H. Töpsöe, 2.308; H. G. F. Schröder, 2.307; W. Muthmann, 2.311; and B. Gossner, 2.317. V. von Lang found the ratio of the thermal conductivities $a : c = 1 : 0.84$; H. de Sénarmont, and H. Töpsöe and C. Christiansen found the indices of refraction for the C-, D-, and F-lines to be respectively $\omega = 1.5721$, 1.5766, and 1.5859; and $\epsilon = 1.5186$, 1.5217, and 1.5296. V. von Lang found the ratio of the diamagnetic induction to be $a : c = 1 : 0.715$. The salt deliquesces in air; and it is sparingly soluble in water—the aq. soln. has an acid reaction. When the salt is decomposed by heat, H. Salkowsky observed the formation of arsenic, arsenic trioxide, and nitrogen, but no ammonia.

V. Kohlschütter and K. A. Hofmann obtained **hydroxylamine orthoarsenate**, $(\text{NH}_3\text{OH})_3\text{AsO}_4$, by mixing an aq. soln. of arsenic acid with an excess of sodium carbonate, and adding hydroxylamine monochloride until the soln. is feebly acid. In a short time feather crystals, resembling the corresponding phosphate, are deposited. The salt is sparingly soluble in cold water, and it can be recrystallized from hot water. It forms microscopic, rhombic prisms; the hot aq. soln. has an acidic reaction; it reduces Fehling's soln., and an ammoniacal soln. of silver nitrate.

§ 16. Arsenates of the Copper-Gold Family

W. Hampe¹ reported the formation of cuprous pyroarsenate, $\text{Cu}_4\text{As}_2\text{O}_7$, by fusing a mixture of equal parts of cupric oxide and arsenic pentoxide in an atm. of carbon dioxide. At a white-heat, this substance gives off arsenic trioxide, forming red cuprous diarsenate, $\text{Cu}_8\text{As}_2\text{O}_9$, or $4\text{Cu}_2\text{O} \cdot \text{As}_2\text{O}_5$. The pyroarsenate furnishes

potassium arsenate when boiled with potash-lye. Evidence for the chemical individuality of W. Hampe's product is wanting. C. Reichard also prepared cuprous pyroarsenate by adding sodium arsenate to an excess of a soln. of cuprous sulphate. This substance is decomposed by heat; it is soluble in aq. ammonia, and in potash-lye. The ammoniacal soln. gives the original salt on evaporation; and the alkaline soln. deposits cuprous oxide on standing.

J. J. Berzelius,² J. L. Proust, J. F. Simon, A. Vogel, E. Mitscherlich, and A. Hirsch reported that when cupric salt soln. are treated with sodium hydroarsenate, a pale blue precipitate is formed. H. Salkowsky said that the filtrate reacts acid when ammonium hydroarsenate is the precipitating agent. The Farbenindustrie A.G. treated basic cupric chloride with an arsenate or arsenic acid. R. Chenevix obtained blue rhombohedral crystals from the acid liquid left after mixing a soln. of copper nitrate with ammonium arsenate. W. Skey did not succeed in producing crystallized copper arsenate by adding a soluble arsenate to a soln. of a copper salt: a green precipitate was produced by dissolving copper arsenide in nitric acid, and adding enough sodium hydroxide to give a ratio Na : As = 2 : 1 by weight. These arsenates were not analyzed so that their empirical composition is unknown. A similar remark applies to the arsenate obtained by A. C. Becquerel, by dipping a strip of copper in silver arsenate immersed under water. The green crystals deposited on the copper are thought to be **cupric orthoarsenate**, $\text{Cu}_3(\text{AsO}_4)_2$. This compound was made by A. Coloriano, and C. Friedel and E. Sarasin by heating to 180°–200° for 18 hrs. in a sealed tube a mixture of 2 grms. of copper, and 32 c.c. of a soln. containing 4.5 grms. of arsenic acid, and separating the copper and arsenic trioxide from the crust of crystals. The green triclinic prisms or plates become dark green when heated; they are insoluble in water, soluble in hydrochloric acid, and are attacked with difficulty by other acids. W. Ipatieff and co-workers observed that copper arsenate, when heated with hydrogen, under press., furnishes copper, copper arsenite and arsenide, arsine, and arsenious acid. H. Debray said that the *monohydrate*, $\text{Cu}_3(\text{AsO}_4)_2 \cdot \text{H}_2\text{O}$, is obtained as a blue powder when a mixture of cupric orthoarsenate and nitrate is heated to 50° or 60°. When heated with water or an aq. soln. of cupric nitrate, the basic salt, $\text{CuO} \cdot \text{Cu}_3(\text{AsO}_4)_2 \cdot \text{H}_2\text{O}$, or copper hydroxyorthoarsenate, $\text{Cu}(\text{AsO}_4)\text{CuOH}$, is formed. A. Hirsch obtained a higher hydrate, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 4$ to $7\text{H}_2\text{O}$, by drying in air the precipitates obtained by treating silver orthoarsenate with a cold soln. of cupric chloride, or by mixing sodium hydroarsenate with an excess of cupric sulphate. P. P. Kosakewitsch obtained the *tetrahydrate*, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 4\text{H}_2\text{O}$, by the action of arsenic acid on copper oxide. T. Shiomu and K. Otsu converted the copper orthoarsenate, produced in the electrodeposition, into calcium arsenate for use as an insecticide.

According to A. Naumann, copper arsenate is insoluble in methyl acetate; J. Schröder, insoluble in pyridine; and E. C. Franklin and C. A. Kraus, insoluble in liquid ammonia. L. Kahlenberg and J. V. Steinle found that arsenic, immersed in a sat. soln. of copper arsenate, reacts: $\text{Cu}_3(\text{AsO}_4)_2 + 2\text{As} = 3\text{Cu} + \text{As}_2\text{O}_3 + \text{As}_2\text{O}_5$. L. Gmelin found that if a soln. of basic cupric arsenate in aq. ammonia be allowed to crystallize; and A. Girard, C. Reichard, and A. Damour, that if a soln. of the diarsenate in aq. ammonia mixed with alcohol be spontaneously evaporated, sky-blue prismatic crystals are formed—triclinic, according to A. Damour; rhombic, according to C. Reichard. The salt is **cupric triaminorthoarsenate**, $\text{Cu}_3(\text{AsO}_4)_2(\text{NH}_3)_3 \cdot 4\text{H}_2\text{O}$. The salt loses water and ammonia at 300°; and at dull redness it gives off arsenic oxide, and the brick-red residue melts at a higher temp. The salt is soluble in hot and cold water; soluble in hydrochloric acid; and it does not decolorize potassium permanganate.

A. Frenzel obtained from Schneeberg, and Zirkwald, rhombic prisms of an emerald-green mineral which he called **chlorotile**. Its composition approximates the *hexahydrate*, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O}$. S. G. Gordon suggested that chlorotile and mixite are the same mineral species. P. Groth represents the hexahydrate as a basic salt: $(\text{CuOH})_3\text{AsO}_4 \cdot \text{Cu}(\text{OH})_2$. A mineral obtained by R. Hermann as an incrustation on the tetrahedrite in the Turginsk

copper mine was called **trichalcite**, and the analysis was supposed to agree with the *pentahydrated*, normal arsenate, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 5\text{H}_2\text{O}$; according to C. F. Rammelsberg, the analysis agrees better with the formula of the basic salt $10\text{CuO} \cdot 3\text{As}_2\text{O}_5 \cdot 16\text{H}_2\text{O}$, or $\text{Cu}_{10}\text{O}(\text{AsO}_4)_6$. Trichalcite occurs in verdigris-green radiating groups or columns, and in dendritic forms. Its hardness is 2.5. E. S. Larsen found the optic axial angle large; the optical character negative; and the indices of refraction $\alpha=1.67$, $\beta=1.686$, and $\gamma=1.698$. A lavender-blue mineral found at Annaberg, Saxony, was named by A. Breithaupt, **lavendulanite**, or rather *lavendulan*. E. Goldsmith's analysis of very impure sample from Chili corresponds with the *trihydrate*, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$. E. Goldsmith found up to 1.35 per cent. of nickel oxide, and 2.51 per cent. of cobalt oxide; he therefore wrote the formula $(\text{Cu}, \text{Co}, \text{Ni})_3(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$. P. Groth used the formula $\text{Cu}_3(\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$ for the idealized mineral. W. F. Foshag regarded it as a cupriferous erythrite, and gave for the indices of refraction $\beta=1.715$, and $\gamma=1.725$.

A. Coloriano prepared **cupric hydroarsenate**, $\text{CuHAsO}_4 \cdot \text{H}_2\text{O}$, by the spontaneous evaporation of an acid soln. of copper carbonate in arsenic acid; H. Debray obtained the same salt by evaporating the soln. at 70° . According to H. Goguel, the pale blue, monoclinic plates are pleochroic. R. Robl observed no fluorescence when the salt is exposed to ultra-violet light. A. Coloriano said that when the salt is boiled with water, a basic salt, $\text{CuO} \cdot \text{Cu}_3(\text{AsO}_4)_2 \cdot \text{H}_2\text{O}$, is formed. According to H. Schiff, if a soln. of the freshly precipitated hydroarsenate in aq. ammonia be evaporated over quicklime, a pale blue powder is formed which is free from water, and is stable in air. Its composition corresponds with **cupric diamminohydroarsenate**, $\text{CuHAsO}_4 \cdot 2\text{NH}_3$; and if in contact with water it swells up, forming the *monohydrate*, $\text{CuHAsO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$. When heated, both water and ammonia are given off; and it loses its water of crystallization at 30° over sulphuric acid.

A. Hirsch and others have reported a series of acid salts. Thus, A. Hirsch said that a salt, $8\text{CuO} \cdot 3\text{As}_2\text{O}_5 \cdot 12\text{H}_2\text{O}$, corresponding with $\text{Cu}_3(\text{AsO}_4)_2 \cdot \text{CuHAsO}_4 \cdot 5\frac{1}{2}\text{H}_2\text{O}$, **cupric hydrotriorthoarsenate**, $\text{Cu}_4\text{H}(\text{AsO}_4)_3 \cdot 5\frac{1}{2}\text{H}_2\text{O}$, is obtained as a blue precipitate by treating a soln. of 2 mols. of sodium hydroarsenate with 5 mols. of copper nitrate, and washing the product for many days. H. Salkowsky mixed a soln. of cupric sulphate with an excess of ammonium hydroarsenate and obtained a blue precipitate almost free from ammonia. E. Mitscherlich remarked on the acid character of the liquid obtained in this reaction. A. Hirsch said that if the pale blue product be dried in air, it retains $9\frac{1}{2}$ mols. of water, forming the *hemineadecahydrate*, $\text{Cu}_5\text{H}_2(\text{AsO}_4)_4 \cdot 9\frac{1}{2}\text{H}_2\text{O}$; and H. Salkowsky found that when dried at 130° , it had the composition $5\text{CuO} \cdot 2\text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, that is, the *dihydrate*, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 2\text{CuHAsO}_4 \cdot 2\text{H}_2\text{O}$, **cupric dihydrotetraorthoarsenate**, $\text{Cu}_5\text{H}_2(\text{AsO}_4)_4 \cdot 2\text{H}_2\text{O}$. This salt seems to have been made by J. L. Proust, and J. F. Simon. A. Vogel observed that it dissolves in sulphurous acid without forming a cuprous salt. A. Hirsch said that if in preparing the hydrotriorthoarsenate, the precipitate be washed until only a trace of copper escapes in the filtrate, the *heptahydrate*, $\text{Cu}_5\text{H}_2(\text{AsO}_4)_4 \cdot 7\text{H}_2\text{O}$, is formed; and if a soln. of sodium hydroarsenate be added to a large excess of cupric sulphate, the air-dried product retains $11\frac{1}{2}$ mols. of water, forming the *hemitricosihydrate*, $\text{Cu}_5\text{H}_2(\text{AsO}_4)_4 \cdot 11\frac{1}{2}\text{H}_2\text{O}$.

A number of basic cupric arsenates have been reported. Most of these occur in nature where they have been formed by the oxidation of the thioarsenides. The most important of these is represented by the mineral now known as olivenite. This was analyzed by M. H. Klaproth³ in 1786, and shortly afterwards was called by A. G. Werner *Olivenerz*; by R. Kirwan, *olive copper ore*; and by P. Rashleigh, *olive-green copper ore*. J. L. Bournon referred to it as *cuvre arsenate en octaèdre aigus*; J. F. L. Hausmann, as *pharmacochalzitè*, and *pharmacolzite*; and R. Jameson, and C. C. von Leonhard gave it its present name **olivenite**, in allusion to its olive-green colour. The mineral was analyzed by M. H. Klaproth, F. von Kobell, A. Damour, K. Biehl, T. Thomson, R. Hermann, and W. F. Hillebrand. The empirical formula is $4\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or $\text{Cu}_4\text{As}_2\text{O}_9 \cdot \text{H}_2\text{O}$, **copper hydroxyorthoarsenate**, in agreement with C. F. Rammelsberg's view of the constitution: $\text{Cu}_3(\text{AsO}_4)_2\text{Cu}(\text{HO})_2$. P. Groth represented it by $\text{HO} \cdot \text{Cu}(\text{AsO}_4)\text{Cu}$. The artificial salt was analyzed by

A. Coloriano, H. Debray, and A. Hirsch. A. Coloriano made it by boiling for half an hour an aq. soln. of copper hydroarsenate; H. Debray, by heating the normal arsenate with a little water or aq. copper nitrate in a sealed tube at 200° ; C. Friedel and E. Sarasin, by similarly heating a mixture of copper carbonate, arsenic acid, and water at 150° ; and A. Hirsch, by dropping a conc. soln. of 2 mols of heptahydrated hydroarsenate into a conc. soln. of 4 mols of cupric chloride, washing the blue precipitate first with cold water, and then with hot water; and drying at 260° . C. Friedel and E. Sarasin added that when sodium arsenate acts on copper sulphate, products other than olivenite may be obtained—e.g. sodium cupric arsenates. Olivenite may be olive-green, passing into various other shades of green, blackish-green, brown, yellow, grey, and white. It may be nodular or massive, or fibrous, when it may be called *wood-copper*, or *wood-arsenate*. The crystals may be prismatic or acicular. The crystals are rhombic, and, according to H. S. Washington, have the axial ratios $a : b : c = 0.9396 : 1 : 0.6726$; K. Biehl gave $0.93934 : 1 : 0.67239$. H. Debray said that the olive-green octahedral crystals are isomorphous with the corresponding salt of zinc; and P. Groth, isomorphous with libethenite, $\text{CuPO}_4(\text{CuOH})$, and with adamite, $\text{ZnAsO}_4(\text{ZnOH})$. The cleavage on the (010)-, (110)-, and (011)-faces is faint. A. des Cloizeaux gave for the optic axial angle with red-, yellow-, and blue-light, $2H_a = 105.5^{\circ}$, 106.6° , and 109.47° respectively; the optical character is negative. E. S. Larsen said it is positive, and he gave $2V = 82^{\circ}$, and the indices of refraction $\alpha = 1.772$, $\beta = 1.810$, and $\gamma = 1.863$. For a Cornish mineral he gave $\alpha = 1.747$, $\beta = 1.788$, and $\gamma = 1.829$. The mineral is not pleochroic. R. Hermann gave $3.913\text{--}4.135$ for the sp. gr., and A. Damour, 4.378 . The hardness is 3. T. W. Case observed that the mineral is a non-conductor of electricity, and that insolation has no measurable effect. A. Hirsch said that water, aq. ammonia, and baryta-water attack this compound with greater difficulty than is the case with the other copper arsenates; and an aq. soln. of silver nitrate does not attack this arsenate at all. The mineral is soluble in nitric acid.

A. Hirsch said that the *hemiennehydrate*, $4\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 4\frac{1}{2}\text{H}_2\text{O}$, is formed as in the case of the monohydrate, by mixing soln. of sodium hydroarsenate, and cupric chloride, washing only with cold water, and drying in air. The mineral **leucochalcite**, described imperfectly by F. Sandberger, and T. Petersen approximates in composition to the *trihydrate*, $4\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$. It occurs in white, slender needles, with a tinge of green, as a coating on the malachite and calcite of the Wilhelmine mine, Spessart, Germany. Little more is known about this rare mineral. E. S. Larsen said that the optical character is positive, the optic axial angle large, and the indices of refraction $\alpha = 1.79$, $\beta = 1.807$, and $\gamma = 1.84$. A. Breithaupt described another mineral occurring at Libethen, Hungary. Its composition resembles that of a hydrated olivenite, being a *heptahydrate*, $4\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$. He called the mineral **euchroite**—from *εὐχρῶα*, beautiful colour. G. Tschermak said that olivenite may be euchroite altered by the loss of water. Analyses were made by F. Wöhler, E. Turner, H. Kühn, and A. H. Church. C. F. Rammelsberg wrote the formula $\text{Cu}_3(\text{AsO}_4)_2 \cdot \text{Cu}(\text{OH})_2 \cdot 6\text{H}_2\text{O}$; and P. Groth, $\text{CuAsO}_4(\text{CuOH}) \cdot 3\text{H}_2\text{O}$. The prismatic crystals have a bright emerald-green or leek-green colour. W. Haidinger gave for the axial ratios of the rhombic crystals $a : b : c = 0.6088 : 1 : 1.0379$. R. H. Solly made some observations on the crystals. Traces of cleavage occur on the (110)- and the (011)-faces. A. des Cloizeaux gave for the optic axial angle $2E = 61^{\circ} 11'$ at 17° , and $56^{\circ} 8'$ at 86° . The optical character is negative. E. S. Larsen said the optical character is positive and the optic axial angle of a Libethen specimen, 29° , and a doubtful Utah specimen, 62° . The indices of refraction of the former are $\alpha = 1.695$, $\beta = 1.698$, and $\gamma = 1.733$, and of the latter $\alpha = 1.723$, $\beta = 1.738$, and $\gamma = 1.781$. The sp. gr. is 3.389 , and the hardness $3.5\text{--}4.0$. The reactions are similar to those with olivenite. A. H. Church found that the mineral loses 1.22 per cent. of water in vacuo; 1.90 per cent. at 100° ; and 16.16 per cent. at dull redness.

W. Haidinger⁴ described an emerald-green or grass-green mineral which was

named **erinite** because it was supposed to come from Ireland; but A. H. Church showed that it came from Cornwall. It also occurs in Utah. Analyses have been reported by E. Turner, R. Pearce, and W. F. Hillebrand and H. S. Washington. These correspond with the empirical formula $5\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$; that is, **copper tetrahydroxyorthoarsenate**, which C. F. Rammelsberg represents by $\text{Cu}_3\text{As}_2\text{O}_8 \cdot 2\text{Cu}(\text{OH})_2$; and P. Groth by $(\text{CuOH})_4\text{Cu}(\text{AsO}_4)_2$. It occurs in mammillated crystalline masses, with a concentric and fibrous structure, and a rough surface from the terminations of minute crystals. The hardness is 4.5–5.0; and the sp. gr. 4.043. E. S. Larsen said that the optical character is negative, and the indices of refraction $\alpha=1.82^\circ$, $\beta=1.820$, and $\gamma=1.88$. The erinite of F. S. Beudant, A. des Cloizeaux, and A. Schrauf is considered to be chalcophyllite. A related mineral with $\text{R}_3(\text{AsO}_4)_2 \cdot 2\text{R}(\text{OH})_2$, with $\text{R}=\text{Ca}:\text{Cu}:\text{Zn}=4:3.5:1$ for the bases was called **staszicite** by J. Morozewicz. He found it at Miedzianka, Poland. It occurs in yellowish-green masses with a fibrous structure, and is presumably rhombic. The sp. gr. is 4.227, and the hardness 5.5–6.0. It loses $1.5\text{H}_2\text{O}$ at 500° to 600° ; and $0.5\text{H}_2\text{O}$ at 800° to 880° . The m.p. is 880° . It may be an oxidation product of miedziankite. The mineral **cornwallite** found in small botryoidal masses on olivenite in Cornwall was described by F. X. M. Zippe.⁵ The colour is emerald-green or verdigris-green. The analyses by J. U. Lerch corresponded with the *pentahydrate*, $5\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, or, as P. Groth wrote it, $(\text{CuOH})_4\text{Cu}(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$; but the analyses by A. H. Church, and W. F. Hillebrand and H. S. Washington agree better with the *trihydrate*, $5\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or, as P. Groth wrote, $(\text{CuOH})_4\text{Cu}(\text{AsO}_4)_2 \cdot \text{H}_2\text{O}$. The hardness of the amorphous mineral is 4.5, and the sp. gr. 4.16. E. S. Larsen said that the optical character is positive; the optical axial angle small; and the indices of refraction $\alpha=1.81$, $\beta=1.815$, and $\gamma=1.85$. A. H. Church said that cornwallite loses no water at 100° . Another mineral, occurring along with copper ores at Schneeberg, and other places, was called by A. G. Werner⁶ *Kupferschaum*, by C. U. Shepard, *kupaphrite*; and by W. Haidinger, *tirolit*, or **tyrolite**. Analyses by F. von Kobell, W. F. Hillebrand and H. S. Washington, R. Pearce, and A. H. Church agree with the *enneahydrate*, $5\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$, or, as C. F. Rammelsberg writes it, $\text{CaCO}_3 \cdot \text{Cu}_5\text{As}_2\text{O}_{10} \cdot 9\text{H}_2\text{O}$, on the assumption that some calcium carbonate is an essential and not an accidental constituent. Some calcium sulphate is also present. P. Groth represents it by the formula, $(\text{CuOH})_4\text{Cu}(\text{AsO}_4)_2 \cdot 7\text{H}_2\text{O}$. Tyrolite is pale apple-green, verdigris-green, or sky-blue. It may occur massive, reniform, in foliated aggregates, and rarely in isolated crystals. E. S. Dana gave for the axial ratios of the tabular rhombic crystals $a:b:c=0.9325:1:-$; the (011)-cleavage is micaceous. The hardness is 1.0 to 1.5; and the sp. gr. 3.02 to 3.098. F. W. Clarke reported 3.27 at 20.5° . The optic axial angle is large, and the optical character negative. E. S. Larsen gave for the optical axial angle $2V=36^\circ$, and for the indices of refraction $\alpha=1.694$, $\beta=1.726$, and $\gamma=1.730$. The pleochroism is $\alpha=\gamma$ =pale grass-green, and β =pale yellowish-green.

A Cornish mineral arsenate was called *strahliges Olivenerz* by M. H. Klaproth⁷ in 1801, *cupreous arsenate of iron* by J. L. Bournon, and analogous terms were used by D. L. G. Karsten, R. J. Häuy, J. F. L. Hausmann, and A. Breithaupt. E. F. Glocker called it *siderochalcite*; F. S. Beudant, *aphanèse*—from *ἀφανής*, not manifest, in allusion to the fact that the crystals are rarely recognizable; C. U. Shepard, *aphanesite*, and J. J. Bernhardt, *abichite*. J. D. Dana called it **clinoclastite** in allusion to the basal cleavage being oblique to the sides of the prism. The mineral also occurs in a few other localities. Analyses have been reported by C. F. Rammelsberg, A. Damour and A. des Cloizeaux, R. Pearce, W. F. Hillebrand and H. S. Washington, and A. H. Church. The results agree with the empirical formula $6\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or **copper hexahydroxyorthoarsenate**, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 3\text{Cu}(\text{OH})_2$. P. Groth wrote the formula $(\text{CuOH})_3\text{AsO}_4$. The colour of the mineral is dark green, or a blackish blue-green. It occurs massive, or in hemispherical or reniform masses with a radiating fibrous structure. It also occurs in prismatic crystals with

rounded uneven faces; and also in crystal aggregates. The monoclinic crystals were found by W. Phillips to have the axial ratios $a : b : c = 1.9069 : 1 : 3.8507$, and $\beta = 80^\circ 50'$. The cleavage on the (110)-face is prismatic. A. Damour and A. des Cloizeaux gave for the optic angles, $2E = 134^\circ 36'$ and $141^\circ 14'$ for green light; and for blue light, $160^\circ 52'$; $2H = 83^\circ 42'$ and $86^\circ 42'$ for blue light, and $81^\circ 56'$ and $84^\circ 12'$ for green light; E. S. Larsen said that the optical axial angle is medium, the optical character is negative; the hardness is 2.5–3.0; and the sp. gr. 4.19–4.38—R. Pearce gave 4.36; and W. F. Hillebrand and H. S. Washington, 4.38 at 19° . A. Coloriano said that water begins to come off at 290° , and is all expelled at 445° . E. S. Larsen gave for the indices of refraction $\alpha = 1.73$, $\beta = 1.870$, and $\gamma = 1.91$; and he found the mineral to be pleochroic. The mineral is soluble in nitric acid. O. Pufahl described pale green crusts of indistinct crystals of a mineral, which he called **duftite**, occurring on azurite at Tsumeb, South Africa. The analyses correspond with **copper octohydroxyorthoarsenate**, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 4\text{Cu}(\text{OH})_2$. Its sp. gr. is 6.19 and its hardness 3. It is soluble in hot dil. hydrochloric acid.

R. J. Haüy,⁸ and L. N. Vauquelin described a mineral from Cornwall which they called *cuvire arsénate lamelliforme*. D. L. G. Karsten called it *Kupferglimmer*; R. Jameson, *copper mica*; A. Breithaupt, *Kupferphyllit*, and **chalcophyllite**; F. S. Beudant, and A. Damour and A. des Cloizeaux, *erinite* (*vide supra*); and H. J. Brooke and W. H. Miller, *tamarite*. It occurs in Cornwall, and a few other localities. Analyses were reported by R. Chenevix, L. N. Vauquelin, R. Hermann, A. Damour, A. des Cloizeaux, A. H. Church, and E. G. J. Hartley. R. Hermann represented his results by $8\text{CuO} \cdot \text{As}_2\text{O}_5 \cdot 24\text{H}_2\text{O}$. This can be written as **copper decahydroxyorthoarsenate**, $\text{Cu}_3(\text{AsO}_4)_2 \cdot 5\text{Cu}(\text{OH})_2 \cdot n\text{H}_2\text{O}$. C. F. Rammeisberg was unable to satisfy himself about the formula, P. Groth gave $(\text{CuOH})_3\text{AsO}_4 \cdot \text{Cu}(\text{OH})_2 \cdot 3\frac{1}{2}\text{H}_2\text{O}$. A. H. Church did not regard as an accidental constituent the 1.8–5.97 per cent. of alumina reported in the analyses, and represented chalcophyllite as *copper aluminium decahydroxyorthoarsenate*: $\text{Cu}_3\text{Al}_2\text{As}_2\text{O}_{16} \cdot 24$ or $25\text{H}_2\text{O}$. The composition of idealized chalcophyllite is still *sub judice*. E. V. Shannon described a complex variety of chalcophyllite, **copper aluminarsenatosulphate**, $4\text{CuO} \cdot (\frac{1}{5}\text{Al}_2\text{O}_3 \cdot 5\text{As}_2\text{O}_5 \cdot \frac{5}{3}\text{SO}_3) \cdot 10\text{H}_2\text{O}$, which he obtained from Rancagua, Chile. It loses half its water at 110° . The indices of refraction of the fresh mineral are $\omega = 1.618$, and $\epsilon = 1.552$, or $\omega - \epsilon = 0.066$; the numbers for the mineral dried in air are 1.620, 1.560, and 0.060 respectively; and for the mineral dried to constant weight at 110° , 1.680, 1.613, and 0.062 respectively. The colour of chalcophyllite is emerald-green, grass-green, and verdigris-green. It occurs foliated and massive; but usually in six-sided tabular crystals with the (0001)-face striated. The axial ratio of the trigonal crystals given by A. Damour and A. des Cloizeaux is $a : c = 1 : 2.5538$; C. Palache and H. E. Merwin gave 1 : 2.671. The cleavage on the (0001)-face is perfect; that on the (10 $\bar{1}$ 1)-face occurs only in traces. The hardness is 2; the sp. gr. 2.40–2.66—R. Hermann gave 2.435, and A. Damour and A. des Cloizeaux, 2.659. P. Gaubert said that 14 per cent. of water is given off above 100° , and the remainder at a much higher temp. A. Damour and A. des Cloizeaux found that the optical character is negative; and P. Gaubert gave for the indices of refraction $\omega = 1.6323$, $\epsilon = 1.5745$, and $\omega - \epsilon = 0.578$. The mineral is easily soluble in hydrochloric and nitric acids, and in aq. ammonia.

W. F. Foshag⁹ described a greenish-blue mineral from Freirini, Chile, and he called it **freirinite**. Its composition approximates $6(\text{Cu}, \text{Ca})\text{O} \cdot 3\text{Na}_2\text{O} \cdot 2\text{As}_2\text{O}_5 \cdot 6\text{H}_2\text{O} \cdot \text{Cu}_3\text{Na}_3(\text{AsO}_4)_2$, **sodium copper orthoarsenate**. It is composed of microscopic uniaxial plates or columns. The mineral is either tetragonal or rhombic with a small optic axial angle. The optical character is negative. The basal cleavage is perfect, the prismatic cleavage is imperfect. The indices of refraction are $\epsilon = 1.645$ —light greenish-blue; and $\omega = 1.748$ —dark greenish-blue. A. Hirsch reported a number of complex salts of copper and sodium arsenates with different values for the ratios $\text{Na}_2\text{O} : \text{CuO} : \text{As}_2\text{O}_5 : \text{H}_2\text{O}$. Thus,

the ratios 2 : 24 : 9 : 23, or **sodium copper hydroenarsenate**, $\text{Na}_2\text{HAsO}_4 \cdot 4\text{Cu}_3(\text{AsO}_4)_2 \cdot 11\text{H}_2\text{O}$, is obtained by mixing a soln. of 4 mols of cupric nitrate with 7 mols of sodium hydroarsenate and washing the precipitate during 10 days. The ratios 1 : 12 : 5 : 12, or **sodium copper dihydropentarsenate**, $\text{NaH}_2\text{AsO}_4 \cdot 2\text{Cu}_3(\text{AsO}_4)_2 \cdot 5\text{H}_2\text{O}$, were obtained by mixing a dil. soln. of 2 mols of sodium hydroarsenate with 4 mols of cupric sulphate, and washing the precipitate many days. H. Salkowsky also made this salt. If in preparing the first of the salts, the precipitate be washed a shorter time, the product has the ratios 2 : 18 : 7 : 20, or **sodium copper bishydrodecatearsenate**, $2\text{Na}_2\text{HAsO}_4 \cdot 6\text{Cu}_3(\text{AsO}_4)_2 \cdot 19\text{H}_2\text{O}$; and this salt is made by treating a soln. of copper nitrate with an excess of sodium hydroarsenate. The ratios 4 : 36 : 15 : 16, or **sodium copper hydrobisdihydrodecapentarsenate**, $\text{Na}_2\text{HAsO}_4 \cdot 2\text{NaH}_2\text{AsO}_4 \cdot 6\text{Cu}_3(\text{AsO}_4)_2 \cdot 16\text{H}_2\text{O}$, was obtained by mixing soln. of 3 mols of cupric sulphate, and 3 mols of sodium hydroarsenate, and washing the precipitate for three days; if the precipitate be washed until the runnings are free from sulphuric acid, a higher hydrate is produced, *viz.*, $33\frac{1}{2}\text{H}_2\text{O}$. There is nothing here to show that these products do not represent arbitrary stages in a process of hydrolysis. C. Lefèvre dissolved 7-8 per cent. of cupric oxide in sodium metarsenite melted at a low temp. The green, crystalline mass has the composition **sodium copper arsenate**, CuNaAsO_4 . It is easily fusible, and is decomposed at a red-heat; it is freely soluble in aq. ammonia and dil. acids. The corresponding **potassium copper arsenate**, KCuAsO_4 , was obtained in an analogous manner. By saturating a fused mixture of sodium metarsenite and chloride with copper oxide, C. Lefèvre obtained **sodium copper tetraorthoarsenate**, $2\text{Na}_3\text{AsO}_4 \cdot \text{Cu}_3(\text{AsO}_4)_2$. This product is easily fused; it decomposes at a red-heat; and is easily soluble in acids. He also made **potassium copper triorthoarsenate**, $\text{KCu}_4(\text{AsO}_4)_3$, or $\text{KCuAsO}_4 \cdot \text{Cu}_3(\text{AsO}_4)_2$, by dissolving 10 per cent. of cupric oxide in molten potassium metarsenate, and heating the fused mass near its m.p. for a long time.

When a soln. of silver nitrate is treated with the primary, secondary, or tertiary arsenate of ammonium, potassium, or sodium, or with arsenic acid, brownish-red **silver orthoarsenate**, Ag_3AsO_4 , is precipitated; and, according to O. B. Kühn,¹⁰ the precipitate is dark purple if the soln. of silver nitrate be boiling, and a conc. soln. of arsenic acid be the precipitant. C. W. Scheele said that the precipitation with arsenic acid, and potassium dihydroarsenate is incomplete because the precipitate is partly soluble in the nitric acid formed in the reaction. E. Mitscherlich also showed that the acid is formed if alkali hydroarsenate be used, but T. Graham said that the liquid remains neutral if normal alkali arsenate be used. T. Graham added that the silver nitrate adsorbed by the precipitate cannot be completely removed by washing; but if ammonium nitrate be present no adsorption of silver nitrate occurs. H. Goguel obtained the arsenate by adding silver nitrate to a hot conc. soln. of arsenic acid. G. P. Baxter and F. B. Coffin found that in preparing normal silver arsenate perceptible hydrolysis occurs in soln. of the salts of the acid even when the base is a strong one. The hydrolysis is greatest with the tertiary salts. Silver orthoarsenate made by precipitation with the normal sodium salt always contains an occluded basic impurity. Silver orthoarsenate cannot be completely dried without fusion owing to the retention of liquid in pockets within the solid. A. Dexheimer prepared **colloidal silver orthoarsenate** by mixing a 5 per cent. soln. of silver nitrate with 2 grms. of protalbinat dissolved in 20 c.c. of water. The precipitate was dissolved in dil. sodium hydroxide and mixed with a soln. of sodium hydroarsenate. The product was dialyzed in darkness until the washings were free from water in vacuo over sulphuric acid. The powder with water yields a hydrosol which is dark green in reflected light and reddish-brown in transmitted light. In thin layers, G. P. Baxter and F. B. Coffin found the colour is ruby-red in transmitted light. The dark reddish-brown silver orthoarsenate obtained by G. P. Baxter and F. B. Coffin, H. Goguel, and H. Dufet was in the form of tetrahedral, hexahedral, or dodecahedral cubic crystals. From the X-radiogram,

R. W. G. Wyckoff calculated that the unit cell of the cubic crystals contains two Ag_3AsO_4 -mols, and has a side 6.12 Å. G. P. Baxter and F. B. Coffin gave 6.657 for the sp. gr. at $25^\circ/4^\circ$. C. W. Scheele found that when heated to the softening temp. of glass, the orthoarsenate begins to fuse; and at a higher temp., it decomposes into silver, etc. J. F. Simon also found that it furnishes silver when heated in the presence of charcoal. G. S. Whitby found that a litre of water dissolved 0.0085 grm. of the salt at 20° . E. C. Franklin and C. A. Kraus said that silver orthoarsenate is insoluble in liquid ammonia, and O. Widman obtained **silver tetramminorthoarsenate**, $\text{Ag}_3\text{AsO}_4 \cdot 4\text{NH}_3$, in colourless needles which lose ammonia in air, and which are freely soluble in water. C. W. Scheele said that silver orthoarsenate is soluble in aq. ammonia; and F. Wöhler found that the ammoniacal soln. becomes brown when treated with hydrogen, and with the long-continued action of hydrogen, a black powder is deposited. G. C. Wittstein found that the normal arsenate dissolves readily in soln. of ammonium carbonate, but not ammonium sulphate, nitrate, or succinate—even when heated. T. Graham said that the salt dissolves sparingly in a soln. of ammonium nitrate, and more freely in acetic acid. C. W. Scheele said that hydrochloric acid converts the arsenate into chloride. J. Setterberg, indeed, said that on evaporating a soln. of silver orthoarsenate in nitric acid, the first crop of crystals is silver orthoarsenate, and this is followed by a crop of crystals of *silver nitratearsenate*, which in contact with water decompose into the orthoarsenate and nitrate. A. Joly found the arsenate to be less soluble than the phosphate in arsenic acid. The silver arsenate dissolved to saturation in a soln. of less than 70 parts of arsenic acid in 100 parts of water at 80° furnishes black dodecahedral crystals of silver orthoarsenate on cooling. F. Wöhler found that if silver arsenate be treated with a soln. of ferrous sulphate it forms a dark grey powder of silver suboxide (*q.v.*). E. V. Zappi and J. J. Landaburu obtained a mixture approximating $2\text{Ag}_3\text{AsO}_4 + \text{Ag}$, and not silver arsenide by reducing silver arsenate with formaldehyde.

J. Setterberg melted together a mol of arsenic acid and 2 mols of silver nitrate until the nitric acid was completely expelled and obtained a mass thought to be **silver hydroarsenate**, Ag_2HAsO_4 ; and A. Joly rapidly heated to 100° crystals of silver dihydroarsenate and obtained **silver metarsenate**, AgAsO_3 , as a white powder; before losing water, the crystals become red owing to the formation of arsenic acid and silver hydroarsenate. If the soln. from which silver dihydroarsenate will crystallize is sat. with silver arsenate at a temp. a little below 100° , it deposits orange-red hexagonal prisms with rhombohedral terminations. The crystalline form resembles that of silver hydrophosphate, but the hydroarsenate could not be purified. J. Setterberg found that the salt is decomposed by water, forming the normal arsenate. H. Dufet said that the crystals of the hydroarsenate are trigonal with axial ratios $a : c = 1 : 0.7297$, and $\alpha = 105^\circ 54'$. According to J. Setterberg, if a soln. of the normal arsenate in arsenic acid be evaporated, colourless, monoclinic crystals of **silver dihydroarsenate**, AgH_2AsO_4 , are formed. L. Hurtzig and A. Geuther could not make this salt. A. Joly found that this salt is best obtained by crystallization from a soln. of precipitated silver orthoarsenate in an acid of the composition $\text{H}_3\text{AsO}_4 \cdot \text{H}_2\text{O}$; it is decomposed by a trace of water, into the normal arsenate and arsenic acid. If the soln. of silver arsenate in arsenic acid be heated above 100° , it yields a white granular powder, **silver paratetrarsenate**, $\text{Ag}_2\text{As}_4\text{O}_{11}$, which is analogous to the product obtained by L. Hurtzig and A. Geuther. H. Dufet found the monoclinic prismatic crystals have the axial ratios $a : b : c = 0.8145 : 1 : 1.1117$, and $\beta = 90^\circ 5'$.

T. Thomson found sodium orthoarsenate gives a yellowish-white precipitate of **gold arsenate** when added to a warm soln. of auric chloride.

§ 17. The Arsenates of the Calcium Family

According to R. Bunsen,¹ and many others, calcium arsenate occurs in some natural spring-waters. Thus, R. Bunsen found 0.7 mgrm. per litre in the waters of Baden-Baden; L. R. von Fellenberg, 0.00015 grm. per litre in the water of Gurnigel; J. Lefort, traces in the water of Jenzat; J. Löwe, in the waters of Kronthal; and C. R. Fresenius, traces in the waters of Weisbaden. Calcium arsenate occurs as the minerals haidingerite, and pharmacolite—*vide infra*. The use of calcium arsenate as an insecticide—e.g. the cotton boll weevil—has been discussed by B. R. Coad,² H. W. Ambruster, etc. C. Brame made calcium arsenate in the dry way by heating to redness a mixture of arsenic trioxide and lime—some arsenic is at the same time volatilized. If arsenic acid be neutralized with calcium

hydroxide, C. Blarez found that the following amounts of heat, Q , are evolved for each eq. of base :

	1 Eq.	2 Eq.	3 Eq.	4 Eq.	5 Eq.
Q { $\text{Ca}(\text{OH})_2$.	14.50	12.50	2.25	0.28	0.25 cal.
{ $\text{Sr}(\text{OH})_2$.	14.17	12.33	3.88	1.03	1.03 „
{ $\text{Ba}(\text{OH})_2$.	14.00	13.50	15.50	0.25	0.50 „

Cochineal reacts alkaline when one eq. of base is added, and phenolphthalein with two eq. H. V. Tartar and co-workers prepared calcium hydroxytrioorthoarsenate, $\text{Ca}(\text{OH})_2 \cdot 3\text{Ca}_3(\text{PO}_4)_2$, by the hydrolysis of calcium orthoarsenate.

Eight grams of the undried material were digested in a 2-litre flask with 1.75 litres of freshly distilled water. The flask was then connected to a reflux condenser and the contents heated to gentle boiling. The boiling was continued for days, the water being siphoned off from the solid material each morning and replaced with fresh distilled water. Qualitative tests on the liquid removed showed from day to day a steadily decreasing content of arsenate ion until about the twelfth day, when it apparently became constant. The solid material was white, amorphous, and almost gelatinous. After being filtered off by suction, it was dried to constant weight at 100° .

They found that 100 grms. of water at 25° dissolve 0.0048 grm. of the salt. If an excess of a dil. soln. of calcium chloride be allowed to stand for a long time in contact with sodium hydroarsenate, P. von Kotschoubey said that a basic salt is formed, namely, **calcium trioxyorthoarsenate**, $3\text{CaO} \cdot \text{Ca}_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O}$; he also found that if calcium chloride be added to an ammoniacal soln. of alkali arsenate, normal **calcium orthoarsenate**, $\text{Ca}_3(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$, is precipitated; when F. Field used an ammoniacal soln. of ammonium arsenate, he said that the precipitate is a mixture of the normal salt and ammonium calcium arsenate. T. Graham mixed an aq. soln. of calcium chloride and sodium orthoarsenate. If the calcium salt be added to an excess of the alkali arsenate, the precipitate entangles more of the alkali arsenate than when the procedure is reversed. H. V. Tartar and co-workers, and R. H. Robinson prepared this salt by adding a soln. of sodium hydroarsenate in slight excess to a soln. of calcium chloride. The resulting mixture was then made distinctly alkaline with sodium hydroxide. After some hours the amorphous, flocculent precipitate was washed, first by decantation and then by suction on a Büchner funnel. C. Blarez prepared this salt by treating an aq. soln. of arsenic acid with an excess of lime-water. The precipitate was washed until the wash-water was neutral. C. L. Bloxam treated a mixture of the required proportions of arsenic trioxide and calcium carbonate with an excess of nitric acid, and calcined the residue. In preparing calcium arsenate, L. Cambi advocated oxidizing the arsenic trioxide with chlorine rather than with nitric acid—the apparatus is simpler, the reaction proceeds spontaneously, and the absorption of chlorine is quantitative—*vide supra*, action of chlorine on arsenic trioxide. M. N. and P. N. Dvornikoff studied the reaction. D. Lopez passed chlorine into a mixture of arsenic trioxide, lime, and luke-warm water, and boiled the product to lessen the production of soluble arsenates. A light, fluffy calcium arsenate was formed. The manufacture was discussed by C. W. Drury and C. W. Simmons, S. S. Sadler, W. H. Simpson, H. W. Ambruster, J. Altwegg, C. Ellis and V. T. Stewart, the Société Chimique des Usines du Rhône, F. C. Cook and N. E. McIndoo, J. G. Lamb, E. R. Rushton, U.S. Smelting, Mining and Refining Co., L. C. Drefahl and C. H. Sakryd, C. B. Dickey, H. Howard and E. A. Taylor, and T. Shiomi and K. Otsu. J. F. Simon said that calcium orthoarsenate is not decomposed at a red-heat; and C. L. Bloxam found that the orthoarsenate is sparingly soluble in water; readily soluble in hydrochloric acid; and the aq. soln. has an alkaline reaction. G. Kemp and J. von Gyulay obtained **colloidal calcium arsenate** by the successive addition of an ammonium salt, acetic acid, and an excess of sodium arsenate to a soln. of a calcium salt. The opalescent jelly crystallizes after some time. L. Cambi and G. Bozza studied the electrometric titration of calcium nitrate or chloride with sodium orthoarsenate or sodium hydroarsenate.

In the manufacture of calcium arsenate as an insecticide for the cotton-plant as an alternative to oxidation of arsenic trioxide or white arsenic by nitric acid, the oxidation can be effected electrolytically. The process has been examined by S. J. Lloyd and A. M. Kennedy. The white arsenic is dissolved in soda-lye so as to produce a soln. of basic sodium arsenite with $\text{As}_2\text{O}_3 : \text{NaOH}$ in the proportion 198 : 250. The reaction is symbolized : $\text{As}_2\text{O}_3 + 6\text{NaOH} = 2\text{NaAsO}_2 + 4\text{NaOH} + \text{H}_2\text{O}$. When this soln. is electrolyzed between iron electrodes, hydrogen and arsenic, corresponding to about one per cent. of the arsenic trioxide employed, are produced at the cathode. Only a small amount of oxygen is evolved at the anode, the remainder serving to convert sodium arsenite to arsenate : $2\text{NaAsO}_2 + 4\text{NaOH} = 2\text{Na}_3\text{AsO}_4 + 2\text{H}_2$. When the oxidation is complete, the soln. is filtered to remove the arsenic Milk of lime is added : $2\text{Na}_3\text{AsO}_4 + 4\text{Ca}(\text{OH})_2 = \text{Ca}_4\text{As}_2\text{O}_9 + 6\text{NaOH} + \text{H}_2\text{O}$; and the sludge is filtered. The calcium arsenate is washed and dried. The filtrate of soda-lye is used to dissolve more white arsenic. The raw materials employed are white arsenic, slaked lime, and sufficient sodium hydroxide to replace the inevitable losses of the operating cycle. Ordinary grey arsenic can be used and the cost of re-roasting to white arsenic avoided. The extra lime beyond that required for the normal orthoarsenate is used so that the solubility of the product in water is sufficiently low to avoid any danger of burning or injuring the foliage of the cotton

FIG. 25.—Current Efficiency of the Oxidation for Electrolytic Calcium Arsenate.

plant. The current efficiency of the oxidation is very high, being practically 100 per cent. for the oxidation of the first 85 per cent. of the trioxide, Fig. 25, and is about 85 per cent. efficiency over the whole range oxidation. The relative toxicity of the different calcium arsenates to locusts and boll weevils was found by S. B. Hendricks, A. M. Bacot, and H. C. Young to be greater with the acid than with the basic arsenates.

P. von Kotschoubey obtained **strontium orthoarsenate**, $\text{Sr}_3(\text{AsO}_4)_2$, by adding ammonia to a soln. of the hydroarsenate in acids ;

C. Blarez, by treating arsenic acid with strontia-water, and washing the precipitate until free from acids ; and C. Lefèvre, by adding the necessary amount of strontia to a fused mixture of equal parts of sodium orthoarsenate and sodium chloride. The sodium salts are washed from the cold mass by water. The colourless rhombic crystals are not decomposed by hot water ; and they are freely soluble in dil. acids.

J. J. Berzelius obtained **barium orthoarsenate**, $\text{Ba}_3(\text{AsO}_4)_2$, by treating a soln. of hydroarsenate with ammonia, and H. Salkowsky showed that the composition of the precipitate depends on the conc. of the ammonia since both the hydroarsenate, and the orthoarsenate may be deposited. P. von Kotschoubey used a similar mode of preparation using a soln. of the hydroarsenate in as little acid as possible. H. Salkowsky said that in this case the precipitate is liable to be contaminated with barium chloride ; and if much ammonium salt is present, a complex salt is formed ; and, according to E. Mitscherlich, some hydroarsenate. T. Graham found that if a soln. of sodium orthoarsenate be gradually added to a soln. of barium chloride, the white pulverulent calcium orthoarsenate which is precipitated should be washed quickly so that it may not absorb carbon dioxide from the air ; if the barium chloride be gradually added to the sodium orthoarsenate, a gelatinous precipitate is formed ; this becomes flocculent when boiled, but the liquid is alkaline, showing that some hydroarsenate has been precipitated. The precipitate also adsorbs some sodium arsenate which cannot be all removed by washing. A. Laugier obtained the orthoarsenate by the action of arsenic acid on an excess of baryta-water ; and F. Field by the action of barium chloride on an ammoniacal soln. of arsenic acid. C. Lefèvre obtained the normal salt in tabular crystals by fusing baryta with a mixture of sodium hydroarsenate and alkali chloride, and washing the cold mass with water ;

and O. Schairer made it by melting a mixture of arsenic trioxide and barium dioxide, and washing the product with cold water—in this case some pyroarsenate is formed. F. Field said that the white powder dried at 100° is almost free from water, and all is lost at 150°; H. Salkowsky said that the salt dried at 130° retains 3.44–4.26 per cent. of water. O. Schairer found that the salt does not fuse in the blast-flame. T. Graham observed that about 0.8 per cent. of carbonate may be formed when the orthoarsenate is ignited in air. F. Field stated that 100 parts of cold water dissolve 0.055 part of the salt; 100 parts of a 5 per cent. soln. of ammonium chloride, 0.193 part; and 100 parts of a 10 per cent. soln. of aq. ammonia, 0.003 part. E. F. Anthon found the salt dissolves readily in cold hydrochloric, nitric, tartaric, and acetic acids; and A. Laugier, that its solubility in water is not increased by ammonia or alkali salts.

The acid salt, **calcium hydroarsenate**, CaHAsO_4 , is represented in nature by the hydrated minerals pharmacolite, and haidingerite. C. J. Selb referred to an *arseniksauer Kalk*, which D. L. G. Karsten called **pharmacolite**—from *φάρμακον*, poison; and F. S. Beudant, *arsenicite*. It occurs along with arsenical ores at Wittichen, Baden; at St. Marie-aux-Mines, Vosges; Völlegg, Styria; Andreasberg, Harz; Joachimsthal, Bohemia; Glücksbrunn, Thuringia; Riechelsdorf and Bieber, Hesse; etc. Analyses by M. H. Klaproth, C. F. Rammelsberg, F. Petersen, E. Jannettaz, and E. Hatle and H. Tauss correspond with the *dihydrate*, $\text{CaHAsO}_4 \cdot 2\text{H}_2\text{O}$, though C. F. Rammelsberg gave $\text{CaHAsO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. The other mineral was described by E. Turner, and called **haidingerite**—after W. Haidinger. The mineral occurs at Joachimsthal, Bohemia; and at Wittichen and Alpirsbach, Baden. Analyses reported by E. Turner, and C. F. Rammelsberg correspond with the *monohydrate*, $\text{CaHAsO}_4 \cdot \text{H}_2\text{O}$.

Calcium hydroarsenate is precipitated on mixing an excess of arsenic acid with lime-water. E. Mitscherlich said that if sodium hydroarsenate be added to a soln. of calcium chloride so long as a precipitate is formed, the normal arsenate is formed, but H. Salkowsky, and P. von Kotschoubey found the composition approximates $\text{CaHAsO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, contaminated with some sodium salt. If the acidic filtrate from sodium hydroarsenate and calcium chloride soln. be boiled, it becomes turbid, the soln. clears up again on cooling. The precipitate deposited from the boiling soln. was found by H. Salkowsky to be the monohydrate, $\text{CaHAsO}_4 \cdot \text{H}_2\text{O}$, contaminated with a little soda. According to H. Dufet, if soln. of calcium nitrate and sodium hydroarsenate be allowed to mix slowly by diffusion, crystals resembling pharmacolite are produced. H. Debray digested calcium carbonate with arsenic acid and found that the product obtained at ordinary temp. was hemitrihydrated; that at 70° was monohydrated; and that at 100° was anhydrous. O. Hörmann found the anhydrous salt is produced when the dihydroarsenate is boiled with water. According to A. de Schulten, if a neutral soln. of 10 grms. of calcium carbonate in hydrochloric acid be diluted to 200 c.c., mixed with 25 c.c. of hydrochloric acid of sp. gr. 1.04, and mixed with a soln. of 30 grms. of heptahydrated sodium hydroarsenate in 20 c.c. of water, in 24 hrs., crystals of the *dihydrate*, pharmacolite, are formed; again, if 70 grms. of calcium carbonate be dissolved in hydrochloric acid, and treated with a conc. soln. of 218 grms. of heptahydrated sodium hydroarsenate, and diluted to a litre, heated to 70° on a water-bath, and treated with conc. ammonia until the precipitate is almost dissolved, the filtered soln. yields crystals of the monohydrate, haidingerite, when kept for 10 days at 50°–70°. The equilibrium conditions are indicated in Fig. 26.

C. M. Smith studied the equilibrium conditions in the system $\text{CaO}-\text{As}_2\text{O}_5-\text{H}_2\text{O}$ at 35°. The composition of the soln. with different proportions of lime and arsenic

FIG. 26.—Equilibrium in the System: $\text{CaO}-\text{As}_2\text{O}_5-\text{H}_2\text{O}$ at 35°.

acid is indicated in Fig. 26. *AB* and *BE* are solubility curves with the solid phase respectively $\text{CaHAsO}_4 \cdot \text{H}_2\text{O}$, and $\text{Ca}(\text{H}_2\text{AsO}_4)_2$; and these are the only calcium arsenates stable under these conditions. The area *X* refers to a soln. plus $\text{CaHAsO}_4 \cdot \text{H}_2\text{O}$; *Z*, soln. plus $\text{Ca}(\text{H}_2\text{AsO}_4)_2$; *Y*, constant soln. with 6.8 per cent. CaO and 27.5 per cent. As_2O_5 plus $\text{CaHAsO}_4 \cdot \text{H}_2\text{O}$ plus $\text{Ca}(\text{H}_2\text{AsO}_4)_2$; *V*, to a constant soln. plus $\text{Ca}(\text{H}_2\text{AsO}_4)_2$ plus $3\text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$; and *W*, to soln. with no solid phase. *F* refers to the hydrate $3\text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$.

According to W. Haidinger, the white, rhombic crystals of haidingerite have the axial ratios $a : b : c = 0.83910 ; 1 : 0.49895$; A. de Schulten gave $0.4273 : 1 : 0.4923$ for the artificial crystals. The minute crystals are usually aggregated into botryoidal forms and drusy crusts. The cleavage on the (010)-face is perfect. The thin plates are slightly flexible. The hardness is 1.5–2.5; and the sp. gr. 2.858. The optical character is positive; and A. des Cloizeaux gave for the index of refraction $\gamma = 1.67$. Pharmacolite commonly occurs in delicate silky fibres, or acicular crystals which may occur in stellated groups. The mineral may also occur massive, and in botryoidal and stalactitic forms. A. Schrauf gave for the axial ratios of the grey or white, monoclinic, prismatic crystals of pharmacolite, $a : b : c = 0.61373 : 1 : 0.36223$, and $\beta = 83^\circ 13\frac{1}{2}'$; while for the artificial crystals, H. Dufet gave $0.6236 : 1 : 0.3548$, and $\beta = 83^\circ 13'$. The crystals are said to be isomorphous with those of gypsum; and to be closely related to those of brushite, $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$. The optic axial angle $2V = 79^\circ 24'$. The cleavage on the (010)-face is perfect. A. des Cloizeaux said that the optic axial angle $2H_0$ for red-light is $113^\circ 24'$; for yellow-light, $112^\circ 30'$; and for blue-light, $111^\circ 47'$; the optical character is negative. The hardness is 2.0–2.5; the sp. gr., 2.64–2.73. A. de Schulten gave 2.730 at 15° for the natural crystals, and 2.754 at 15° for the artificial ones. The indices of refraction found by H. Dufet are $\alpha = 1.5825$, $\beta = 1.5891$, and $\gamma = 1.5937$ for Na-light. F. C. B. Schiefer said that calcium hydroarsenate is slightly soluble in acetic acid; and, according to C. H. Pfaff, it is insoluble in water, but dissolves freely in hydrochloric and nitric acids, as well as in an aq. soln. of ammonium chloride, sulphate, nitrate, or acetate. C. F. Wach added that the amount dissolved by soln. of ammonium salts at ordinary temp. is but slight, and that the soln. on standing deposits crystals of a complex salt. When boiled with an ammonium salt, the arsenate is dissolved with the evolution of ammonia. A. Laugier said that with ammonium oxalate, calcium oxalate is formed. According to H. Salkowsky, when hydrated calcium hydroarsenate is heated to 125° , a little water is given off; all the water of crystallization is lost at 160° ; and most of the constitutional water is given off at 240° , and the remainder at a red-heat. A. H. Church found that pharmacolite lost one and retained one mol. of water at 100° – 200° . The dehydrated product has been regarded as **calcium pyroarsenate**, $\text{Ca}_2\text{As}_2\text{O}_7$. C. Lefèvre made crystals of a similar substance by fusing calcium oxide or carbonate with potassium hydroarsenate; or with a mixture of the arsenate with less than 40 per cent. of calcium chloride. It forms colourless rhombic plates which when treated with cold water form calcium hydroarsenate. The pyrophosphate is decomposed at a higher temp.

H. Salkowsky prepared **strontium hydroarsenate**, SrHAsO_4 , by mixing soln. of strontium chloride and sodium hydroarsenate, and warming the acid filtrate from the sodium strontium arsenate to 75° , or, according to A. Joly, to 60° . Crystals of the required salt are deposited. O. Hörmann obtained this salt by the action of hot water on the dihydroarsenate. C. Lefèvre obtained this salt by treating the pyroarsenate with water. A. de Schulten mixed 10 grms. of hexahydrated strontium chloride in 150 c.c. of water, with 177 grms. of heptahydrated sodium hydroarsenate dissolved in 350 c.c. of water. The resulting precipitate was dissolved in conc. hydrochloric acid, and ammonia gradually added until the precipitate produced no longer redissolved. The filtered liquid was heated to 90° , treated with 0.3 per cent. of ammonia, and allowed to stand for a few days, when the anhydrous hydroarsenate crystallized out. If the mother-liquor be allowed to stand at ordinary temp. in an

atm. of ammonia, the *monohydrate*, $\text{SrAsO}_4 \cdot \text{H}_2\text{O}$ —*strontium haidingerite*—separates out in crystals. The prismatic crystals belong to the triclinic system and have the axial ratios $a : b : c = 0.6466 : 1 : 0.8346$, and $\alpha = 92^\circ 4'$, $\beta = 86^\circ 32'$, and $\gamma = 90^\circ 46'$. The sp. gr. of the anhydrous salt is 4.035° at 15° , and that of the monohydrate is 3.306 at 15° . H. Salkowsky found that the water of crystallization is expelled at 130° , and O. Hörmann, that at 360° **strontium pyroarsenate**, $\text{Sr}_2\text{As}_2\text{O}_7$, is formed. C. Lefèvre prepared the pyroarsenate by a method analogous to that employed for the calcium salt. The salt is sparingly soluble in mineral acids.

Several of the phosphate and arsenate minerals occur in isomorphous associations, and the so-called phosphatoarsenates may be isomorphous mixtures. Hexagonal, pyramidal crystals of a **calcium strontium phosphatoarsenate**, $3(\text{Ca}, \text{Sr})_3(\text{P}, \text{As})_2\text{O}_8 \cdot \text{Ca}(\text{OH}, \text{F})_2$, occur native at Sitapar, India; and G. F. H. Smith and G. T. Prior called it **fermorite**—after L. L. Fermor. The mineral is supposed to be a member of the apatite family. It is white with possibly a pink tinge. It is uniaxial; and optically negative. Its hardness is 5; its sp. gr., 3.518; and its refractive index, about 1.660.

According to J. J. Berzelius, and E. Mitscherlich, when sodium hydroarsenate is mixed with an excess of barium chloride, **barium hydroarsenate**, BaHAsO_4 , is precipitated in small scaly crystals. The barium chloride should be in excess, and the sodium arsenate added slowly, drop by drop. The precipitate first formed disappears; if the barium chloride be gradually added to the alkali arsenate, the precipitate is a mixture of orthoarsenate and hydroarsenate, while barium dihydroarsenate remains in soln. According to C. W. Scheele, arsenic acid does not give a precipitate with soln. of barium chloride, nitrate, or acetate. L. Gmelin, and P. von Kotschoubey said that it does give a precipitate with the acetate; and G. Moretti, that it gives a precipitate even with acid barium sulphate. A. Joly obtained the hydroarsenate by adding baryta-water drop by drop to a soln. of arsenic acid until a soln. of phenolphthalein is reddened. The gelatinous precipitate can be crystallized by shaking. O. Hörmann obtained this salt by treating the dihydroarsenate with hot water; A. de Schulten, by a method analogous to that used for the strontium salt; and C. Lefèvre, by the action of water on the pyroarsenate. S. B. Hendricks studied the equilibrium conditions in the system $\text{BaO}-\text{As}_2\text{O}_5-\text{H}_2\text{O}$ at 30° , and the results are summarized in Fig. 27. The

FIG. 27.—Equilibrium in the System: $\text{BaO}-\text{As}_2\text{O}_5-\text{H}_2\text{O}$ at 30° .

solid phases are barium hydroarsenate, $\text{BaHAsO}_4 \cdot \text{H}_2\text{O}$; barium dihydroarsenate, $\text{Ba}(\text{H}_2\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$; and $3\text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$. Alkaline hydrolysis of the former salt gave the orthoarsenate, $\text{Ba}_3(\text{AsO}_4)_2 \cdot n\text{H}_2\text{O}$. F. C. B. Schiefer recrystallized the salt from acetic acid. K. von Haushofer described this salt as forming rhombic or monoclinic plates isomorphous with the phosphate. A. de Schulten gave for the axial ratios of the rhombic crystals $a : b : c = 0.4171 : 1 : 0.4430$. J. J. Berzelius, and E. Mitscherlich said that the salt is a hemitrihydrate, $\text{BaHAsO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$; while P. von Kotschoubey, J. Setterberg, E. J. Maumené, H. Salkowsky, O. Hörmann, and F. C. B. Schiefer found it to be a monohydrate, $\text{BaHAsO}_4 \cdot \text{H}_2\text{O}$, when dried over sulphuric acid, or at 100° ; at $120^\circ-130^\circ$ it loses its water of crystallization, and at 320° its constitutional water, forming, according to O. Hörmann, **barium pyroarsenate**, $\text{Ba}_2\text{As}_2\text{O}_7$. This same substance was prepared by C. Lefèvre by the method employed for the strontium salt. A. de Schulten gave 3.926 at 15° for the sp. gr. of the hydroarsenate. It is sparingly soluble in water, and in soln. of barium chloride and sodium hydroarsenate. It is soluble in dil. mineral acids. L. Gmelin found it to be decomposed by dil. sulphuric acid, and E. Du villier, by dil. nitric acid. J. J. Berzelius, and C. Lefèvre said that water transformed it into a mixture of the orthoarsenate, and hydroarsenate, but H. Salkowsky could not confirm this.

Aq. ammonia was found by E. Mitscherlich to transform more or less of this salt into the normal arsenate.

C. L. Bloxam prepared **calcium dihydroarsenate**, $\text{Ca}(\text{H}_2\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$, by the action of nitric acid on eq. proportions of calcium carbonate and arsenic trioxide; and O. Hörmann, by treating calcium carbonate, or one of the preceding calcium arsenates, with an excess of arsenic acid, and evaporating the soln. The equilibrium conditions are indicated in Fig. 27. The colourless plates lose their water of crystallization at 180° , and at 360° form a crystalline mass of **calcium metarsenate**, $\text{Ca}(\text{AsO}_3)_2$, which is insoluble in hydrochloric acid. The dihydroarsenate is sparingly soluble in cold water, and is decomposed by hot water into arsenic acid and the hydroarsenate. O. Hörmann obtained **strontium dihydroarsenate**, $\text{Sr}(\text{H}_2\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$, from an excess of arsenic acid and strontium carbonate. The crystals lose their water of crystallization at 240° – 250° , and at a red-heat furnish **strontium metarsenate**, $\text{Sr}(\text{AsO}_4)_2$. J. J. Berzelius, and E. Mitscherlich obtained **barium dihydroarsenate**, $\text{Ba}(\text{H}_2\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$, by adding baryta-water to an aq. soln. of arsenic acid so long as a precipitate continues to form; and by crystallization from a soln. of the hydroarsenate in arsenic acid. O. Hörmann obtained it from a soln. of barium carbonate in an excess of arsenic acid. C. F. Rammelsberg reported the monoclinic crystals to have the axial ratios $a : b : c = 1.160 : 1 : 0.625$, and $\beta = 108^\circ 34'$. E. Mitscherlich said that one mol. of water is lost at 120° – 140° , and the other mol. at 180° – 230° ; at a higher temp. **barium metarsenate**, $\text{Ba}(\text{AsO}_3)_2$, is formed. O. Hörmann found that the dihydroarsenate is sparingly soluble in water, and that an excess of water converts it into the hydroarsenate. The salt is freely soluble in hydrochloric acid, and less soluble in acetic acid.

C. F. Wach found that when lime-water is mixed with a dil. soln. of potassium, sodium, or ammonium arsenate and ammonium chloride, nitrate, or acetate, no precipitate is formed at first, but after a while, **ammonium calcium arsenate**, $\text{Ca}(\text{NH}_4)\text{AsO}_4 \cdot \text{H}_2\text{O}$, separates in needle-like crystals; with more conc. soln., the lime-water produces a copious precipitate at once, and when this is digested with an excess of the ammonium salt, it does not dissolve but becomes crystalline. If arsenic acid be added to lime-water until a strong turbidity is produced, and an ammoniacal salt be then added, the liquid first becomes clear and afterwards deposits crystals of the complex salt. If calcium hydroarsenate be immersed in a soln. of ammonium chloride, it takes up a mol. of ammonia, forming this same complex salt. C. F. Wach thus described the preparation of this salt:

One part each of ammonium arsenate and chloride are dissolved in 4 parts of water, and lime-water is added so long as crystals begin to form. The crystals increase in quantity when the liquid is set aside in a cool place for 24 hrs. The salt is washed with water and dried between bibulous paper. The salt resembled ammonium magnesium arsenate.

F. Field made this salt by adding an excess of an ammoniacal soln. of ammonium arsenate to a soln. of calcium chloride; C. L. Bloxam, by adding arsenic acid to an ammoniacal soln. of calcium chloride; C. Lefèvre, by adding ammonia to a soln. of calcium arsenate in dil. hydrochloric acid; and E. Baumann, by mixing soln. of calcium nitrate and arsenic acid in aq. ammonia. The salt may appear as a white crystalline powder, in needle-like crystals, or rhombic plates. The crystals effloresce in air, and, according to C. L. Bloxam, they lose all their combined water in 36 days. C. Lefèvre said that half the water is lost at 100° , and F. Field, that all is expelled at 140° . P. von Kotschoubey said that the salt dried at 125° is monohydrated. C. L. Bloxam regarded the salt as hexahydrated and said that when dried in vacuo over sulphuric acid, the composition is $(\text{NH}_4)\text{Ca}_3\text{H}_2(\text{AsO}_4)_3 \cdot 3\text{H}_2\text{O}$; and when dried at 100° , $(\text{NH}_4)\text{Ca}_6\text{H}_5(\text{AsO}_4)_6 \cdot 3\text{H}_2\text{O}$. When heated to a higher temp., calcium arsenate is formed. F. Field said that 100 parts of water dissolve 0.02 part of salt; and C. Lefèvre, 0.046 part of the hemihydrate at 15° . F. Field said that 100 parts of a 5 per cent. soln. of ammonium chloride dissolve 0.42 part; and 100 parts of a 3.5 per cent. ammonia, 0.001 part of salt; while C. Lefèvre said that 100 parts of a soln. of one part of ammonium chloride in 7 parts of water dissolve 0.0023

he gave $\omega=1.778$, and $\epsilon=1.801$. L. Michel found the hardness to be 5.5; and the sp. gr. given by A. Breithaupt and F. W. Fritzsche, is 4.123, and by L. Michel, 4.15. It dissolves in acids. C. Palache and E. V. Shannon⁴ described a mineral, which they called **higginsite**, from the Higgins mine, Bisbee, Arizona. The analysis corresponds with **calcium copper hydroxyarsenate**, $\text{CuCa}(\text{OH})(\text{AsO}_4)$, say $\text{Cu}=\text{AsO}_4-\text{Ca}(\text{OH})$. The bright green rhombic crystals have the axial ratio $a : b : c = 0.6242 : 1 : 0.7940$. Its sp. gr. is 4.33; its hardness, 4.5; the birefringence is 0.030; the index of refraction α is greater than 1.745; E. S. Larsen found the optical character is negative, the optic axial angle about 90° , and the indices of refraction, $\alpha=1.800$, $\beta=1.831$, and $\gamma=1.846$. C. Palache and E. V. Shannon found that the pleochroism α =green, β =yellowish-green, and γ =bluish-green. The mineral is readily soluble in hydrochloric or nitric acid, partly soluble in sulphuric acid, and insoluble in aq. ammonia. W. F. Foshag found a greenish-blue mineral at San Juan, Freirini Dept., Chile, and he called it **freirinite**. The analysis corresponds with **sodium calcium copper arsenate**, $6(\text{Cu},\text{Ca})\text{O} \cdot 3\text{Na}_2\text{O} \cdot 2\text{As}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$. It is uniaxial and negative; the refractive index $\epsilon=1.645$ and $\omega=1.748$; it is pleochroic, ϵ being light greenish-blue, and ω , dark greenish-blue; the optic axial angle $2V$ is small; and the basal cleavage, good.

§ 18. The Arsenates of the Beryllium-Mercury Family

While the magnesium arsenates are stable, those of aluminium can be obtained in aq. soln. only in a highly basic form, and those of beryllium are intermediate between the two. A. Atterberg¹ made **beryllium orthoarsenate**, $\text{Be}_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O}$, as a flocculent precipitate, by adding sodium orthoarsenate to a soln. of a beryllium salt. J. J. Berzelius also made this salt, and said that it is insoluble in water but soluble in an excess of arsenic acid. B. Bleyer and B. Müller made this salt by mixing sodium hydroarsenate and beryllium sulphate in the proportions required for $\text{BeSO}_4 + \text{Na}_2\text{HASO}_4 = \text{BeHASO}_4 + \text{Na}_2\text{SO}_4$; the product is hydrolyzed and these products furnish a voluminous white powder. The air-dried product is the *pentadecahydrate*, $\text{Be}_3(\text{AsO}_4)_2 \cdot 15\text{H}_2\text{O}$. If this salt remains for a long time in contact with the mother-liquor it is hydrolyzed into a basic salt. If an attempt is made to prepare the orthoarsenate by the reaction: $2\text{Na}_3\text{AsO}_4 + 3\text{BeSO}_4 = \text{Be}_3(\text{AsO}_4)_2 + 3\text{Na}_2\text{SO}_4$, the basic salt, **beryllium oxyorthoarsenate**, $\text{BeO} \cdot \text{Be}_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$, is deposited as a white amorphous powder. A. Atterberg obtained **beryllium hydroarsenate**, $\text{BeHASO}_4 \cdot 2\text{H}_2\text{O}$, by dissolving the hydroxide in arsenic acid, and precipitating with alcohol. It is viscous solid. B. Bleyer and B. Müller obtained the anhydrous salt by heating arsenic pentoxide and beryllium hydroxide in a sealed tube at about 220°. The product is impure. It was not possible to obtain it in soln. They also prepared beryllium dihydroarsenate, $\text{Be}(\text{H}_2\text{AsO}_4)_2$, by the action of a hot sat. soln. of arsenic acid on beryllium hydroxide. The conc. soln. over sulphuric acid yields colourless hygroscopic crystals which can be dried on porous tiles. They prepared **ammonium beryllium orthoarsenate**, $\text{NH}_4\text{BeAsO}_4 \cdot 4\frac{1}{2}\text{H}_2\text{O}$, from a mixture of ammonium sulphate, sodium hydroarsenate, and arsenic acid. This salt readily undergoes hydrolysis, and the basic products $2(\text{NH}_4)_2\text{O} \cdot 3\text{As}_2\text{O}_5 \cdot 7\text{BeO} \cdot 11\text{H}_2\text{O}$, and $(\text{NH}_4)_2\text{O} \cdot 2\text{As}_2\text{O}_5 \cdot 5\text{BeO} \cdot 7\text{H}_2\text{O}$ —respectively **ammonium beryllium hexaorthoarsenate**, $2(\text{NH}_4)_2\text{Be}_2(\text{AsO}_4)_2 \cdot \text{Be}_3(\text{AsO}_4)_2$, and **ammonium beryllium tetraorthoarsenate**, $(\text{NH}_4)_2\text{Be}_2(\text{AsO}_4)_2 \cdot \text{Be}_3(\text{AsO}_4)_2$, result. The potassium and sodium salts are even more easily hydrolyzed, so that B. Bleyer and B. Müller could prepare only the basic salts **sodium beryllium oxydiorthoarsenate**, $2\text{NaBeAsO}_4 \cdot \text{BeO} \cdot 12\text{H}_2\text{O}$; and **potassium beryllium oxydiorthoarsenate**, $2\text{KBeAsO}_4 \cdot \text{BeO} \cdot 10\text{H}_2\text{O}$, from the alkali hydroarsenate, and beryllium sulphate.

When a soln. of magnesium sulphate is treated with the eq. amount of sodium orthoarsenate, and the amorphous precipitate is allowed to stand in contact with the mother-liquid for some days, F. Kinkelin² observed that crystals of the *docoshydrate* of normal magnesium arsenate, or **magnesium orthoarsenate**,

$Mg_3(AsO_4)_2 \cdot 22H_2O$, are produced; and if ammonium or potassium magnesium orthoarsenate be digested with water for a long time, crystals of the *decahydrate*, $Mg_3(AsO_4)_2 \cdot 10H_2O$, appear. A. de Schulten mixed a soln. of 20 grms. of heptahydrated magnesium sulphate in a litre of water with a mixture of 16.9 grms. of heptahydrated sodium hydroarsenate and 4.5 grms. of sodium hydrocarbonate in 800 c.c. of water, and allowed the amorphous precipitate to stand for 24 hrs. at 20°. Crystals of the *octohydrate*, $Mg_3(AsO_4)_2 \cdot 8H_2O$, were formed. Again, L. Chevron and A. Droixhe mixed soln. of sodium dihydroarsenate, magnesium sulphate, and sodium hydrocarbonate, and obtained the *heptahydrate*, $Mg_3(AsO_4)_2 \cdot 7H_2O$. The octohydrate also occurs in nature as the mineral **hoernesite**—named after R. Hoernes—which was described by W. Haidinger. It was first recognized by A. Kenngott in a collection of minerals from Barnat, Hungary. The analysis agrees closely with $Mg_3(AsO_4)_2 \cdot 8H_2O$. E. Bertrand found the hoernesite from Nagyag, Hungary, contained a little calcium and manganese. W. Haidinger said that the crystals of hoernesite are monoclinic and probably isomorphous with those of vivianite, bobierrite, and erythrite. The snow-white crystals have the gypsum habit. The crystals are also columnar and stellar foliated. The clinodiagonal cleavage is perfect. F. Zambonini, and A. de Schulten made a few measurements of the crystal angles. W. Haidinger gave for the hardness of hoernesite 1, and for the sp. gr. 2.474; A. de Schulten found the artificially prepared octohydrate to have a sp. gr. of 2.609 at 15°. W. Haushofer found the tabular crystals of the dicosihydrate to be monoclinic and isomorphous with the corresponding phosphate. E. S. Larsen found the optic axial angle to be 60°; the optical character positive; and the indices of refraction of the monoclinic crystals to be $\alpha=1.548-1.563$, $\beta=1.556-1.571$, and $\gamma=1.574-1.596$. The sp. gr. is 1.788 at 15°. The optical properties were also studied by F. Ulrich, A. de Schulten, and F. Zambonini. Hoernesite is easily soluble in acids. F. Kinkelin found that when the dicosihydrate is dried over conc. sulphuric acid it contains 6 mols. of water; when dried at 100°, 5 mols.; and when dried at 200°, one mol. The dicosihydrate effloresces slowly in air, and when kept under water it forms the decahydrate which does not change in air. According to C. Blarez, the neutralization of arsenic acid furnishes 14.87 cal. for the first eq. of base; 11.46 cal. for the second; and 2.03 cal. for the third. In the coagulation of magnesium arsenate, gel formation was found by E. O. Kraemer to occur comparatively suddenly following an initial induction period.

T. Graham obtained **magnesium hydroarsenate**, $MgHAsO_4 \cdot nH_2O$, by the action of sodium hydroarsenate on magnesium sulphate in aq. soln.; and, added F. Kinkelin, some of the normal arsenate is precipitated at the same time. F. Kinkelin neutralized a soln. of sodium hydroarsenate with acetic acid, added the calculated amount of magnesium sulphate, allowed the amorphous precipitate to stand for some days, and thus obtained crystals of the *heptahydrate*, $MgHAsO_4 \cdot 7H_2O$. P. von Kotschoubey said both T. Graham's and F. Kinkelin's products are heptahydrates. F. C. B. Schiefer said that the salt which crystallizes from a soln. of the calcined residue of ammonium magnesium arsenate in acetic acid is the *pentahydrate*, $MgHAsO_4 \cdot 5H_2O$, but F. Kinkelin said that it is the heptahydrate. A. de Schulten heated magnesium carbonate with an excess of arsenic acid in a sealed tube at 225°, and obtained monoclinic prisms of the *hemihydrate*, $MgHAsO_4 \cdot \frac{1}{2}H_2O$. Heptahydrated magnesium hydroarsenate occurs in nature as the mineral **roesslerite**—named after K. Roessler—described by J. R. Blum as occurring in thin plates with a columnar or fibrous structure at Bieber, Hasse. The monoclinic crystals of roesslerite were found by K. von Haushofer to have the axial ratios $a : b : c = 0.4473 : 1 : 0.2598$, and $\beta = 94^\circ 26'$. The cleavage on the (111)-face is incomplete. A. de Schulten gave 3.155 for the sp. gr. at 15° of the salt he prepared. The heptahydrate is stable in air; and F. Kinkelin found that it is decomposed by much water into the normal orthoarsenate and soluble acidic salt. C. Reischauer said that the heptahydrate loses 4.5 mols. of water when dried over sulphuric acid;

F. Kinkelin said 5.5 mols. are so lost; and 5 mols. at 100° —T. Graham said 6 mols.—and 6 mols. at 200° . T. Graham, and F. Kinkelin found that when the hydroarsenate is calcined, the so-called **magnesium pyroarsenate**, $Mg_2As_2O_7$, is formed. The same product was obtained by G. C. Wittstein, A. Levul, and C. R. Fresenius, by calcining ammonium magnesium arsenate—*vide infra*. The pyroarsenate is a white powder which H. Stallo found to have a sp. gr. of 3.7305–3.7649 at 15° – 18° ; and, added T. Graham, it melts at a high temp., and by a strong calcination becomes insoluble in acids. T. Graham regarded **magnesium dihydroarsenate**, $Mg(H_2AsO_4)_2$, as a gummy mass soluble in water; and F. C. B. Schiefer said that very deliquescent crystals of what was assumed to be this salt, are formed from a soln. of magnesium oxide in arsenic acid.

C. F. Wach found that **ammonium magnesium arsenate**, $(NH_4)MgAsO_4 \cdot 6H_2O$, is produced by adding ammonium orthoarsenate to a soln. of magnesium chloride, sulphate, or nitrate so long as a translucent, crystalline precipitate is formed, and washing and drying the precipitate. A. Levul found that this salt is deposited when an ammoniacal soln. of an arsenate is treated with a soln. of a magnesium salt containing ammonium chloride—*vide supra*, analytical reactions of arsenic. If an excess of magnesium sulphate be used, R. E. O. Puller, and C. Freidheim and P. Michaelis observed that the precipitate may be contaminated with basic magnesium sulphate. L. F. Wood, and C. Freidheim and P. Michaelis precipitated the complex salt from alcoholic soln. A. de Schulten reported that measurable crystals of the complex salt are produced by allowing a mixture of 20 grms. of heptahydrated sodium hydroarsenate, 20 grms. of ammonium sulphate, 6 grms. of arsenic acid of sp. gr. 1.350, in 80 c.c. of water with a soln. of 16 grms. of heptahydrated magnesium sulphate in 120 c.c. of water, to stand for 24 hrs. Analyses in agreement with the above formula were made by C. F. Wach, R. E. O. Puller, and M. Austin. The white powder, said J. A. Streng, consists of minute crystals. According to A. de Schulten, the rhombic crystals have the axial ratios $a : b : c = 0.5675 : 1 : 0.9122$; and the sp. gr. is 1.932 at 15° . C. F. Wach found the crystals slowly effloresce in dry air. C. F. Wach, H. Rose, and R. E. O. Puller said that when dried over sulphuric acid, the salt is the *hexahydrate*; H. Rose, F. Field, R. E. O. Puller, and C. Lefèvre, that when dried at approximately 100° , the salt is the *hemihydrate*, and, at 102.5° – 104.5° , R. Bunsen said that the water is all expelled, though R. E. O. Puller found that a little water is retained at that temp.; and E. W. Parnell, C. F. Rammelsberg, and L. Chevron and A. Droixhe, that some ammonia is lost at 100° – 110° . As indicated in connection with magnesium hydroarsenate, when this salt is heated, it yields the pyroarsenate. In order to avoid a slight reduction of arsenate to arsenite, C. R. Fresenius heated the salt in an atm. of oxygen, and F. G. Reichel moistened it with nitric acid. The reaction was examined by B. Brauner, A. Levul, R. E. O. Puller, C. F. Rammelsberg, H. Rose, G. C. Wittstein, and L. F. Wood. H. Rose, and R. E. O. Puller said that if ammonium magnesium arsenate be rapidly heated, a little arsenic pentoxide is reduced to volatile arsenic trioxide, and C. Lefèvre found that this occurs even in an atm. of oxygen. O. Popp observed no luminescence during the formation of the pyroarsenate such as occurs with the pyrophosphate. C. Blarez gave for the heats of formation: $(Mg(OH)_2, H_3AsO_4) = 26.50$ Cals., and $(MgHASO_4, NH_3) = 11.44$ Cals. On account of the part played by this salt in analytical work, a few special observations have been made on its solubility in various menstrua. The salt is but sparingly soluble in water, and freely soluble in acids. F. Field said that 100 parts of *water* dissolve 0.014 part of the salt. C. R. Fresenius gave for the solubility in 100 parts of water at 15° , 0.0377 part of the hemihydrate and 0.0359 part of the anhydrous salt, while R. E. O. Puller gave 0.0377 part of the hemihydrate, and 0.0359 part of the anhydrous salt. P. Wenger gave for the solubility of the hexahydrate in water expressed in grms. of salt per 100 grms. of soln.:

	0°	20°	40°	50°	60°	70°	80°
$NH_4MgAsO_4 \cdot 6H_2O$	0.03338	0.02066	0.02746	0.02261	0.02103	0.01564	0.02364

from which it appears that the character of the solid phase undergoes changes. This has not been worked out. F. Kinkelin showed that water slowly transforms ammonium magnesium arsenate into normal magnesium arsenate; and C. Freidheim and P. Michaelis represented the reaction with water, $(\text{NH}_4)\text{MgAsO}_4 + 2\text{H}_2\text{O} = \text{Mg}(\text{OH})_2 + (\text{NH}_4)\text{H}_2\text{AsO}_4$. C. R. Fresenius said that at 15°, 100 parts of soln. of 1·14, and 12·5 per cent. of *ammonium chloride* dissolve respectively 0·076 and 0·118 part of the hemihydrate, and 0·0725 and 0·113 part of the anhydrous salt; while R. E. O. Puller gave for 1·64 and 12·5 per cent. soln. of ammonium chloride respectively 0·0757 and 0·118 part of the hemihydrate, and 0·0722 and 0·113 part of the anhydrous salt. F. Field said that 100 parts of an aq. soln. of 10 parts of ammonium chloride dissolve 0·095 part of the anhydrous salt. R. E. O. Puller found that 100 parts of a 2 per cent. soln. of *ammonium nitrate*, containing a few drops of aq. ammonia, dissolve 0·0239 part of the hemihydrate, and 0·0233 part of the anhydrous salt. P. Wenger gave for the solubility of the hexahydrate in grams per 100 grms. of 5 per cent. soln. of ammonium nitrate and chloride:

	0°	20°	30°	40°	50°	60°	70°	80°
NH_4NO_3	0·09216	0·11358	0·11758	0·13936	0·18945	0·21115	0·18880	0·18945
NH_4Cl	0·08397	0·12284	0·11264	0·19016	0·18889	0·21952	0·22092	0·23144

The solubility is reduced in ammoniacal soln. Thus, R. E. O. Puller found that 100 parts of a 2·6 per cent. soln. of *ammonia* dissolve 0·00660 part of the hemihydrate, and 0·00630 part of the anhydrous salt; C. R. Fresenius said 0·00664 part and 0·00633 part respectively at 15°; and F. Field found that 90 parts of water and 10 parts of aq. ammonia of sp. gr. 0·880 dissolve 0·007 part of ammonium magnesium arsenate, while P. Wenger gave for the solubility in grams of the hexahydrate in 100 grms. of aq. ammonia containing 4 parts of water and one part of ammonia of sp. gr. 0·96:

	0°	20°	40°	50°	60°	70°	80°
NH_4OH	0·00874	0·00958	0·01173	0·01005	0·00902	0·00949	0·00912

P. Wenger added that 100 grms. of a soln. containing 4 per cent. of ammonia and 5 per cent. ammonium chloride at 20° and 60°, dissolved respectively 0·01331 and 0·04691 gm. of the hexahydrate; and with 100 grms. of a similar soln. but with twice as much ammonium chloride, the data were respectively 0·03165 and 0·05353 gm. R. E. O. Puller also found that 100 parts of a soln. of *magnesium sulphate*, 100 c.c. of which was eq. to 0·0286 gm. $\text{Mg}_2\text{As}_2\text{O}_7$, dissolved 0·0374 part of the hemihydrate, and 0·0345 part of the anhydrous salt; 100 parts of *magnesia mixture*—10 c.c. of a soln. of one part each of ammonium chloride and magnesium sulphate in 4 parts of aq. ammonia, of sp. gr. 0·96, and 8 parts of water, mixed with 200 c.c. of water—dissolved 0·0032 part of the hemihydrate and 0·0031 part of the anhydrous salt; 100 parts of a 5 per cent. soln. of *sodium arsenate* dissolved 0·0228 part of the hemihydrate and 0·0217 part of the anhydrous salt; 100 parts of a 1·5 per cent. soln. of *potassium chloride* dissolved 0·0410 part of the hemihydrate, and 0·0390 part of the anhydrous salt; 100 parts of a soln. of *ammonium tartrate*—containing 3·5 grms. of tartaric acid made feebly alkaline with ammonia and diluted to 250 c.c.—dissolved 0·0709 part of the hemihydrate, and 0·0703 part of the anhydrous salt; while 100 parts of a soln. of *ammonium citrate*—containing 2·5 grms. of citric acid made feebly alkaline with ammonia and diluted to 250 c.c.—dissolved 0·112 part of the hemihydrate, and 0·107 part of the anhydrous salt.

According to H. Rose, and R. E. O. Puller, when ammonium magnesium arsenate is heated in hydrogen, reduction occurs and arsenic is lost by volatilization; similarly also with sulphur, and with ammonium chloride. It is not possible to free the resulting magnesia from arsenic oxide by repeated ignition with ammonium chloride, but it is possible to do so by means of ammonium hydro-sulphate, and, according to C. W. Zenger, by means of ammonium oxalate.

H. Rose reported white, pulverulent, **sodium magnesium arsenate**, NaMgAsO_4 , to be formed by melting eq. proportions of sodium carbonate and magnesium pyroarsenate; and C. Lefèvre, colourless prisms, by saturating with magnesia molten sodium dihydroarsenate or a mixture of the salt and sodium chloride, and removing the by-products with very dil. nitric acid. F. Kinkelin obtained the

enneahydrate, $\text{NaMgAsO}_4 \cdot 9\text{H}_2\text{O}$, by allowing a soln. of sodium orthoarsenate to react with less than the calculated amount of magnesium sulphate. The amorphous precipitate slowly crystallizes, forming, according to K. von Haushofer, triclinic crystals with the axial ratios $a : b : c = 1.2401 : 1 : 1.4796$, and $\alpha = 87^\circ 22'$; $\beta = 84^\circ 40'$; and $\gamma = 87^\circ 24'$. The crystals are isomorphous with the corresponding phosphate. F. Kinkelin said that the *enneahydrate* is stable in air, and at 110° , passes into the *octohydrate*, $\text{NaMgAsO}_4 \cdot 8\text{H}_2\text{O}$. The salt is decomposed by water into normal magnesium arsenate. The anhydrous salt, said C. Lefèvre, is very slowly soluble in acids. C. Lefèvre obtained colourless, transparent plates of $\text{Na}_4\text{Mg}_4\text{As}_3\text{O}_{21}$, **sodium magnesium hexarsenate**, from a soln. of 5 per cent. magnesia in molten dihydroarsenate; and he obtained the corresponding **potassium magnesium hexarsenate**, $\text{K}_4\text{Mg}_4\text{As}_6\text{O}_{21}$, in an analogous way.

H. Rose and C. Lefèvre prepared **potassium magnesium arsenate**, KMgAsO_4 , by methods analogous to those they employed for the complex salt; and F. Kinkelin obtained needle-like crystals of the *heptahydrate*, $\text{KMgAsO}_4 \cdot 7\text{H}_2\text{O}$, by the method employed for the analogous *enneahydrated* sodium complex salt. The crystals are stable in air; and at 100° , form the *monohydrate*, $\text{KMgAsO}_4 \cdot \text{H}_2\text{O}$, which is decomposed by water into magnesium and potassium orthoarsenates. F. Kinkelin mixed soln. of equimolar parts of potassium orthoarsenate and hydroarsenate with 2 mols. of magnesium sulphate, and observed that the amorphous precipitate rapidly crystallized, forming monoclinic prisms of **potassium magnesium hydrodiorthoarsenate**, $\text{Mg}_2\text{K}(\text{AsO}_4)_2 \cdot 15\text{H}_2\text{O}$, isomorphous with the corresponding phosphate. The *pentadecahydrate* is stable in air, but forms the *dihydrate*, $\text{Mg}_2\text{KH}(\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$, at 110° . It is decomposed by water into magnesium orthoarsenate, and potassium hydroarsenate. L. Chevron and A. Droixhe reported the *pentahydrate*, $\text{Mg}_2\text{KH}(\text{AsO}_4)_2 \cdot 5\text{H}_2\text{O}$, to crystallize from a dil. soln. of potassium dihydroarsenate and hydrocarbonate, and magnesium sulphate; and crystals of the *tetrahydrate*, $\text{Mg}_2\text{KH}(\text{AsO}_4)_2 \cdot 4\text{H}_2\text{O}$, from a filtered soln. of magnesia in aq. potassium dihydroarsenate. They obtained crystals of **potassium magnesium dihydrotriorthoarsenate**, $\text{Mg}_3\text{KH}_2(\text{AsO}_4)_3 \cdot 5\text{H}_2\text{O}$, from a conc. soln. of magnesium sulphate and potassium dihydroarsenate and hydrocarbonate. F. Kinkelin reported crystals of **sodium potassium magnesium diorthoarsenate**, $\text{Mg}_2\text{KNa}(\text{AsO}_4)_2 \cdot 14\text{H}_2\text{O}$, to separate from a mixed soln. of potassium and sodium orthoarsenates, and magnesium sulphate.

H. Behrens found that *magnesium orthoarsenate and ammonium cupric arsenate* form a series of mixed crystals. F. Stromeyer³ described crystals of a **calcium magnesium arsenate**, which occurred as a mineral at Riechelsdorf, and which was named **picropharmacolite**—*πικρός*, bitter—in allusion to the contained magnesia—*magnesium pharmacolite*. Specimens have been also obtained at Freiberg, and Joplin, Mo. Analyses were reported by F. Stromeyer, A. Frenzel, and F. A. Genth. C. F. Rammelsberg represented it by the formula $5\text{Ca}_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O} \cdot \text{Mg}_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O}$; A. Frenzel used $\text{Ca}_5\text{As}_4\text{O}_{15} \cdot 12\text{H}_2\text{O}$, without reference to the contained magnesia; F. A. Genth gave $(\text{H}_2\text{Ca}, \text{Mg})_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O}$; and P. Groth, $(\text{Ca}, \text{Mg})_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O}$. It occurs in white or grey aggregates of small spherical or botryoidal forms with a radiating foliated structure; and rarely in slender acicular crystals. E. S. Larsen found the optic axial angle of the monoclinic crystals is 40° ; the optical character, positive; and the indices of refraction, $\alpha = 1.631$, $\beta = 1.632$, and $\gamma = 1.640$. F. A. Genth gave 2.583 for the sp. gr., and found that when dried for a month over sulphuric acid, it loses a mol. of water, forming the pentahydrate, $(\text{H}_2\text{Ca}, \text{Mg})_3(\text{AsO}_4)_2 \cdot 5\text{H}_2\text{O}$.

Another calcium magnesium arsenate occurring at Schneeberg, and Joachimsthal was named by A. Frenzel⁴ **wapplerite**—after H. W. Wappler. The analysis corresponds with $(\text{Ca}, \text{Mg})\text{HAsO}_4 \cdot 3\frac{1}{2}\text{H}_2\text{O}$. The mineral loses 19 of its 29.5 per cent. of water at 100° , and the remainder at 360° . According to A. Schrauf, the crystals are monoclinic with the axial ratios $a : b : c = 0.9125 : 1 : 0.2660$, and $\beta = 84^\circ 35'$; while P. Groth regards them as triclinic with the axial ratios $a : b : c$

$=0.9007 : 1 : 0.2616$, and $\alpha=90^\circ 14'$, $\beta=95^\circ 20'$, and $\gamma=90^\circ 11'$. The optical axial angle is $2E=55^\circ$; the hardness, 2.0–2.5; and the sp. gr., 2.48. A. de Schulten said that wapperite is not a definite mineral species, but rather a mixture of magnesium and calcium arsenates which are not isomorphous and do not form solid soln.

The mineral **adelite** reported by H. Sjögren⁵ to occur at Nordmarken and Langban, Wermland, has the composition of a basic salt, **calcium magnesium hydroxyarsenate**, $\text{Ca}(\text{MgOH})\text{AsO}_4$, and he represents it by the formula $\text{Ca}=\text{O}_2=\text{AsO}-\text{O}-\text{MgOH}$. It is supposed to be related to the wagnerite family of minerals, having magnesium phosphate replaced by calcium arsenate, and fluorine by hydroxyl—*vide infra*, tilasite. A related mineral from Nordmark was described by L. J. Igelström, and C. H. Lundström as a calcium magnesium arsenate related to berzeliiite. It occurs in white or grey masses, and in monoclinic prisms with the axial ratios $a : b : c = 1.0989 : 1 : 1.5642$, and $\beta = 73^\circ 15'$. The optic axial angle is 58.47° for Na-light, and the optical character is negative. E. S. Larsen said positive, and he gave $2V=90^\circ$, and the indices of refraction $\alpha=1.712$, $\beta=1.721$, and $\gamma=1.731$. The sp. gr. is 3.71–3.76, and the hardness nearly 5. The water is expelled only at a high temp. The mineral fuses easily, and is easily soluble in dil. acids.

A. de Schulten⁶ reported **zinc orthoarsenate**, $\text{Zn}_3(\text{AsO}_4)_2$, to be formed by evaporating a mixed soln. of arsenic acid and zinc chloride to dryness, and heating the residue to about 730° . The mass is washed with water, and then rapidly with dil. acetic acid and triturated in a mortar to remove basic zinc chloride. The rhombic prisms are probably isomorphous with those of zinc orthophosphate. The sp. gr. is 4.913 at 15° . T. A. Mitchell obtained a hydrated zinc orthoarsenate by treating arsenic trioxide and zinc with nitric acid. H. Salkowsky, and W. Demel obtained the *trihydrate*, $\text{Zn}_3(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$, as a white voluminous precipitate, by treating a soln. of zinc sulphate with sodium orthoarsenate; and by adding alkali-lye to a soln. of the hydroarsenate in hydrochloric acid. A. Bette prepared trihydrated **zinc diamminorthoarsenate**, $\text{Zn}_3(\text{AsO}_4)_2 \cdot 2\text{NH}_3 \cdot 3\text{H}_2\text{O}$, by mixing a soln. of zinc chloride with enough ammonium chloride to prevent it giving a precipitate with ammonia, and digesting the liquid with a mixture of ammonia and potassium arsenate. The flocculent precipitate soon becomes crystalline. The white powder loses almost all its water and a little ammonia at 100° ; it is insoluble in water; and soluble in acids, ammonia, and potash-lye. H. B. Weiser and A. P. Bloxson prepared a **hydrogel of zinc arsenate** by mixing soln. of a salt of a strong acid with potassium dihydroarsenate in the cold.

The *octohydrate*, $\text{Zn}_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$, was prepared by W. Skey, by adding a soluble arsenate to a soln. of a zinc salt so long as the liquor remains acidic. A. de Schulten mixed soln. of 18 grms. of heptahydrated zinc sulphate in 2 litres of water with 12 grms. of heptahydrated zinc hydroarsenate in a litre of water; or similarly with soln. one-fourth this conc. In each case, the amorphous precipitate was allowed to stand in contact with the mother-liquor a few days in which crystals of the octohydrate were formed. O. Köttig, and C. F. Naumann described a zinc arsenate occurring with smaltite in a cobalt mine near Schneeberg. J. D. Dana called it **köttigite**—after O. Köttig. The mineral is coloured red owing to the presence of about 2 per cent. of nickel oxide and 6.9 per cent. of cobalt oxide, so that the formula can be written $(\text{Zn}, \text{Co}, \text{Ni})_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$. The mineral occurs massive, or in crystalline crusts with a fibrous structure. According to P. Groth, the crystals are monoclinic and isomorphous with vivianite; A. de Schulten found that artificial köttigite occurs in colourless, monoclinic prisms which are optically positive. E. S. Larsen found the optic axial angle to be 77° ; and the indices of refraction $\alpha=1.662$, $\beta=1.683$, and $\gamma=1.717$. The optical properties of the mineral were studied by F. Ulrich. The hardness of the mineral is 2.5–3.0, and the sp. gr. 3.1; A. de Schulten gave for the sp. gr. of the artificial crystals 3.309 at 15° . The salt loses about 2 mols. of water at 100° . It is easily soluble in dil. acids.

The basic salt, **zinc hydroxyorthoarsenate**, $\text{Zn}(\text{AsO}_4)\text{Zn}(\text{OH})$, $\text{Zn}_3(\text{AsO}_4)_2 \cdot \text{Zn}(\text{OH})_2$, or $4\text{ZnO} \cdot \text{As}_2\text{O}_5 \cdot \text{H}_2\text{O}$ —*vide* sarkinite—is represented by the mineral **adamite**, discovered by C. Friedel, and named by him *adamine*—after M. Adam. It occurs at Chanarcillo, Chili; at Mte. Valerio, Campiglia Maritima; at Cap Garonne, Hyères, France; and in the ancient zinc mines of Laurium, Greece, where it fills some drusy cavities in the cellular smithsonite. The colour may be white, yellow, green, rose-red, or violet. Analyses were reported by C. Friedel, A. des Cloizeaux, A. Damour, F. Pisani, V. Rosicky, V. Dürrfeld, and P. Aloisi. C. F. Rammelsberg, and V. Dürrfeld represented the analyses by the formula $\text{Zn}_3(\text{AsO}_4)_2 \cdot \text{Zn}(\text{OH})_2$; and A. de Schulten, and P. Groth, by $\text{Zn}(\text{ZnOH})\text{AsO}_4$, when part of the zinc is replaced mainly by copper. A. Lacroix called the mineral *cupro-adamite*, and when by cobalt, *cobaltoadamite*. A. de Schulten synthesized the mineral by keeping artificial *köttigite* in its mother-liquor for some time; and also by adding gradually 3 grms. of heptahydrated sodium hydroarsenate dissolved in a litre of water, and made acid with a few drops of sulphuric acid, to a soln. of 4.5 grms. of heptahydrated zinc sulphate dissolved in 2 litres of water, and heated on a water-bath. After standing 3 weeks, crystals of adamite appear covering the bottom of the containing vessel. The mineral was also synthesized by C. Friedel and E. Sarasin by heating zinc phosphate with arsenic acid and water in a sealed tube at 130° – 140° —*vide infra*, action of boiling water on zinc hydroarsenate. The crystals may be grouped in crusts, or fine granular aggregates. The prismatic crystals are rhombic, and A. des Cloizeaux gave for the axial ratios $a : b : c = 0.9733 : 1 : 0.7158$; P. Aloisi, $0.97359 : 1 : 0.701315$; and V. Rosicky, $0.704869 : 1 : 0.976427$. Adamite is isomorphous with libethenite, and olivenite. A. des Cloizeaux found the optic axial angles to be $2H_a = 108^\circ 34'$ for red light, and $111^\circ 39'$ for blue light; $2H_o = 115^\circ 51'$ for red light, and $113^\circ 52'$ for blue light; while V. Rosicky gave $2V = 82^\circ 57\frac{2}{3}'$. The optical character is positive—perhaps also negative. The mean index of refraction for Na-light is 1.728. E. S. Larsen gave $\alpha = 1.708$, $\beta = 1.734$, and $\gamma = 1.758$. The dispersion is large. The crystals were examined by L. J. Spencer, H. Ungenmach, and A. H. Means. The hardness of adamite is 3.5; and the sp. gr. given by C. Friedel is 4.338; and A. Damour gave 4.352; while A. de Schulten gave 4.475 for the sp. gr. of artificial adamite. C. Friedel said that the mineral is easily fused; and is readily soluble in dil. hydrochloric acid, and is attacked by acetic acid.

J. J. Berzelius referred to the formation of cubic crystals of acidic zinc arsenate by evaporating the soln. obtained by treating zinc, zinc oxide, or zinc pyroarsenate with arsenic acid; N. W. Fischer obtained a gelatinous mass by the action of zinc on arsenic acid; and H. Goguel said that if the gelatinous substance be heated it forms monoclinic plates. According to G. Kemp and J. von Gyulay, when a soln. of zinc salt is treated with alkali orthoarsenate or hydroarsenate neutralized with hydrochloric acid, a gelatinous mass of **zinc hydroarsenate**, ZnHAsO_4 , is formed which crystallizes on standing for 2 or 3 months, or when dried in a water-oven. J. H. Debray reported crystals of the *monohydrate*, $\text{ZnHAsO}_4 \cdot \text{H}_2\text{O}$, to be formed when ammonium arsenate is treated with zinc sulphate, and digested for 8–14 days at 100° . W. Demel, and H. Salkowsky obtained it as a crystalline crust by evaporating a soln. of zinc oxide in arsenic acid; H. Salkowsky, by allowing zinc orthoarsenate to stand for a long time in contact with a soln. of arsenic acid; and A. Coloriano, by the action of arsenic acid on zinc. The rhombic prismatic crystals are decomposed by prolonged boiling with water, forming the basic arsenate; and the hydrochloric acid soln., when treated with alkali, yields the trihydrated orthoarsenate. H. Goguel found that when the hydroarsenate is heated in a sealed tube at 200° , rhombic, probably triclinic, plates of **zinc dihydrotetrarsenate**, $\text{Zn}_3(\text{AsO}_4)_2 \cdot 2\text{ZnHAsO}_4 \cdot n\text{H}_2\text{O}$, or $\text{Zn}_5\text{H}_2(\text{AsO}_4)_4 \cdot n\text{H}_2\text{O}$, are formed.

C. Lefèvre reported **zinc pyroarsenate**, $\text{Zn}_2\text{As}_2\text{O}_7$, to be formed by dissolving zinc oxide in fused potassium metarsenate. The tabular crystals are isomorphous with manganese pyroarsenate. H. Stallo gave 4.6989–4.7034 for the sp. gr. at 21° .

The salt is decomposed by water. A. Coloriano treated zinc with an excess of arsenic acid, and boiled the filtered soln.—replacing the water lost by evaporation from time to time—until crystals appear. The rhombic or monoclinic prisms of the *trihydrate*, $\text{Zn}_2\text{As}_2\text{O}_7 \cdot 3\text{H}_2\text{O}$, are attacked by cold water, and transformed by boiling water into the dihydroxyorthoarsenate. H. Goguel prepared a basic salt, **zinc dihydroxypyroarsenate**, $\text{Zn}(\text{OH})_2 \cdot \text{Zn}_2\text{As}_2\text{O}_7 \cdot 7\text{H}_2\text{O}$, by treating 100 c.c. of a 10 per cent. soln. of zinc acetate with 10 c.c. of a 25 per cent. soln. of zinc arsenate, and digesting the product for a few weeks. The fine, silky needles lose all their water at 300° . H. Salkowsky prepared **zinc metarsenate**, $\text{Zn}(\text{AsO}_3)_2$, adding water to the product obtained by heating zinc oxide with arsenic acid at 200° .

A. Schrauf described a **copper zinc phosphatoarsenate**, $9\text{CuO} \cdot 6\text{ZnO} \cdot \text{P}_2\text{O}_5 \cdot \text{As}_2\text{O}_5 \cdot 18\text{H}_2\text{O}$, which occurs as a mineral at Morawitz, Hungary. It is thought to be an isomorphous mixture of $\text{Zn}_3(\text{AsO}_4)_2 \cdot 3\text{Zn}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$, $\text{Cu}_3(\text{PO}_4)_2 \cdot 3\text{Cu}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$, and $\text{Cu}(\text{OH})_2 \cdot \text{H}_2\text{O}$; or $(\text{Zn}, \text{Cu})_3(\text{P}, \text{As})_2\text{O}_4 \cdot 4(\text{Zn}, \text{Cu})(\text{OH})_2 \cdot 5\text{H}_2\text{O}$. It was called **veszelyite**—after M. Veszelyi. The crystals are thought to be triclinic with the axial ratios $a : b : c = 0.7101 : 1 : 0.9134$, and $\alpha = 89^\circ 31'$, $\beta = 103^\circ 51'$, and $\gamma = 89^\circ 34'$. E. S. Larsen said that the optical character is negative, the optic axial angle negative, and the indices of refraction $\alpha = 1.640$, $\beta = 1.658$, and $\gamma = 1.695$. A. Schrauf said that the mineral loses 2.30 per cent. of water at 150° ; 4.39 per cent. at 200° ; and 17.05 per cent. at a red-heat. The hardness is 3.5–4.0.

H. Salkowsky obtained a gelatinous precipitate by the action of sodium orthoarsenate on a soln. of cadmium sulphate; and the washed product, dried at 100° , had the composition of **cadmium orthoarsenate**, $\text{Cd}_3(\text{AsO}_4)_2$. W. Demel obtained it by treating a hydrochloric acid soln. of the hydroarsenate with alkali-lye. W. Demel, and H. Salkowsky made cadmium hydroarsenate, $\text{CdHAsO}_4 \cdot \text{H}_2\text{O}$, by evaporating on a water-bath a soln. of 16 grms. of cadmium carbonate in a soln. of 100 grms. of arsenic acid; A. de Schulten, by evaporating on a water-bath a sat. soln. of cadmium dihydrotetraorthoarsenate in arsenic acid; and A. Coloriano, by treating with water the product of the action of arsenic acid on cadmium at 200° . The white, needle-like crystals have a sp. gr. 4.164 at 150° . The salt is easily soluble in dil. hydrochloric acid. When treated with water, this salt furnishes **cadmium dihydrotetraorthoarsenate**, $5\text{CdO} \cdot 2\text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, or $\text{Cd}_3(\text{AsO}_4)_2 \cdot 2\text{CdHAsO}_4 \cdot 4\text{H}_2\text{O}$. H. Salkowsky made the same salt as a gelatinous precipitate by adding sodium hydroarsenate to a soln. of cadmium sulphate. The precipitate soon forms a white crystalline mass easily soluble in dil. hydrochloric acid. G. Klemp and J. von Gyulay found that by the successive addition of ammonium sulphate, acetic acid, and an excess of sodium arsenate to a soln. of a cadmium salt, an opalescent, yellow, colloidal arsenate is deposited which quickly crystallizes into $\text{Cd}_3(\text{AsO}_4)_2 \cdot 2\text{CdHAsO}_4 \cdot 4\frac{1}{2}\text{H}_2\text{O}$. A. de Schulten evaporated a soln. of the dihydrotetraorthoarsenate in dil. arsenic acid at ordinary temp., and obtained triclinic crystals of **cadmium dihydroarsenate**, $\text{Cd}(\text{H}_2\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$, isomorphous with the corresponding phosphate. The sp. gr. is 3.241 at 15° . At 70° – 80° , this salt loses all its water of crystallization and some of its constitutional water, and forms with an excess of water, the dihydrotetraorthoarsenate. A. de Schulten made **cadmium pyroarsenate**, $\text{Cd}_2\text{As}_2\text{O}_7$, by melting 22 parts of cadmium bromide, 2 parts of potassium bromide, and 9 parts of ammonium arsenate. After washing with dil. hydrochloric acid to remove the yellow crystals of the analogue of apatite which are formed, C. Lefèvre made the salt in colourless crystals by fusing potassium metarsenate with cadmium oxide or carbonate. H. Salkowsky treated a soln. of cadmium chloride in arsenic acid at 200° , washed the residue with water, and dried it at 100° . The product corresponded with **cadmium metarsenate**, $\text{Cd}(\text{AsO}_3)_2$. H. B. Weiser and A. P. Bloxson prepared **hydrogel of cadmium arsenate** as in the case of the zinc salt.

C. Lefèvre obtained prismatic or lamellar crystals of **sodium zinc arsenate**, NaZnAsO_4 , by dissolving zinc oxide in fused sodium meta-, pyro-, or orthoarsenate; if an excess of zinc oxide be avoided, **sodium zinc pyroarsenate** is formed, $\text{Na}_2\text{ZnAs}_2\text{O}_7$. He also obtained **potassium zinc arsenate**, KZnAsO_4 , by a process like that used

for the analogous sodium salt. C. Lefèvre obtained isomorphous **potassium cadmium arsenate**, KCdAsO_4 , in an analogous way; and likewise **sodium cadmium diorthoarsenate**, $\text{Na}_4\text{Cd}(\text{AsO}_4)_2$, from a soln. of cadmium oxide in molten sodium metarsenate; and **sodium cadmium trispyroarsenate**, $\text{Na}_8\text{Cd}_2(\text{As}_2\text{O}_7)_3$, from a soln. of cadmium oxide in molten sodium ortho- or pyro-arsenate.

A. Coloriano,⁷ and H. Goguel obtained **mercurous orthoarsenate**, Hg_3AsO_4 , by heating 35 c.c. of a soln. of 5 grms. of arsenic pentoxide and 5 grms. of mercury in a sealed tube at 230° for about 60 hrs. The reaction is very slow. K. Haack obtained this compound by dropping a cold soln. of a mol of mercurous nitrate into a cold soln. of sodium hydroarsenate, washing the yellow product with cold water, and drying in air. If the soln. of hydroarsenate be dropped into the soln. of mercurous nitrate, a basic nitroarsenate is formed which is converted into the normal arsenate by treatment with a soln. of sodium hydroarsenate. H. Goguel prepared this compound by adding a soln. of 5 grms. of mercurous nitrate acidified with nitric acid to a soln. of 5 grms. of arsenic acid. The orange, rhombic, prismatic crystals are pleochroic—*a*, pale brown; *b*, brown; and *c*, brownish-green. The birefringence is strong and negative. The salt is insoluble in water, and is attacked slowly by acids; with hydrochloric acid, it forms mercurous chloride and arsenic acid; and with a soln. of mercurous nitrate, it forms a double salt.

According to J. F. Simon, when a soln. of mercurous nitrate is dropped into a conc. soln. of arsenic acid, the white precipitate which is first formed redissolves in the excess of acid, and becomes permanent when more of the soln. of the mercurous salt is added. The salt remains white during the washing, but becomes red when dried. The analysis corresponds with **mercurous hydroarsenate**, $\text{HgHASO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$. The same salt was obtained by adding arsenic acid or sodium arsenate to a soln. of a mercurous salt; the white complex of mercurous arsenate and nitrate first precipitated soon turns yellow, then red, and finally assumes the purple-red colour of mercurous arsenate—particularly if warmed. The brownish-red or purple-red salt is composed of fine needles. When dried at 100° , and afterwards heated, it loses its water of crystallization, then gives off mercury to form yellow mercuric arsenate, which, at a higher temp., yields mercury, arsenic trioxide, and oxygen. Cold conc. hydrochloric acid converts it into a soln. of arsenic trioxide, and insoluble mercurous chloride; cold nitric acid dissolves the salt and it is reprecipitated by ammonia, the boiling acid converts it into mercuric nitrate. Mercurous hydroarsenate dissolves very sparingly in a soln. of ammonium nitrate from which it separates on evaporation as a red, crystalline mass. It is insoluble in water, aq. ammonia, and acetic acid.

J. J. Berzelius described a **mercurous pyroarsenate**, HgAs_2O_7 , which K. Haack said was probably a complex salt with the nitrate. J. F. Simon stated that when the hydroarsenate is heated, the pyroarsenate is formed. He also reported **mercurous metarsenate**, HgAsO_3 , to be produced as a white non-crystalline mass when mercuric oxide, or mercurous hydroarsenate, is mixed with an aq. soln. of arsenic acid and boiled to dryness; the dry mass is triturated with cold water, washed, and dried on a water-bath. H. Goguel obtained it by heating mercury with a 50–75 per cent. soln. of arsenic acid in a sealed tube at 150° for a long time. The pale yellow hexagonal plates so obtained have the axial ratio $a : c = 1 : 1.5096$. The crystals have a strong positive birefringence. They are blackened superficially by exposure to light, and when heated in a closed tube they become yellow, red, and brown with the loss of mercury. J. F. Simon noted that the salt is converted into mercuric arsenate by heat. The salt is insoluble in water, alcohol, and acetic acid. When treated with a soln. of potassium hydroxide it forms hydroarsenate; it behaves like the hydroarsenate towards cold nitric acid; and when the nitric acid soln. is heated, and ammonia added, the hydroarsenate is precipitated. For *mercurous amidoarsenate*, see 8. 49, 21.

P. P. Kosakewitch found that when mercuric oxide and arsenic acid are in contact, the solid phase consisted of two layers, one of which was mercuric oxide,

and the other, **mercuric trioxyarsenate**, $6\text{HgO} \cdot \text{As}_2\text{O}_5$, or $3\text{HgO} \cdot \text{Hg}_3(\text{AsO}_4)_2$. According to T. Bergman, when sodium arsenate is treated with mercuric chloride, a yellow precipitate is produced; but C. J. Pretzfeld did not confirm this, and K. Haack did not obtain the precipitate by adding an aq. soln. of arsenic acid to one of mercuric chloride. T. Bergman, however, did obtain **mercuric orthoarsenate**, $\text{Hg}_3(\text{AsO}_4)_2$, by heating mercury with arsenic pentoxide whereby arsenic trioxide is also formed. He obtained the same salt by the action of arsenic acid on mercuric nitrate, and K. Haack, by dropping a soln. of arsenic acid into an excess of a soln. of mercuric nitrate; and similarly, by the action of mercuric nitrate on sodium dihydroarsenate. The soln. of mercuric nitrate should be acidified with nitric acid, or the precipitate will be contaminated with mercuric and sodium nitrates. H. Goguel obtained crystals of mercuric orthoarsenate by the action of 25 c.c. of an acidified soln. of 5 grms. of mercuric nitrate on 5 c.c. of a 50 per cent. soln. of arsenic acid heated in a sealed tube for some hours at 180° . According to K. Haack, if the basic sulphate $2\text{HgO} \cdot \text{HgSO}_4$ is boiled with an excess of a soln. of sodium hydroarsenate, frequently renewed, sulphur trioxide is eliminated, and a mixture of mercuric oxide and orthoarsenate is formed—not the basic arsenate. He also found that a soln. of mercuric chloride transforms silver orthoarsenate into mercuric orthoarsenate. A. Dexheimer prepared **colloidal mercuric orthoarsenate** as follows:

A soln. of one gram of sodium protalbinat in 10 c.c. of water, is mixed with mercuric chloride until a precipitate is no longer produced. The precipitate is washed free from chlorides, dissolved in sodium hydroxide, and treated with a soln. of sodium hydroarsenate. The product is dialyzed until the outflowing water is free from arsenic, evaporated on a water-bath, and then in vacuo over sulphuric acid until quite dry. The olive-green mass is very soluble in water, forming a soln. which is grey in reflected light, and olive-green in transmitted light.

Normal mercuric orthoarsenate forms a yellow powder, and prismatic or acicular crystals. H. Goguel said that the crystals belong to the monoclinic system, and have a positive birefringence. They melt at a red-heat and decompose. They are not affected by hot or cold water; K. Haack said that they are very sparingly soluble in hot water. T. Bergman, K. Haack, and H. Goguel found that mercuric orthoarsenate is soluble in nitric acid, arsenic acid, and hydrochloric acid. K. Haack said that it is soluble in arsenic acid; it is transformed by a soln. of sodium chloride into reddish-brown mercuric oxychloride; it is coloured brown by a soln. of potassium bromide; and forms mercuric iodide with a soln. of potassium iodide. It undergoes double decomposition with silver nitrate. According to P. Ray and P. C. Bandopadhyay, when mercuric arsenate is digested with ammonia, washed with dil. ammonia, and then with alcohol, and dried in vacuo over sulphuric acid, there is produced a yellowish-white arsenate of Millon's base—**mercuric oxyamidoarsenate**, $[\text{O}=\text{Hg}_3=\text{NH}_3]_3\text{AsO}_4 \cdot 3\text{H}_2\text{O}$, presumably by the reactions $\text{Hg}_3(\text{AsO}_4)_2 + 6\text{NH}_3 \rightleftharpoons (\text{NH}_2\text{Hg})_3\text{AsO}_4 + (\text{NH}_4)_3\text{AsO}_4$; and $2(\text{NH}_2\text{Hg})_3\text{AsO}_4 + 6\text{H}_2\text{O} = (\text{NH}_4)_3\text{AsO}_4 + (\text{HO} \cdot \text{Hg} \cdot \text{NH}_2 \cdot \text{HgOH})_3\text{AsO}_4$.

§ 19. The Arsenates of the Aluminium Family of Elements

E. Berger¹ obtained boron arsenate, BAsO_4 , by evaporating an aq. soln. of boric and arsenic acids, and calcining the product. It is reduced when heated with aluminium or calcium silicide. C. Palache and L. H. Bauer described a mineral, which was named **cahnite**—after L. Cahn—and obtained

from Franklin, New Jersey. The composition approximates **calcium boroarsenate**, $4\text{CaO} \cdot \text{B}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$. It is white and glassy occurring in tetragonal sphenoids characteristically occurring in interpenetrating twins. The axial ratio $a : c = 1 : 0.615$. The prismatic cleavage is well defined. The sp. gr. is 3.15; the hardness, about 3; and the refractive index, about 1.662, or $\omega = 1.662$ and $\epsilon = 1.663$. The optical character is positive.

According to A. Coloriano, if a soln. of sodium orthoarsenate and an excess of aluminium sulphate be heated to 220° in a sealed tube, lentiform crystals of **aluminium orthoarsenate**, AlAsO_4 , are produced. N. S. Maskelyne reported a white, pale blue, or greenish-blue incrustation on quartz or other minerals at Liskeard, Cornwall. The mineral was called **liskeardite**. The analysis by W. Flight corresponds in the idealized case with the *octohydrate*, $\text{AlAsO}_4 \cdot 8\text{H}_2\text{O}$; actually, about 7.64 per cent. of ferric oxide is present so that the formula becomes $(\text{Fe}, \text{Al})\text{AsO}_4 \cdot 8\text{H}_2\text{O}$. The mineral lost 4.35 per cent. of water at ordinary temp.; 10.96 per cent. more at 100° ; 5.55 per cent. more at 120° , and 8.22 per cent. more at 140° – 190° ; and 4.97 per cent. more at a red-heat. A. Lacroix has described a similar mineral from Hyères. It had an optic axial angle $2E_a = 115^\circ$; and a sp. gr. 3.011.

P. Berthier obtained a white powder, possibly **aluminium hydroarsenate**, $\text{Al}_2(\text{HASO}_4)_3$, by treating a soln. of aluminium sulphate with sodium hydroarsenate. The powder is readily soluble in acids, and when the soln. in hydrochloric acid is boiled with ammonium sulphite, alumina is precipitated while all the arsenic remains in soln. H. Rose said that when heated alone or mixed with sulphur in a current of hydrogen, the arsenic is incompletely volatilized—C. Lefèvre said that the arsenic is completely volatilized. P. Berthier obtained a soln. of an acid arsenate which he could not crystallize. C. Lefèvre melted together 15.5–15.7 parts of potassium or sodium dihydroarsenate with one part of alumina, at as low a temp. as possible, and obtained colourless, transparent prisms of **aluminium pyroarsenate**, $\text{Al}_4(\text{As}_2\text{O}_7)_3$, which are only slightly attacked by hot water, but are easily soluble in dil. acids.

C. Lefèvre prepared transparent plates of **sodium aluminium triorthoarsenate**, $\text{Na}_3\text{Al}_2(\text{AsO}_4)_3$, by dissolving alumina in a molten mixture of sodium dihydroarsenate and chloride. The corresponding **potassium aluminium triorthoarsenate**, $\text{K}_3\text{Al}_2(\text{AsO}_4)_3$, was made in an analogous way. A. Rosenheim and S. Thon prepared **sodium dihydroaluminioarsenate**, $\text{NaH}_2[\text{Al}(\text{AsO}_4)_2] \cdot \frac{1}{2}\text{H}_2\text{O}$; and **barium hydroaluminioarsenate**, $\text{BaH}_4[\text{Al}(\text{AsO}_4)_3] \cdot \text{H}_2\text{O}$.

H. Dufet² reported massive clay-like material made up of very minute turquoise-blue crystals from a mine at Huanaco, Chile. It was called **coeruleite**, or ceruleite, and its analysis corresponds with $\text{CuO} \cdot 2\text{Al}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$ —**copper aluminium tetroxydiarsenate**. The water is expelled only at a high temp., for at 180° only 1.4 per cent. is given off. The mineral has a sp. gr. 2.803. It dissolves in acids leaving only a slight residue of a white clay. In 1801, J. L. Bournon,³ and in 1802, P. Rashleigh, described what was called octahedral arsenate of copper as a mineral occurring with various ores of copper, pyrite, and quartz in Cornwall; and specimens have since been reported from Herrengrund, Hungary; and from Voigtland. The mineral was called *Linzenersz* by A. G. Werner, C. F. Ludwig, and D. L. G. Karsten; *Linzenkupfer*, by J. F. L. Hausmann; *Lirokonmalachite*, by F. Mohs; *Chalcophacite*, by E. F. Glocker; and **liroconite**—from *λερός*, pale; *κονία*, powder—by J. D. Dana. Analyses were reported by R. Hermann, A. Damour, and A. H. Church. C. F. Rammelsberg represented the composition by the formula $\text{Cu}_{18}\text{Al}_3\text{As}_{10}\text{O}_{55} \cdot 60\text{H}_2\text{O}$; and P. Groth, by $\text{Al}_4\text{Cu}_9(\text{AsO}_4)_5(\text{OH})_{15} \cdot 20\text{H}_2\text{O}$, that is, **copper aluminium pentadecahydroxy-pentarsenate**, but the available information is too meagre to enable satisfactory inferences to be made. The sky-blue or verdigris-green mineral usually occurs in crystals, rarely granular. The crystals were found by A. des Cloizeaux to be monoclinic, and to have the axial ratios $a : b : c = 1.3191 : 1 : 1.6808$, and $\beta = 88^\circ 32\frac{1}{2}'$.

The thin crystals appear octahedral with the (110)- and (011)-faces faintly striated; the cleavage on these two faces is indistinct. A. des Cloizeaux found the optical axial angles for red-, yellow-, and blue-light to be respectively $2E=132^{\circ} 54'$, $132^{\circ} 57'$, and $133^{\circ} 46'$; $2H_a=77^{\circ} 24\frac{2}{3}'$, $77^{\circ} 18'$, and $76^{\circ} 57\frac{2}{3}'$. The optical character is negative. J. L. Bournon gave 2.882 for the sp. gr.; R. Hermann, 2.985; and A. Damour, 2.964. The hardness is 2.0-2.5. The mineral is easily soluble in aq. ammonia and in acids. F. W. Clarke⁴ described an amorphous mineral from the mercury district of Utah. The analysis corresponds with $4CaO \cdot 5Al_2O_3 \cdot 3As_2O_5 \cdot 20H_2O$, or $Ca_{20}\{Al(OH)_2\}_5(AsO_4)_3 \cdot 10H_2O$, **calcium aluminium decahydroxytriarsenate**.

The *arsenates of gallium and indium* have not been described. J. E. Willm⁵ treated thallos dihydroarsenate with ammonia and obtained white silky needles of **thallos orthoarsenate**, Tl_3AsO_4 . E. Franke gave for the conductivity of soln. with an eq. of the normal salt in v litres of water at 25° , $\lambda=107.0$, 114.3 , and 119.3 for $v=170$, 340 , and 680 respectively. A. Lamy saturated a boiling soln. of arsenic acid with thallos carbonate, and obtained **thallos hydroarsenate**, Tl_2HASO_4 , in needle-like crystals; and P. S. Oettinger obtained the same salt from a filtered soln. of thallium in arsenic acid. E. Franke found the conductivity of soln. with an eq. of the salt in v litres of water at 25° to be:

v	.	.	16	32	64	128	256	512	1024
λ	.	.	70.4	74.3	78.3	81.2	82.8	84.2	85.4 mhos.

P. S. Oettinger found the salt to be sparingly soluble in water, and to melt to a glassy mass at 120° . At an elevated temp., it gives off white fumes of arsenic trioxide, and leaves behind black thallos oxide. J. E. Willm prepared **thallos dihydroarsenate**, TlH_2AsO_4 , by boiling thallic oxide with a soln. of arsenic trioxide; if the soln. be not too dil., it furnishes needle-like crystals which are not changed at 150° . J. E. Willm found that when a soln. of thallic nitrate is treated with arsenic acid, a lemon-yellow, gelatinous mass is produced, **thallic arsenate**, $TlAsO_4 \cdot 2H_2O$. It is not dissolved or changed by boiling water; but it dissolves in hydrochloric acid; it is decomposed by aq. ammonia or potash-lye with the separation of thallic hydroxide or a basic salt. A. Rosenheim and S. Thon could not prepare **thalliarsenates** like the aluminarsenates.

W. Hisinger and J. J. Berzelius⁶ treated cerous oxide with soln. of arsenic acid and obtained **cerous hydroarsenate**, $Ce_4(HAsO_4)_3$, as a white, insoluble powder; and by evaporating a soln. of this salt in arsenic acid, the gelatinous mass obtained was said to be **cerous dihydroarsenate**, $Ce(H_2AsO_4)_3$. These statements have not yet been confirmed. G. A. Barbieri and J. Calzolari found that when a mixture of a mol of cerous nitrate, 4 mols of arsenic acid, and conc. nitric acid is heated for some hours, and the excess of nitric acid is distilled off, the resulting pale yellow soln. deposits white needles of **ceric dihydroarsenate**, $Ce(H_2AsO_4)_4 \cdot 4H_2O$. When this salt is dissolved in the minimum quantity of nitric acid, and the cold soln. diluted with water, a white crystalline deposit of **ceric hydroarsenate**, $Ce(HAsO_4)_2 \cdot 6H_2O$, appears, while arsenic acid remains in soln. A few qualitative observations have been made on the arsenates of the rare earths. F. Frerichs and F. Smith described gelatinous precipitates of **lanthanum hydroarsenate**, $La_2(HAsO_4)_3 \cdot nH_2O$, and of pale-red **didymium hydroarsenate**, $Di(HAsO_4)_3 \cdot nH_2O$, obtained by adding sodium hydroarsenate to a soln. of the corresponding sulphate. A. Rosenheim and S. Thon could not prepare lanthanoarsenates like the aluminarsenates. J. J. Berzelius, O. Popp, and N. J. Berlin treated yttrium hydroarsenate with ammonia and obtained what he regarded as **yttrium orthoarsenate**, presumably $YAsO_4 \cdot nH_2O$; and also by treating an yttrium salt with sodium hydroarsenate. The white gelatinous precipitate dries to a yellow horny mass which when treated with nitric acid becomes gelatinous and then dissolves. N. J. Berlin obtained **yttrium dihydroarsenate**, $Y(H_2AsO_4)_3 \cdot nH_2O$, by adding a salt of yttrium to a soln. of sodium hydroarsenate in excess. The white precipitate is soluble in nitric acid, and the soln. yields a crystalline crust as the acid evaporates. A. G. Ekeberg

found that arsenic acid dissolves yttria, forming a soln. of **yttrium hydroarsenate**, presumably $Y_2(HAsO_4)_3 \cdot nH_2O$, and when the soln. is warmed arsenic acid is precipitated.

§ 20. The Arsenates of the Titanium and Tin Families

S. J. Thugutt's¹ observations on the **arsenatosodalite** have been previously mentioned—**6**, 40, 40 and 46. H. Rose obtained what may have been **titanyl-arsenate**, by adding arsenic acid to a soln. of titanic acid in hydrochloric acid made as nearly neutral as possible. The flocculent precipitate is insoluble in an excess of either reagent.

O. Kulka,² and S. R. Paykull reported zirconium arsenate, or **zirconyl pyroarsenate**, $Zr_2As_2O_9 \cdot H_2O$, or $(ZrO)_2As_2O_7 \cdot H_2O$, to be precipitated as a white powder when a soln. of zirconium sulphate is treated with sodium hydroarsenate. The former regarded the product dried at 100° – 110° as a *monohydrate*; the latter, the product dried at 100° as a hemipentahydrate. The product is insoluble in water, but soluble in hydrochloric acid. M. Weibull obtained a voluminous white precipitate by treating an hydrochloric acid soln. of zirconyl fluoride with sodium hydroarsenate. He represented the analysis by the formula $3ZrO_2 \cdot 2As_2O_5 \cdot 5H_2O$, or **zirconium orthoarsenate**, $Zr_3As_4O_{16} \cdot 5H_2O$, *i.e.* $Zr_3(AsO_4)_4 \cdot 5H_2O$. E. Wedekind and H. Wilke studied the adsorption of arsenic acid by zirconium dioxide, and it was assumed that there is a slow chemical reaction whereby **zirconium hydroarsenate**, $Zr(HAsO_4)_2$, *i.e.* $HO \cdot AsO : O_2 : Zr : O_2 : AsO \cdot OH$, is formed.

J. J. Berzelius³ treated a neutral or acid thorium salt with arsenic acid or sodium hydroarsenate, and obtained a white flocculent precipitate insoluble in water and arsenic acid. G. A. Barbieri obtained basic salts of variable composition by adding to a thorium salt soln. insufficient arsenic acid for complete precipitation. He found crystalline **thorium hydroarsenate**, $Th(HAsO_4)_2 \cdot 6H_2O$, is precipitated when a 40 per cent. aq. soln. of 4 mols of arsenic acid is added to a boiling soln. of thorium

nitrate holding the eq. of 2 per cent. thoria in soln. If cold dil. soln. be used no precipitate is formed, but a gelatinous mass is produced which eventually passes into the crystalline hydroarsenate. If less arsenic acid be used, an amorphous precipitate of variable composition is produced. The salt loses some water of crystallization when dried in air. It is insoluble in water; but is slowly hydrolyzed by that menstruum. It is insoluble in dil. nitric and arsenic acids. Colourless crystals of **thorium dihydroarsenate**, $\text{Th}(\text{H}_2\text{AsO}_4)_4 \cdot 4\text{H}_2\text{O}$, are precipitated when a 50 per cent. soln. of arsenic acid is added to a soln. of thorium nitrate containing 5 per cent. thoria. Eight mols of arsenic acid per mol of thoria are used. The salt is decomposed by water, forming the hydroarsenate.

According to C. W. Scheele,⁴ tin dissolves in an aq. soln. of arsenic acid with the evolution of arsine, and the formation of tin arsenate; and arsenic acid reacts with stannous acetate, or potassium arsenate with stannous chloride, forming a white insoluble precipitate. E. Lenssen showed that the voluminous precipitate formed when a conc. acetic acid soln. of potassium arsenate is mixed in small quantities at a time with stannous chloride, is **stannous hydroarsenate**, $\text{SnHAsO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$. It decomposes when heated, forming arsenic trioxide and stannic oxide, as well as a trace of arsenic. W. C. Williams found that a mixture of moderately conc. aq. soln. of arsenic acid and stannic chloride thickens on standing, and in a few weeks forms a transparent, colourless, non-crystalline mass. After dialysis, the jelly has a sp. gr. 1.135. A great deal of water is given off at 100° , but a little is retained tenaciously even at 200° . Below dull redness, decomposition occurs with the evolution of arsenic trioxide. An analysis agrees with **stannic orthoarsenate**, $\text{Sn}_3(\text{AsO}_4)_4 \cdot 6\text{H}_2\text{O}$. Conc. acids, and alkali-lye dissolve it readily; water dissolves it slowly—possibly by peptization. The aq. soln. gives a gelatinous precipitate of the arsenate when treated with sulphuric, nitric, or hydrochloric acid, ammonium, calcium, barium, or iron chloride, silver nitrate, and potassium iodide; but not by acetic acid, alcohol, mercuric chloride, sodium phosphate, or the carbonate of sodium, potassium, or ammonium. E. Haefely obtained **stannic pyroarsenate**, $\text{Sn}_2\text{As}_2\text{O}_9 \cdot 10\text{H}_2\text{O}$, by boiling a soln. of sodium stannate with an excess of sodium arsenate and nitric acid. The white gelatinous precipitate dried at ordinary temp. retains 10 mols. of water which it loses at 120° . He also obtained **sodium tetrarsenatostannate**, $6\text{Na}_2\text{O} \cdot \text{SnO}_2 \cdot 2\text{As}_2\text{O}_5 \cdot 50\text{H}_2\text{O}$, in needle-like crystals by boiling normal sodium arsenate with stannic hydroxide; or by treating stannic arsenate with sodium hydroxide. W. Prandtl and O. Rosenthal also reported colourless needles of **sodium pentarsenatostannate**, $\text{Na}_2\text{SnO}_3 \cdot 5\text{Na}_3\text{AsO}_4 \cdot 60\text{H}_2\text{O}$, to be formed by mixing 50 grms. of pentahydrated stannic chloride in aq. soln. with a soln. of 33 grms. of arsenic pentoxide in soda-lye, and neutralizing the soln.

The **lead arsenates** attracted no special attention until 1893, when F. C. Moulton⁵ recommended their use for the destruction of leaf-eating insects. Since then, lead arsenate in different forms has been extensively employed as an insecticide in places of Paris green; and several thousand tons are used annually in the United States. This subject has been discussed by H. Astruc and co-workers, C. E. Bradley and H. V. Tartar, H. V. Tartar and R. H. Robinson, A. Cutolo, C. H. Hall, A. L. Lovett and R. H. Robinson, L. Moreau and E. Vinet, W. E. Ruth, C. B. Sprague, F. T. Shutt, etc. Products derived from the reaction between lead acetate or nitrate, and sodium hydroarsenate are the active constituents in various spraying mixtures employed as insecticides. These prophylactics usually contain mixtures of normal lead arsenate, and hydroarsenate. They have been described or patented by A. O. Allen, B. T. Barreto, E. O. Barstow, M. W. Butler, L. Cambi, F. C. Cook and N. E. McIndoo, J. F. Cullen and T. E. Harper, B. E. Curry and T. O. Smith, P. Denniston and J. McMillan, C. W. Drury and C. W. Simmons, Grasselli Chemical Co., G. P. Gray and A. W. Christie, A. Hamilton, J. K. Haywood and C. C. McDonnell, W. P. Headden, O. F. Hedenburg and D. S. Pratt, F. Herrmann, M. S. Hopkins, and N. Underwood, H. Howard, J. Kirby and co-workers, I. P. Lihme, J. Lytle, C. C. McDonnell and J. J. T. Graham, B. E. A. McGill, Merrimac Chemical

Co., W. Middleton, T. A. Mitchell and K. Toabe, G. R. Riches and W. C. Piver, R. H. Robinson, C. H. Sakryd and H. M. Rosencrans, F. T. Shutt, H. V. Tartar and G. G. Grant, M. L. Tower and co-workers, and R. E. Wilson. The preparation of lead arsenate by the electrolytic process indicated in connection with calcium arsenate has been discussed by S. J. Lloyd and A. M. Kennedy, J. F. Cullen and T. E. Harper, and H. V. Tartar and G. G. Grant.

The early work on the lead arsenates by J. J. Berzelius, E. Mitscherlich, G. C. Wittstein, T. Graham, H. Rose, and H. Salkowsky embodies several contradictions. The term neutral lead arsenate was applied indiscriminately to both the hydroarsenate and pyroarsenate, and the mineral mimetite was regarded as a

FIG. 28.—Part of the Freezing-point Curve of the Binary Mixtures: PbO-As₂O₅.

arsenate as well as chloroarsenate. They also studied the equilibrium conditions in the reaction $\text{Ca}_3(\text{AsO}_4)_2 + 3\text{Pb}(\text{NO}_3)_2 \rightleftharpoons \text{Pb}_3(\text{AsO}_4)_2 + 3\text{Ca}(\text{NO}_3)_2$. There is a thermal change at 834° corresponding with the formation of an unstable **lead oxyorthoarsenate**, 4PbO.As₂O₅.

O. Schairer prepared **lead orthoarsenate**, Pb₃(AsO₄)₂, by gradually heating lead dioxide and arsenic trioxide in a covered crucible, and boiling the product with water. Some pyrophosphate was formed at the same time. O. W. Brown and co-workers roasted a mixture of lead oxide with 22.81 per cent. of arsenic trioxide at about 450°. The oxidation proceeds rapidly at first, and the speed of the reaction then slows down. M. Amadori's observations on the conditions of equilibrium of this compound, with respect to arsenic pentoxide and lead oxide, are indicated in Fig. 28. C. C. McDonnell and C. M. Smith obtained it by fusing a mixture of lead oxide and lead pyroarsenate or hydroarsenate in theoretical proportions. I. McDougall and F. Holwes mixed colloidal lead oxide with arsenic acid at 80°, and obtained a precipitate of lead arsenate in a few minutes. The normal arsenate is not an easy salt to prepare by wet processes. J. J. Berzelius reported it to be formed by the action of ammonia on lead hydroarsenate, and when a neutral hydroarsenate is mixed with neutral lead acetate. W. H. Volck said that the product has less than the theoretical quantity of arsenic pentoxide. H. V. Tartar and R. H. Robinson said that when aq. ammonia acts on lead hydroarsenate, a basic arsenate, and not the normal arsenate is produced. E. Mitscherlich obtained the same salt by adding a neutral lead salt to an excess of a soln. of an arsenate. S. U. Pickering, and G. C. Wittstein used this process; H. Salkowsky said that the product is a pyroarsenate; and E. Mitscherlich obtained the normal arsenate by adding lead acetate to the dihydroarsenate, and boiling the mixture. W. H. Volck observed the formation of the normal arsenate by the protracted treatment of the hydroarsenate with water, but H. V. Tartar and R. H. Robinson could not confirm this by using either hot or cold water. T. Graham said that the normal arsenate is produced by adding lead acetate to a soln. of sodium orthoarsenate. R. D. Holland and B. B. Reed treated sodium hydroarsenate with lead acetate in certain proportions and obtained a product with the normal ratio

PbO : As₂O₅ as 3 : 1, but H. V. Tartar and R. H. Robinson said that the orthoarsenate cannot be obtained by a reaction between these two substances. C. C. McDonnell and C. M. Smith studied the action of lead nitrate and acetate on sodium orthoarsenate and hydroarsenate in different proportions, and found that the product is close to the 3 : 1 ratio only when lead acetate is mixed with an excess of sodium hydroarsenate. The facts thus indicate that lead orthoarsenate is relatively unstable and can exist within only very limited conditions. C. C. McDonnell and C. M. Smith agitated for seven hours on two successive days mixtures of lead hydroarsenate and water containing a constant proportion of ammonia in order to keep lead hydroxide in soln., otherwise the low solubility of lead hydroxide prevents the system being followed beyond lead hydroarsenate. Working at 32°, the dil. aq. ammonia is assumed to have no solvent action on the lead arsenates, and to form no complex salts under the conditions of the experiment, so that the system is assumed to behave like one of three components. The results are summarized in Fig. 29. The first additions of ammonia furnish the curve *AB*, indicating the existence of two solid phases—one being lead hydroarsenate, and the other the normal arsenate. Hence *AB* indicates that the lead hydroarsenate is being changed to the normal arsenate; and at *B*, the change is complete. Along *BC*, a series of solid soln. between lead orthoarsenate, *B*, and a basic arsenate, *C*, are produced. The basic arsenate—*vide infra*, lead hydroxytriarsenate—changes very little in composition as the curve progresses from *C* to *D*. B. Ormont obtained lead arsenate by the electrolytic oxidation of a soln. of lead arsenite.

C. C. McDonnell and C. M. Smith reported a *hemihydrate*, Pb₃(AsO₄)₂·½H₂O, to be formed by treating lead hydroarsenate with the theoretical proportion of 0·1*N*-ammonia. The water is not expelled at 110°. The amorphous powder has a sp. gr. of 7·00, at 15°/4°. A. Dexheimer did not succeed in making a **colloidal solution of lead arsenate**, by the method analogous to those employed with the other metal arsenates—*vide supra*. F. J. Brinley prepared colloidal lead arsenate, stable for a few days, by dissolving a mixture of 311·96 g. of sodium hydroarsenate, and 17·35 g. of gelatin in a small quantity of hot water diluted to 10 litres, and slowly adding a soln. of 331·4 g. of lead nitrate in 10 litres of water, with constant stirring, avoiding an excess of lead. More conc. soln. than 0·1*M*-soln. give a curdy precipitate, and in 0·01*M*-soln. there is tendency for needle-shaped crystals to form.

Anhydrous lead orthoarsenate prepared by the fusion processes is described as a yellowish-white crystalline mass which, according to C. C. McDonnell and C. M. Smith, has a sp. gr. 7·30 at 15°/4°. That prepared by the wet process is described as an amorphous mass with a sp. gr. 7·00 at 15°/4°. S. Motylewsky found the drop-weight of lead arsenate to be 262 when that of water at 0° is 100. M. Amadori gave 1042° for the m.p. H. V. Regnault, 0·0728 for the sp. ht., and 65·4 for the mol. ht.; and C. C. McDonnell and C. M. Smith, 2·14 for the index of refraction. E. F. Smith and J. G. Hibbs said that the arsenate is decomposed completely when heated with hydrogen chloride, forming lead chloride and volatile arsenic chloride. G. C. Wittstein found that the arsenate is insoluble in water, aq. ammonia, and soln. of ammonium salts; and C. E. Bradley and H. V. Tartar, less soluble than the hydroarsenate in dil. alkali-lye, soln. of sodium chloride, and of calcium polysulphide. E. Duvillier found that hot nitric acid liberates arsenic acid; and decomposition is complete if the conc. of the acid is so great that the lead nitrate does not dissolve. H. V. Tartar and L. A. Bundy said that unlike the hydroarsenate, the normal arsenate is only sparingly soluble in soap soln. M. Amadori gave for mixtures of lead phosphate with 0, 25, 50, 75, 100 per cent. of lead arsenate the respective f.p. 1014°, 1020°, 1028°, 1035°, and 1042°. V. Zotier studied the decomposition of hydrogen dioxide in the presence of lead arsenate.

A number of basic salts have been reported with the ratio PbO : As₂O₅ ranging from 8 : 1 to 5 : 21. M. Amadori's diagram, Fig. 29, shows the conditions of

stability of **lead pentoxyorthoarsenate**, $8\text{PbO} \cdot \text{As}_2\text{O}_5$, or $\text{PbO} \cdot \text{Pb}_3(\text{AsO}_4)_2$, with a m.p. of 860° . A. V. M. Kroll has reported an analogous phosphate—7. 47, 1. C. C. McDonnell and C. M. Smith obtained the hemihydrate, $5\text{PbO} \cdot \text{Pb}_3(\text{AsO}_4)_2 \cdot \frac{1}{2}\text{H}_2\text{O}$. The same salt appears to have been formed by D. Strömholm by shaking freshly precipitated lead hydroxide with 0.05*N*-sodium hydroarsenate until the soln. has the calculated alkalinity owing to the formation of sodium hydroxide. He assigned a formula between $9\text{PbO} \cdot \text{As}_2\text{O}_5$ and $5\text{PbO} \cdot \text{As}_2\text{O}_5$ to the product—preferring

FIG. 29.—Equilibrium in the System: $\text{PbO}-\text{As}_2\text{O}_5-\text{H}_2\text{O}$ at 32° .

$15\text{PbO} \cdot 2\text{As}_2\text{O}_5$ —but C. C. McDonnell and C. M. Smith showed that the composition is $8\text{PbO} \cdot \text{As}_2\text{O}_5 \cdot \frac{1}{2}\text{H}_2\text{O}$. They also made it by pouring a filtered sat. soln. of lead hydroarsenate in cold 10 per cent. potash-lye into 5–8 vols. of boiling water, and drying the product at 110° ; and by adding 100 c.c. of a 25 per cent. soln. of lead nitrate to 600 c.c. of a soln. of 50 grms. of dodecahydrated sodium orthoarsenate; treating the filtrate with 100 c.c. more of the lead nitrate soln.; repeating the operation twice more; and finally washing and drying the product at 105° . The first three washing precipitates are mixtures of lead hydroxide and basic lead acetate; the fourth precipitate is the

required one. The product may be crystalline or amorphous. The white plates have a sp. gr. of 8.04 at $15^\circ/15^\circ$; an index of refraction 2.22 for Na-light at 20° ; and a feeble, positive birefringence. The compound is not completely dehydrated at 200° ; it melts without decomposition, and solidifies to a crystalline mass. The basic salt prepared from commercial lead salts becomes dark brown or purple in a few minutes, perhaps owing to the presence of silver salts.

M. Amadori's lead oxyorthoarsenate, $4\text{PbO} \cdot \text{As}_2\text{O}_5$, has been indicated in connection with Fig. 29. C. C. McDonnell and C. M. Smith reported **lead dihydroxy-tetrarsenate**, $\text{Pb}_5(\text{PbOH})_2(\text{AsO}_4)_4$, or $7\text{PbO} \cdot 2\text{As}_2\text{O}_5 \cdot \text{H}_2\text{O}$, to be formed by pouring into 25.5 vols. of boiling water, a soln. of potassium or sodium hydroxide sat. with lead hydroarsenate. The washed product dried at 105° consists of small prismatic crystals which are doubly refractive, have a negative elongation, and an index of refraction of 2.07 for Na-light at 20° . The sp. gr. is 7.08 at $15^\circ/15^\circ$.

The action of ammonia on lead hydroarsenate has been indicated above. J. J. Berzelius said that the normal arsenate is produced, but W. H. Volck said the product appears more basic than this, owing to the adsorption of other lead compounds. H. V. Tartar and R. H. Robinson said that with an excess of ammonia the basic arsenate $7\text{Pb}_3(\text{AsO}_4)_2 \cdot 2\text{Pb}(\text{OH})_2 \cdot 5\text{H}_2\text{O}$ is formed—owing to an arithmetical error in calculating the formula from the analysis, they gave a more complex formula, namely 21 : 2 : 10. C. C. McDonnell and C. M. Smith's observations are summarized in Fig. 29. They found that when ammonia is distilled into water containing lead hydroarsenate, this is changed into what they called *hydroxymimetite*, $\text{Pb}_4(\text{PbOH})(\text{AsO}_4)_3 \cdot \text{H}_2\text{O}$:

that is, **lead hydroxytriarsenate**. They represented the reaction: $10\text{PbHAsO}_4 + n\text{NH}_3 + \text{Aq.} = 10\text{PbO} \cdot 3\text{As}_2\text{O}_5 \cdot m\text{H}_2\text{O} + 4(\text{NH}_4)_3\text{AsO}_4 + (n-12)\text{NH}_3 + \text{Aq.}$ This is in agreement with the observations of G. E. Smith, who made the same compound by digesting lead hydroarsenate in 5 per cent. aq. ammonia for 3 hrs. on a water-bath, and filtering, washing, and drying the product at 110° . C. C. McDonnell and C. M. Smith recommended this procedure:

Lead hydroarsenate was added to a boiling 50 per cent. soln. of ammonium acetate mixed with about a quarter of its vol. of conc. aq. ammonia. Some of the lead salt passed into soln. The filtered liquid was poured into 5–10 times its vol. of boiling water, when a voluminous white precipitate was formed. This was washed with boiling distilled water, and dried to a constant weight at 105° .

C. C. McDonnell and J. J. T. Graham said that the prolonged action of water on the hydroarsenate yields crystals of hydroxymimetite; and H. V. Tartar and L. A. Bundy found salts of the weak acids act in a similar way—*vide infra*. The preparation of this compound was studied by L. R. Streeter and R. W. Thatcher. G. E. Smith obtained the same salt by adding lead nitrate or acetate to a soln. of sodium hydroarsenate diluted to 0.001 mol per litre. The precipitate was immediately washed by decantation and dried. The analyses of products obtained by G. E. Smith, C. C. McDonnell and C. M. Smith, and H. V. Tartar and R. H. Robinson do not discriminate between the formulæ $Pb_4(PbOH)(AsO_4)_3 \cdot H_2O$ and $7Pb_3(AsO_4)_2 \cdot 2Pb(OH)_2 \cdot 5H_2O$. The first one is taken to represent best the composition of the product. The white powder obtained by C. C. McDonnell and C. M. Smith consisted of hexagonal prisms terminated by the basal pinacoid frequently having the corners truncated by the second order pyramid. The crystals have parallel extinction, and are uniaxial. The average index of refraction is 2.09 at 20° with Na-light. These results closely resemble those obtained with artificial mimetite. The sp. gr. is 6.86 at 15°/15°.

The secondary salt, **lead hydroarsenate**, $PbHAsO_4$, has received many names—neutral lead arsenate, acid lead arsenate, lead hydrogen arsenate, secondary lead arsenate, diplumbic hydrogen arsenate, diplumbic arsenate, dilead orthoarsenate, and in commerce simply lead arsenate because this is the commonest form of the lead arsenates. J. J. Berzelius, G. C. Wittstein, H. Rose, G. E. Smith, H. Salkowsky, R. D. Holland and B. B. Reed, W. C. Ebaugh, produced this salt by adding an excess of lead nitrate to a soln. of sodium arsenate; E. Mitscherlich, J. Valentin, C. C. McDonnell and C. M. Smith, by adding lead acetate to a soln. of a dihydroarsenate—the product may be mixed with normal lead arsenate; E. Duvillier, by diluting with water a boiling soln. of lead arsenate in nitric acid; H. Goguel, by adding conc. arsenic acid to a boiling soln. of lead nitrate acidified with one per cent. of nitric acid; and A. de Schulten, and H. V. Tartar and R. H. Robinson, by slowly adding with constant stirring a 0.3 per cent. soln. of ammonia to a hot sat. soln. of lead arsenate in nitric acid. C. C. McDonnell and C. M. Smith found that if lead chloride be employed in place of the nitrate or acetate, a chloroarsenate is formed—*vide infra*. B. E. Curry and T. O. Smith allowed dil. soln. of lead nitrate and of sodium hydroarsenate to remain in contact for 3 months, and the results of the analysis of the filtrates is summarized in Fig. 30. They therefore concluded that in the system sodium hydroarsenate, lead nitrate, and water, at 25°, only one compound, lead hydroarsenate, exists. Working under other conditions, F. J. Smith, S. U. Pickering, J. K. Haywood, and H. V. Tartar and R. H. Robinson noted that the reaction between lead nitrate and sodium hydroarsenate may give a product rather more basic than the hydroarsenate; but these systems may not have all been in equilibrium. C. C. McDonnell and C. M. Smith obtained salts more basic than the normal arsenate from lead acetate and sodium hydroarsenate. Analyses in agreement with the above formula were reported by L. J. Thénard, R. Chenevix, J. J. Berzelius, H. Goguel, H. V. Tartar and R. H. Robinson, A. de Schulten, H. Salkowsky, and C. C. McDonnell and C. M. Smith. L. J. Spencer found that the colourless, transparent, lustrous plates of a mineral from Tsumeb, Otavi, S.W. Africa, which he called **schultenite**—after A. de Schulten—were lead hydroarsenate.

Well-developed crystals of lead hydroarsenate were obtained by E. Duvillier, and C. C. McDonnell and C. M. Smith by pouring a boiling soln. of nitric acid (1:4) sat. with lead hydroarsenate into about 6 times its vol. of boiling water. Larger crystals were obtained by cooling the nitric acid soln. without dilution. L. J. Spencer said that the monoclinic crystals of schultenite have the axial ratios

FIG. 30.—Equilibrium in the System: $Na_2HAsO_4-Pb(NO_3)_2-H_2O$ at 25°.

$a : b : c = 0.8643 : 1.0 : 0.7181$, and $\beta = 84^\circ 36'$. The crystallographic data for the mineral agree with those previously determined for the artificial hydroarsenate. The optic axial angles $2V_a = 58^\circ 14'$; and $2E_a = 136^\circ 38'$ for Na-light. The artificial crystals obtained by H. Goguel, and A. de Schulten were described as monoclinic leaflets with an acute angle about 84° . The former said extinction occurred at $21^\circ - 22^\circ$, the latter at 38° , while C. C. McDonnell and C. M. Smith gave 29° . The birefringence is high; the optical character positive; the indices of refraction $\alpha = 1.90$, and $\gamma = 1.97$. L. J. Spencer gave for schultenite $\alpha = 1.8903$, $\beta = 1.9077$, and $\gamma = 1.9765$. P. Niggli said that the crystals are triclinic. A. de Schulten gave 6.076 for the sp. gr. of the crystals at 15° ; H. V. Tartar and R. H. Robinson gave 5.786 at $20^\circ/4^\circ$ for the amorphous powder; and C. C. McDonnell and C. M. Smith, 6.053 at $15^\circ/15^\circ$ for the crystals, and 5.93 for the amorphous powder. L. J. Spencer gave for schultenite 5.943. H. Goguel said that the hydroarsenate can be heated to 200° without loss of weight, and it is not decomposed; H. V. Tartar and R. H. Robinson added that the formation of pyroarsenate occurs at a dull red-heat, while C. C. McDonnell and C. M. Smith found that the passage into pyroarsenate occurs at 280° . It melts at a bright red-heat, and on cooling forms a crystalline mass of the pyroarsenate. H. Goguel, and H. V. Tartar and R. H. Robinson found the hydroarsenate to be insoluble in cold water; C. C. McDonnell and co-workers showed that cold water has very little solvent action, while 100 c.c. of boiling water dissolved only 2 mgrms. of arsenic pentoxide in 6 hrs. W. H. Volck said that the prolonged action of fog, dew, and rain will convert the hydroarsenate into the orthoarsenate, but H. V. Tartar and R. H. Robinson could not confirm this. It was noted by W. P. Headen, and J. K. Haywood, and C. C. McDonnell and co-workers that when sprayed on tender foliage, the leaves may appear pitted owing to the decomposition of the arsenate by water; and, as indicated above, C. C. McDonnell and J. J. T. Graham showed that water slowly hydrolyzes lead hydroarsenate, forming hydroxymimetite: $5\text{PbHASO}_4 + \text{H}_2\text{O} \rightleftharpoons 2\text{H}_3\text{AsO}_4 + \text{Pb}_4(\text{PbOH})(\text{AsO}_4)_3$. The reaction reaches equilibrium when the conc. of the arsenic acid is very low, but if the water be constantly changed, the end-product is lead hydroxytriarsenate. According to W. C. Ebaugh, hydrogen chloride acts on the heated hydroarsenate, forming lead chloride, and a volatile arsenic compound; hydrogen bromide acts similarly; C. C. McDonnell and C. M. Smith said that the hydroarsenate dissolves in hydrochloric acid, and that the soln. yields crystals of lead chloroarsenate, and lead chloride and hydroarsenate; while conc. and dil. soln. of alkali chlorides, and lead chloride also form the chloroarsenate; while sodium chloride and potassium bromide, and iodide act in an analogous manner. The action of aq. ammonia has been already discussed. J. J. Berzelius, and H. Goguel said that the hydroarsenate is soluble in nitric acid—*vide supra*. C. E. Bradley and H. V. Tartar found that soln. of calcium polysulphides form lead sulphide, and dissolve much of the contained arsenic. J. J. Berzelius, and J. Valentin said that the salt is not soluble in acetic acid; while G. E. Smith showed that salts of the weak acids—borax, sodium silicate, and sodium salts of the fatty acids—convert the hydroarsenate into lead hydroxytriarsenate. H. V. Tartar and L. A. Bundy found that 22.77–45.82 per cent. is dissolved by soap soln.

According to C. C. McDonnell and C. M. Smith, **lead dihydroarsenate**, $\text{Pb}(\text{H}_2\text{AsO}_4)_2$, is produced only when the conc. of the arsenic acid in soln. is high. The ordinary hydroarsenate is formed by the action of lead nitrate or acetate on an alkali dihydroarsenate: $\text{Pb}(\text{NO}_3)_2 + \text{KH}_2\text{AsO}_4 = \text{PbHASO}_4 + \text{KNO}_3 + \text{HNO}_3$; likewise also when arsenic acid acts on lead nitrate and acetate at ordinary concentrations. A 50 per cent. soln. of arsenic acid does not convert the hydroarsenate into the dihydro-salt, but the transformation occurs when the conc. is raised above 86 per cent. arsenic acid. 400 grms. of an 86 per cent. soln. of arsenic acid, boiling at about 130° , with or without 2 per cent. nitric acid, was treated with 10 grms.

of lead hydroarsenate. The mixture was boiled a few minutes, and filtered through asbestos. The crystals were drained in the centrifuge, washed with alcohol, and dried at 110°. The Merrimac Chemical Co. treated 60 parts of lead and 25 parts of arsenic trioxide slowly with 25 kgms. of nitric acid of sp. gr. 1.384, without allowing the temp. to rise above 90°. With these proportions the dihydro-salt is formed. C. C. McDonnell and C. M. Smith said that the crystals are long, narrow, rhomboidal plates. The acute angle is 68°. The crystals are biaxial, and probably negative. They are monoclinic or triclinic—probably the latter. The birefringence is strong; and the indices of refraction at 20° for Na-light are $\alpha=1.74$, $\beta=1.84$, and $\gamma=1.82$. When the dihydro-salt is heated very slowly, it begins to lose water at 140°; and when kept 7 hrs. at 150°, it loses the eq. of a mol. of water, and the entire amount was not lost after heating 15 hrs. at 210°, but all was lost below a red-heat. When fused, some arsenic trioxide volatilizes. The salt is chemically very unstable, and when treated with water, it immediately forms lead hydroarsenate and arsenic acid. J. C. Brünnich and F. Smith said that lead dihydroarsenate $\text{PbH}_2\text{As}_2\text{O}_7$, occurs even in commercial arsenates, but C. C. McDonnell and C. M. Smith said that this is unlikely. The latter believe that the dehydration of lead dihydroarsenate takes place in two stages so that at 150° the reaction is $\text{Pb}(\text{H}_2\text{AsO}_4)_2 = \text{H}_2\text{O} + \text{PbH}_2\text{As}_2\text{O}_7$. B. Brauner said that lead tetracetate forms by double decomposition with arsenates a very unstable lead dihydroarsenate, presumably $\text{Pb}(\text{HAsO}_4)_2$; and A. Hutchinson and W. Pollard obtained a salt of this composition by the action of arsenic acid on lead tetracetate.

According to J. J. Berzelius, L. J. Thénard, and H. Salkowsky, **lead pyroarsenate**, $\text{Pb}_2\text{As}_2\text{O}_7$, is formed when lead hydroarsenate is heated to whiteness; H. V. Tartar and R. H. Robinson said at a dull red-heat; and C. C. McDonnell and C. M. Smith, at 300°. C. Lefèvre obtained it in transparent rhombic leaflets by saturating fused potassium metarsenate with lead oxide; and C. C. McDonnell and G. M. Smith, by fusing a mixture of lead oxide and arsenic pentoxide, or lead nitrate and ammonium dihydroarsenate in eq. amounts. The fusion always results in a slight reduction to arsenite. M. Amadori's curve, Fig. 29, shows the conditions of stability. According to C. C. McDonnell and C. M. Smith, the statements of E. E. Luther and W. H. Volck that lead pyroarsenate is produced by the action of arsenic acid on basic lead carbonate, and of W. H. Volck, that it may occur in commercial "lead arsenate pastes," are not supported by facts. The mass which has been fused has a crystalline structure; the crystals are biaxial and positive with a medium birefringence, and an index of refraction $\beta=2.03$ with Na-light at 20°. C. Lefèvre said that the rhombic leaflets are isomorphous with the pyrophosphates of the alkaline earths. The sp. gr. was found by C. C. McDonnell and C. M. Smith to be 6.85 at 15°/15°. M. Amadori gave 802° for the m.p. C. Lefèvre found that when heated at 500° in hydrogen, the salt is reduced to arsenic trioxide, arsenic, and lead. Cold water makes the crystals opaque; and, added C. C. McDonnell and C. M. Smith, forms lead hydroarsenate.

According to C. C. McDonnell and C. M. Smith, lead hydroarsenate loses its combined water below a red-heat and forms **lead metarsenate**, $\text{Pb}(\text{AsO}_3)_2$; the same salt is formed by heating a mixture of arsenic pentoxide and litharge, red-lead, or lead nitrate in the correct proportions. The mixture readily fuses to a mobile liquid which solidifies to a transparent glassy mass; if the glass be broken into fragments, and heated until incipient fusion occurs, the whole mass becomes crystalline. There is a slight reduction to arsenite during the preparation of this compound. Lead metarsenate consists of hexagonal tablets. The sp. gr. was 6.42 at 15°/15°. The salt is decomposed by water. The glass absorbs moisture rapidly from air and becomes opaque, the crystalline salt is less readily attacked.

C. Lefèvre treated a molten mixture of potassium chloride with over 25 per cent. of potassium orthoarsenate, or over 60 per cent. of the pyroarsenate, and obtained small transparent prisms of **potassium lead arsenate**, KPbAsO_4 ; similarly

with **sodium lead arsenate**, NaPbAsO_4 . If molten sodium metarsenate be treated with 15 per cent. of lead oxide, colourless plates of **sodium lead tripyroarsenate**, $\text{Na}_4\text{Pb}_4(\text{As}_2\text{O}_7)_3$, are produced. The crystals are altered superficially by water. A. H. Church⁶ described a green mineral occurring in small mammillary concretions in Cornwall; he named it **bayldonite**—after J. Bayldon. The analysis corresponds with **copper lead hydroxyarsenate**, $(\text{Cu,Pb})_4\text{As}_2\text{O}_9 \cdot 2\text{H}_2\text{O}$, analogous with libethenite, or, as P. Groth represents it, $(\text{Cu,Pb})\text{AsO}_4(\text{CuOH}) \cdot \frac{1}{2}\text{H}_2\text{O}$. K. Biehl described a series of bayldonites which he called **cuproplumbites**. Their composition ranged over $\text{R}_3(\text{AsO}_4)_2 \cdot \text{R}(\text{OH})_2 \cdot \text{H}_2\text{O}$ with $\text{PbO} : \text{CuO} : \text{HO}_2 = 1 : 3 ; 1 : 5 : 3 ;$ and $2 : 3$, with H_2O and $0.5\text{H}_2\text{O}$. He suggested the name *parabayldonite* for the mineral last indicated. In another series of bayldonites or cuproplumbites of the formula $2\text{R}_3(\text{AsO}_4)_2 \cdot 3\text{R}(\text{OH})_3$ the ratio $\text{PbO} : \text{CuO} = 2.5 : 1$; the monohydrate with $\text{PbO} : \text{CuO} = 4 : 5$; and the dihydrate with $\text{PbO} : \text{CuO} = 2.5 : 5$. E. S. Larsen gave for the indices of refraction $\alpha = 1.95$, and $\gamma = 1.99$. The optic axial angle is large, and the optical character positive. The hardness is $1.5-4.5$; and the sp. gr. $5.21-5.504$. O. Pufahl described a mineral from Tsumeb, South Africa, which he called **duffite**, and which occurs in small, pale olive-green, indistinct crystals soluble in hot, dil. hydrochloric acid, and which have the composition $2\text{Pb}_3(\text{AsO}_4)_2 \cdot \text{Cu}_3(\text{AsO}_4)_2 \cdot 4\text{Cu}(\text{OH})_2$, **copper lead octohydroxyhexaorthoarsenate**.

§ 21. Arsenates of the Antimony-Vanadium Family

J. J. Berzelius¹ reported the formation of **antimony arsenate** as a white precipitate on adding potassium metarsenate to a hydrochloric acid soln. of antimony trichloride. P. Berthier heated an alloy of arsenic and antimony with nitric acid, and diluted the soln. with water. He assumed that the white precipitate, soluble in nitric and hydrochloric acids, was *arsenatoantimonic acid*. If the soln. in hydrochloric acid be evaporated, the antimonic acid is precipitated while the arsenic acid remains in soln. There is here nothing to show that the product was not a mixture.

According to C. W. Scheele,² and J. J. Berzelius, a soln. of arsenic acid or of an alkali arsenate gives a white precipitate with a soln. of bismuth nitrate. H. Salkowsky found that the composition of the precipitate agrees with **bismuth orthoarsenate**, $\text{BiAsO}_4 \cdot \frac{1}{2} \text{H}_2\text{O}$, whether it is produced in soln. strongly or feebly acidified with nitric acid, and whether the arsenic acid is in small or great excess. M. Kuhara founded on this reaction a method for precipitating bismuth in analytical work. R. Schneider added that this salt separates when arsenical bismuth is treated with nitric acid. L. Vanino and F. Hartl obtained the same precipitate when bismuth nitrate dissolved in a soln. of mannite is treated with arsenic acid. H. Salkowsky said that the salt dried at $100^\circ\text{--}120^\circ$ is the *hemihydrate*, and that the water is expelled at a red-heat. A. de Schulten obtained crystals of the anhydrous salt by heating on the water-bath a mixture of bismuth nitrate, sodium arsenate, and nitric acid. A little water is added, and after some days, microscopic, monoclinic prisms of sp. gr. 7.142 at 15° are obtained. According to K. Haushofer, the hemihydrate is a white powder which appears under the microscope as small, spherical, stellate, or octahedral forms, and if a large excess of arsenic acid is employed in its preparation, the precipitate is inclined to be amorphous. H. Salkowsky found that the salt is sparingly soluble in water, and

is less soluble in the presence of arsenic or nitric acid, but more soluble in a soln. of bismuth nitrate. On the other hand, R. Schneider said that bismuth orthoarsenate is very sparingly soluble in a soln. of bismuth nitrate containing a little free nitric acid, and that it is more soluble in hot nitric acid than in the cold acid. L. J. Thénard said that bismuth orthoarsenate is soluble in hydrochloric acid; and H. Salkowsky found that the arsenate is not completely decomposed by boiling alkali-lye or aq. ammonia; the bismuth can be precipitated by repeatedly treating the hydrochloric acid with ammonia.

A. Cavazzi mixed ammoniacal soln. of sodium arsenate and bismuth citrate, and obtained a basic salt assumed to be *bismuth enneaoxydiarsenate*, $4\text{Bi}_2\text{O}_3 \cdot \text{As}_2\text{O}_5$, $3\text{Bi}_2\text{O}_3 \cdot 2\text{BiAsO}_4$, or possibly $(\text{BiO} \cdot \text{O})_4 \text{As} \cdot \text{O} \cdot \text{As}(\text{O} \cdot \text{BiO})_4$, *i.e.* **bismuthyl diarsenate**, $(\text{BiO})_8 \text{As}_2\text{O}_9$. If the alkali arsenate be added to the citrate soln., the basic salt is mixed with some citrate. The white product is sparingly soluble in water, but easily soluble in mineral acids. Another basic salt was found by G. vom Rath in a mine near Schneeberg, Saxony, and called by A. Breithaupt **atelestitute**—from *ἀτελής*, incomplete, presumably because its composition was not known when described by G. vom Rath. It occurs in minute sulphur-yellow crystals which K. Busz assigned to the monoclinic system, with the axial ratio $a:b:c = 0.9334:1:1.5051$, and $\beta = 70^\circ 43'$. The basal cleavage is indistinct. The analysis by K. Busz corresponds with $3\text{Bi}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, or $\text{Bi}_3\text{H}_2\text{AsO}_8$, which may be **bismuthyl orthoarsenate**, $(\text{BiO})_3 \text{AsO}_4 \cdot \text{H}_2\text{O}$, $\text{AsO}(\text{O} \cdot \text{BiO})_3 \cdot \text{H}_2\text{O}$, or $(\text{BiO} \cdot \text{O})_2 \text{As} \cdot \text{O}_2 \cdot \text{Bi}(\text{OH})_2$. The hardness is 3.0–4.5; and the sp. gr. 6.4. Yet a third basic salt was reported by A. Weisbach in a mine at Neustädte, Saxony, and named **rhagite**—from *ράξ*, a grape, in allusion to the colour and botryoidal grouping. The yellowish-green or yellow mineral occurs in crystalline mammyllary or spherical aggregates. C. Winkler's analysis corresponds with $5\text{Bi}_2\text{O}_3 \cdot 2\text{As}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, or better, according to C. F. Rammelsberg, with $5\text{Bi}_2\text{O}_3 \cdot 2\text{As}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$. This may be represented as **bismuthyl tetrarsenate**, $(\text{BiO})_{10} \text{As}_4\text{O}_9 \cdot 9\text{H}_2\text{O}$, or $(\text{BiO} \cdot \text{O})_4 \text{As} \cdot \text{O} \cdot \text{AsO}(\text{O} \cdot \text{BiO}) \cdot \text{O} \cdot \text{AsO}(\text{O} \cdot \text{BiO}) \cdot \text{O} \cdot \text{As}(\text{O} \cdot \text{BiO})_4 \cdot 9\text{H}_2\text{O}$; or as $\text{BiAsO}_4 \cdot 2\text{BiO}(\text{OH})$. The hardness is 5; and the sp. gr. 6.82. The mineral fuses easily; it is readily soluble in hydrochloric acid, but not so easily dissolved by nitric acid. A. H. Means described **arsenobismite**, $4\text{Bi}_2\text{O}_3 \cdot 3\text{As}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, as an impure mineral from the Mammoth Mine, Utah. Its sp. gr. is 5.70, and hardness about 3.

A. Schrauf found an emerald-green, bluish-green, or pale green mineral occurring with the bismuth ochre at Joachimsthal, and at Wittichen, Baden. The mineral was named **mixite**—after A. Mixa. According to W. F. Hillebrand and H. S. Washington, it also occurs in the Tintic district, Utah. The analyses agree with **copper bismuth arsenate**, $\text{Cu}_{20}\text{Bi}_2\text{As}_{10}\text{O}_{48} \cdot 22\text{H}_2\text{O}$. P. Groth writes the formula $\text{BiCu}_{10}(\text{AsO}_4)_5(\text{OH})_8 \cdot 7\text{H}_2\text{O}$. The slender acicular crystals are triclinic or monoclinic. The mineral also occurs as an incrustation in irregular particles, and spherical or reniform granules sometimes with a fibrous concentric structure. The mineral loses 4.08 per cent. of water at 100° , and 5.8 per cent. at 175° . The hardness is 3–4. A. Schrauf gave 2.66 for the sp. gr., while W. F. Hillebrand and H. S. Washington gave 3.79 at 23.5° . E. S. Larsen gave for the indices of refraction $\omega = 1.730$, and $\epsilon = 1.810$; the optical character is positive. When treated with nitric acid, the copper arsenate goes into soln., and white bismuth arsenate remains. A. Rosenheim and S. Thon could not prepare **bismutharsenates** like the aluminarsenates.

According to J. J. Berzelius,³ when aq. arsenic acid is sat. with vanadyl hydroxide, it yields on evaporation a gummy mass, easily soluble in water, and also crystalline grains of **vanadyl arsenate**, $\text{V}_2\text{O}_4 \cdot 2\text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or $\text{V}_2\text{O}_2(\text{AsO}_3)_4 \cdot 3\text{H}_2\text{O}$, *vanadyl metarsenate*. W. Schmitz-Dumont considered the water to be constitutional, and he wrote the formula (arsenic quinquevalent):

J. J. Berzelius found the same compound was deposited on evaporating a soln. of vanadyl hydroxide in an excess of arsenic acid. W. Schmitz-Dumont made this salt by producing a hot soln. of vanadium arsenate with the theoretical quantity of arsenic trioxide. The dark green liquid absorbs oxygen from the air, forming a blue soln. of the vanadyl salt: $V_2O_5 \cdot As_2O_5 + As_2O_3 + O = V_2O_4 \cdot 2As_2O_5$. The evaporation of the soln. yields the amorphous salt; but if an excess of arsenic acid is employed, the atm. oxidation proceeds rapidly and sky-blue crystals are deposited. The rectangular, prismatic crystals can be melted without decomposition, but at a higher temp., say, 500° , arsenic trioxide volatilizes and red vanadium arsenate is formed: $V_2O_4 \cdot 2As_2O_5 \cdot 3H_2O = O + 3H_2O + As_2O_3 + V_2O_5 \cdot As_2O_5$. J. J. Berzelius said that the salt dissolves slowly when in boiling water, and in water containing arsenic acid, and when once dissolved, it does not separate on cooling the soln.; the addition of alcohol precipitates the salt from its aq. soln. The salt is freely soluble in hydrochloric acid.

J. J. Berzelius prepared vanadium arsenate by evaporating a soln. of vanadyl arsenate in nitric acid until the liquid turns red, and nitrous fumes are evolved. On cooling, a lemon-yellow compound separates which is analogous to vanadium phosphate. The analysis by W. Schmitz-Dumont agrees with the formula $V_2O_5 \cdot As_2O_5 \cdot nH_2O$. Vanadium pentoxide is a stronger base than arsenic pentoxide, and in harmony with the nomenclature for the phosphates, it is simplest to regard this compound as **vanadium arsenate**, $V_2O_2(AsO_4)_2$, or *vanadyl orthoarsenate*. P. F. y Chavarri prepared this compound by adding vanadium pentoxide in small quantities at a time, to a boiling conc. soln. of arsenic acid of sp. gr. 2. The red liquid is then diluted, filtered, and allowed to crystallize. If arsenic trioxide be present, the soln. will have a green colour. The crystals are washed with absolute alcohol to free them from mother-liquid. C. Friedheim and W. Schmitz-Dumont employed this process; and they also made the anhydrous compound by heating the preceding salt at 500° until arsenic trioxide is no longer evolved. The anhydrous salt is similarly formed by heating the hydrate to 440° . If the salt be crystallized from conc. nitric acid, the dihydrate, $V_2O_2(AsO_4)_2 \cdot 2H_2O$, is formed; and if crystallized from aq. soln., the *decahydrate*, $V_2O_2(AsO_4)_2 \cdot 10H_2O$. A. Ditte reported that the *tetradecahydrate* separates from a hot sat. soln., and the *octodecahydrate* by cooling a hot soln. W. Schmitz-Dumont suggested that A. Ditte's preparations were incompletely dried. The yellow, tabular crystals of the decahydrate belong to the tetragonal system. They lose water of crystallization when exposed to air—one-third being lost in 14 days, and over desiccating agents, 9 to $9\frac{1}{2}$ mols. are lost. At 100° , nine mols. of water are given off, but the tenth mol. is retained more tenaciously; all the water is lost at 440° . In agreement with this observation, C. Friedheim and W. Schmitz-Dumont represented the constitution of the anhydride and of the hydrates

When the crystals are carefully warmed, they become brick-red, but the yellow colour is resumed on cooling. The crystals melt at a dull-redness, and arsenic trioxide is volatilized. The crystals dissolve in water, and this the more slowly, the less water of crystallization they contain. The aq. soln. has an acid reaction, and when warmed darkens in colour. When a conc. aq. soln. is heated, vanadic acid separates. The decomposition can be reversed by the addition of nitric acid, and it is prevented by the presence of arsenic acid. Hydrogen sulphide precipitates arsenic as sulphide from the soln. in hydrochloric acid, and the vanadium pentoxide is reduced to the tetroxide. The salt is insoluble in alcohol, but is not precipitated from its aq. soln. by alcohol. Alkaloids—brucine, quinine, strychnine, and nicotine—produce green, or yellowish-brown precipitates. G. Gain obtained the compound **vanadyl metabeharsenate**, $(V_2O_2)AsO_{17} \cdot H_2O$, or $V_2O_4 \cdot 3As_2O_5 \cdot H_2O$, in blue

crystals by the action of arsenic acid on hydrated vanadium tetroxide. The salt becomes green when exposed to air.

O. W. Gibbs reported orange-red crystals of a compound of the composition $8V_2O_5 \cdot 5As_2O_5 \cdot 27H_2O$, to be formed by the addition of nitric acid to a hot soln. of sodium arsenate and vanadate, and evaporating the orange-red liquid on a water-bath; also $6V_2O_5 \cdot 7As_2O_5 \cdot 3H_2O$ by oxidizing with nitric acid and potassium permanganate the residue obtained in the preparation of vanadyl vanadium arsenate. C. Friedheim and W. Schmitz-Dumont were unable to obtain either of these two products; they were no doubt mixtures.

A number of complex arsenatovanadates have been reported; and most of them can be represented as members of three series in which the ratios $R_2O : V_2O_5 : As_2O_5 : H_2O$, are as 1:1:1:1; as 1:2:1:0, or as 2:2:3:1. C. Friedheim and W. Schmitz-Dumont represented typical members of each series by the formulæ

The first series was obtained by C. Friedheim and W. Schmitz-Dumont by the decomposition of aq. soln. of salts of the third series; from vanadium arsenate and the calculated quantity of either base; and by adding a metavanadate to salts of the third series. The salts are decomposed at a red-heat, with the evolution of arsenic trioxide and oxygen. The original salt cannot always be obtained by treating with water the salt dehydrated at 150° . When the aq. soln. are warmed, or treated with alkali-lye, a yellow, gelatinous mass may be precipitated. C. Friedheim and W. Schmitz-Dumont described **copper hydroarsenatovanadate**, $Cu(HAsVO_6)_2 \cdot 3H_2O$, in microscopic greenish-white needles which are sparingly soluble; **magnesium hydroarsenatovanadate**, $Mg(HAsVO_6)_2 \cdot 9H_2O$, in pale yellow needles, fairly soluble in water; **zinc hydroarsenatovanadate**, $Zn(HAsVO_6)_2 \cdot H_2O$, in pale yellow needles which dissolve slowly in water; and **cobalt hydroarsenatovanadate**, $Co(HAsVO_6)_2 \cdot 8H_2O$, in microscopic, ochre-yellow needles, soluble in water.

The second series of salts prepared by C. Friedheim and W. Schmitz-Dumont represented by **ammonium arsenatodivanadate**, $NH_4(VO_2)_2AsO_4 \cdot 2\frac{1}{2}H_2O$, was obtained by evaporating a soln. of ammonium arsenate sat. with vanadium pentoxide; the first two crops of crystals were ammonium vanadate, and then followed a small yield of the arsenitodivanadate. A. Ditte obtained in this way yellow plates of a salt $5(NH_4)_2O \cdot 4As_2O_5 \cdot 2V_2O_5 \cdot 18H_2O$, but C. Friedheim and W. Schmitz-Dumont were unable to confirm this, and they suggested that A. Ditte's product is a mixture of ammonium arsenatodivanadate with ammonium dihydroarsenate, or a double salt of ammonium vanadate and arsenate. Analogous remarks apply to the sodium and potassium salts reported by A. Ditte. The ammonium salt was also prepared by C. Friedheim and W. Schmitz-Dumont by mixing vanadium pentoxide, ammonium vanadate, and a large excess of arsenic acid and allowing the liquid to stand for some weeks; by mixing the theoretical quantities of vanadium arsenate and potassium or ammonium vanadate; by the decomposition of an aq. soln. of the ammonium or potassium salt of the third series below; and by mixing potassium metavanadate and arsenic acid. The ammonium salt forms small reddish-yellow needles, which acquire a superficial green tinge on exposure to air. It loses its water of crystallization in air dried by calcium chloride. It is sparingly soluble in cold water, readily soluble in hot water without precipitating vanadic hydroxide. Pale yellow **potassium arsenatodivanadate**, $K(VO_2)_2AsO_4 \cdot 5H_2O$, was obtained as pale yellow microscopic needles which lose their water of crystallization at 100° .

The third series of salts reported by C. Friedheim and W. Schmitz-Dumont includes the ammonium salt and salts of the bivalent metals. They separate

from a soln. of the carbonate, vanadium arsenate, and arsenic acid mixed in theoretical proportions. The soln. is liable to decompose, producing salts of the first series, but not if an excess of vanadium arsenate is present. P. F. y Chavarri first prepared a series of salts by this process. C. Friedheim and W. Schmitz-Dumont obtained salts of this series by the action of an excess of arsenic acid on a metavanadate—potassium metavanadate yields a salt of the second series, but the ammonium and magnesium salts are obtained in well-defined crystals. The barium and silver salts are not produced by double decomposition with the magnesium salt. These salts are usually red; they are decomposed by crystallization from aq. soln. and salts of the first series are usually formed, but with the ammonium salt, the arsenatodivanadate is formed. If vanadium arsenate be present in the aq. soln., the decomposition does not occur. **Ammonium triarsenatotettravanadate**, $2(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, is a red, crystalline powder; **sodium triarsenatotettravanadate** appears as a yellow, amorphous powder; **copper triarsenatotettravanadate**, $2\text{CuO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, in greenish-white, microscopic needles, sparingly soluble in water; G. Canneri made the compounds in acidic soln. (1) by means of soln. containing a small proportion of an arsenate together with vanadic and molybdic (or tungstic) acids; (2) by addition of vanadic anhydride to a soln. of molybdoarsenates or tungsto-arsenates; (3) by addition of arsenic acid to soln. containing molybdates (or tungstates) and vanadates. The composition of the complex compound varies with the conc. and acidity of the soln. He stated that the variety of the ratios in which combination occurs between the constituent oxides in these compounds would appear to indicate that many of the compounds are mere isomorphous mixtures of far simpler true compounds. On the other hand, however, from the very small and but slightly variable proportions of arsenic present it may be assumed that the miscibility is effected between groupings of which the arsenic constitutes the central nucleus. The typical heterotri-arsenates may thus be represented by the

where R_6' represents six atoms of a monad, or three of a dyad radicle; R'' represents vanadium; and R''' , molybdenum or tungsten. F. Rodolico found that for the end-member of the series $(\text{NH}_4)_6\text{H}[\text{As}(\text{W}_2\text{O}_7)_x(\text{V}_2\text{O}_6)_y] \cdot n\text{H}_2\text{O}$, the axial ratio is $a : c = 1 : 0.9994$ for 40.26 per cent. WO_3 and 31.60 per cent. V_2O_5 ; and $1 : 1.0011$ for 63.28 per cent. WO_3 and 13.06 per cent. V_2O_5 . The salts approximated to this scheme only in a few cases, **calcium triarsenatotettravanadate**, $2\text{CaO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 21\text{H}_2\text{O}$, appears as an orange-red aggregate of tabular crystals; **strontium triarsenatotettravanadate**, $2\text{SrO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 21\text{H}_2\text{O}$, forms orange-red prisms; **magnesium triarsenatotettravanadate**, $2\text{MgO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 23\text{H}_2\text{O}$, furnishes red monoclinic crystals, **zinc triarsenatotettravanadate**, $2\text{ZnO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 23\text{H}_2\text{O}$, yields orange-red monoclinic crystals which lose 18 mols. of water at 150° ; **cadmium triarsenatotettravanadate**, $2\text{CdO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, as a compact granular mass; **manganese triarsenatotettravanadate**, $2\text{MnO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, was obtained by P. F. y Chavarri in purple-red, rhombic crystals; **cobalt triarsenatotettravanadate**, $2\text{CoO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$; and **nickel triarsenatotettravanadate**, $2\text{NiO} \cdot 2\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 24\text{H}_2\text{O}$, in yellowish-brown, probably tetragonal, crystals.

O. W. Gibbs reported a series of phosphatovanadylvanadates and also the **ammonium arsenatovanadylvanadates**: $5(\text{NH}_4)_2 \cdot 12\text{VO}_2 \cdot 6\text{V}_2\text{O}_5 \cdot 12\text{As}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, and $4(\text{NH}_4)_2 \cdot 0.9\text{VO}_2 \cdot 8\text{V}_2\text{O}_5 \cdot 9\text{As}_2\text{O}_5 \cdot 11\text{H}_2\text{O}$. J. Meisel was unable to establish their chemical individuality, and concluded that the phosphato- and arsenato-vanadylvanadates are not chemical individuals. They are isomorphous mixtures of vanadates and phosphates or arsenates in which the vanadyl radicle plays the rôle of a base in part with strong bases like potash, or ammonia.

A series of **arsenatovanadatomolybdates** has been reported by O. Decker, E. Diem, and A. Rüdüsüle, and by G. Canneri. They have been grouped in terms

of the molar proportion of vanadium pentoxide they contain. Thus, (i) *The tetravanadates*: **potassium arsenatotetrvanadatohemipentamolybdate**, $6 \cdot 5K_2O \cdot As_2O_5 \cdot 2V_2O_5 \cdot 2 \cdot 5MoO_3 \cdot 62H_2O$. (ii) *The hexavanadates*: yellow, microcrystalline **ammonium arsenatohexavanadatoicosimolybdate**, $5(NH_4)_2O \cdot As_2O_5 \cdot 3V_2O_5 \cdot 20MoO_3 \cdot 50H_2O$; **potassium arsenatohexavanadatopentadecamolybdate**, $6K_2O \cdot As_2O_5 \cdot 3V_2O_5 \cdot 15MoO_3 \cdot nH_2O$; **sodium arsenatohexavanadatopentadecamolybdate**, $6Na_2O \cdot As_2O_5 \cdot 3V_2O_5 \cdot 15MoO_3 \cdot nH_2O$; yellow **barium arsenatohexavanadatohexacosimolybdate**, $15BaO \cdot As_2O_5 \cdot 3V_2O_5 \cdot 26MoO_3 \cdot 62H_2O$. (iii) *The octovanadates*: red **ammonium arsenatoctovanadatopentacosimolybdate**, $11(NH_4)_2O \cdot As_2O_5 \cdot 4V_2O_5 \cdot 25MoO_3 \cdot 96H_2O$; **potassium arsenatoctovanadatodimolybdate**, $3K_2O \cdot As_2O_5 \cdot 4V_2O_5 \cdot 2MoO_3 \cdot 32H_2O$, yellow **barium arsenatoctovanadatotricontamolybdate**, $7BaO \cdot As_2O_5 \cdot 4V_2O_5 \cdot 33MoO_3 \cdot 34H_2O$. (iv) *The decavanadates*: **ammonium arsenatodecavanadatoheptamolybdate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 11MoO_3 \cdot 50H_2O$, as an orange-yellow microcrystalline powder; **ammonium arsenatodecavanadatotridecamolybdate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 13MoO_3 \cdot nH_2O$; **ammonium arsenatodecavanadatopentadecamolybdate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 15MoO_3 \cdot nH_2O$; **ammonium potassium arsenatodecavanadatohexadecamolybdate**, $7(NH_4)_2O \cdot K_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 16MoO_3 \cdot nH_2O$; **potassium arsenatodecavanadatohexadecamolybdate**, $7K_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 16MoO_3 \cdot nH_2O$; **ammonium arsenatodecavanadatoheptadecamolybdate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 17MoO_3 \cdot nH_2O$; and **ammonium arsenatodecavanadatoctodecamolybdate**, $7(NH_4)_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 18MoO_3 \cdot nH_2O$; and yellow **thallium arsenatodecavanadatodotricontamolybdate**, $3Tl_2O \cdot As_2O_5 \cdot 5V_2O_5 \cdot 33MoO_3 \cdot 45H_2O$. (v) *The dodecavanadates*: **potassium arsenatododecavanadatoheptamolybdate**, $6K_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 7MoO_3 \cdot 5H_2O$; **potassium arsenatododecavanadatododecamolybdate**, $6K_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot nH_2O$; **ammonium potassium arsenatododecavanadatodecamolybdate**, $6(NH_4)_2O \cdot K_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 10MoO_3 \cdot nH_2O$; **ammonium arsenatododecavanadatododecamolybdate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot 12H_2O$; **sodium arsenatododecavanadatododecamolybdate**, $6Na_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot nH_2O$; **potassium arsenatododecavanadatododecamolybdate**, $6K_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot nH_2O$; and **ammonium arsenatododecavanadatopentadecamolybdate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 15MoO_3 \cdot nH_2O$. (vi) *The tetradecavanadates*: **ammonium arsenatotetradecavanadatoheptamolybdate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 7V_2O_5 \cdot 11MoO_3 \cdot nH_2O$ —O. Decker gave $6(NH_4)_2O \cdot As_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot nH_2O$ for the formula of this compound; **ammonium potassium arsenatotetradecavanadatododecamolybdate**, $7(NH_4)_2O \cdot K_2O \cdot As_2O_5 \cdot 7V_2O_5 \cdot 12MoO_3 \cdot nH_2O$; **potassium arsenatotetradecavanadatotridecamolybdate**, $6K_2O \cdot As_2O_5 \cdot 7V_2O_5 \cdot 13MoO_3 \cdot nH_2O$; and **ammonium potassium arsenatotetradecavanadatotridecamolybdate**, $6(NH_4)_2O \cdot K_2O \cdot As_2O_5 \cdot 7V_2O_5 \cdot 13MoO_3 \cdot nH_2O$. (vii) *The hexadecavanadates*: **potassium arsenatohexadecavanadatododecamolybdate**, $8K_2O \cdot As_2O_5 \cdot 8V_2O_5 \cdot 12MoO_3 \cdot nH_2O$, where n is 15 and 28. (viii) *The octodecavanadates*: **potassium arsenatoctodecavanadatopentamolybdate**, $K_2O \cdot As_2O_5 \cdot 9V_2O_5 \cdot 5MoO_3 \cdot 34H_2O$. (ix) *The icosivanadates*: **potassium arsenatoicosivanadatopentamolybdate**, $7K_2O \cdot As_2O_5 \cdot 10V_2O_5 \cdot 5MoO_3 \cdot 77H_2O$, and **potassium arsenatoicosivanadatohexamolybdate**, $10K_2O \cdot As_2O_5 \cdot 10V_2O_5 \cdot 6MoO_3 \cdot 87H_2O$. (x) *The tetracosivanadates*: **potassium arsenatotetracosivanadatoctomolybdate**, $7K_2O \cdot As_2O_5 \cdot 12V_2O_5 \cdot 8MoO_3 \cdot 45H_2O$. (xi) *The octocosivanadates*: **potassium arsenatoctocosivanadatoheptamolybdate**, $10K_2O \cdot As_2O_5 \cdot 14V_2O_5 \cdot 7MoO_3 \cdot 132H_2O$.

A. Rogers obtained a series of complex salts of arsenic, phosphoric, tungstic, and vanadic acids. The evidence in favour of the chemical individuality of the products is not decisive. There are the **ammonium arsenatovanadatotungstate**, $17(NH_4)_2O \cdot 14 \cdot 5V_2O_5 \cdot 2As_2O_5 \cdot 29WO_3 \cdot 98H_2O$, which crystallizes in black octahedra sparingly soluble in cold water; **ammonium arsenatovanadatotungstate**, $18(NH_4)_2O \cdot 13V_2O_5 \cdot 2As_2O_5 \cdot 39WO_3 \cdot 88H_2O$, forming octahedral crystals soluble in water which appears to form a *copper salt* when treated with an ammoniacal soln. of copper nitrate; black **ammonium arsenatovanaditovanadatotungstate**, $17(NH_4)_2O \cdot 4V_2O_5 \cdot 7V_2O_5 \cdot 2As_2O_5 \cdot 32WO_3 \cdot 73H_2O$; **ammonium phosphoarsenatovanaditotungstate**, $88(NH_4)_2O \cdot 9V_2O_5 \cdot 12P_2O_5 \cdot 2As_2O_5 \cdot 148WO_3 \cdot 484H_2O$, in greenish-

black octahedral crystals soluble in water; **ammonium phosphatoarsenatovanadatungstate**, $82(\text{NH}_4)_2\text{O} \cdot 12\text{P}_2\text{O}_5 \cdot 52\text{V}_2\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 201\text{WO}_3 \cdot 567\text{H}_2\text{O}$, in dark red octahedra; and **ammonium phosphatoarsenatovanaditovanadatotungstate**, $99(\text{NH}_4)_2\text{O} \cdot 12\text{P}_2\text{O}_5 \cdot 6\text{V}_2\text{O}_3 \cdot 66\text{V}_2\text{O}_5 \cdot 2\text{As}_2\text{O}_5 \cdot 191\text{WO}_3 \cdot 522\text{H}_2\text{O}$, in black octahedra. G. Canneri prepared **ammonium arsenatooctovanadatohenicositungstate**, $18(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 21\text{WO}_3 \cdot 13\text{H}_2\text{O}$, as red prismatic crystals; **barium arsenatodocosivanadatotetracontatungstate**, $12\text{BaO} \cdot 2\text{As}_2\text{O}_5 \cdot 11\text{V}_2\text{O}_5 \cdot 34\text{WO}_3 \cdot 80\text{H}_2\text{O}$, in blood-red octahedra; and **thallium arsenatooctovanadatohenicositungstate**, $6\text{Tl}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 21\text{WO}_3 \cdot 13\text{H}_2\text{O}$, as a red powder—*vide supra*, the corresponding molybdates, and phosphates.

§ 22. The Arsenates of the Sulphur-Chromium Family

For *sulphur arsenates*, *vide infra*, arsenic sulphate. R. F. Weinland and G. Barttlingck¹ obtained some complex selenium arsenates typified by **ammonium selenatoarsenate**, $2(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 2\text{SeO}_3 \cdot 3\text{H}_2\text{O}$, or $(\text{NH}_4)_2\text{H}[\text{AsO}_3(\text{SeO}_4)_2] \cdot \text{H}_2\text{O}$, from a soln. containing a mol of selenic acid, and 2 mols each of arsenic acid and ammonia; and **potassium selenatoarsenate**, $\text{K}_2\text{H}[\text{AsO}_3(\text{SeO}_4)_2] \cdot \text{H}_2\text{O}$, and **rubidium selenatoarsenate**, $\text{Rb}_2\text{H}[\text{AsO}_3(\text{SeO}_4)_2] \cdot \text{H}_2\text{O}$, were similarly prepared. The evaporation, over sulphuric acid, of a soln. of a mol each of selenic acid and potassium hydroxide and 2 mols of arsenic acid, furnishes prismatic crystals with the composition $35\text{K}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 5\text{SeO}_3 \cdot 5\text{H}_2\text{O}$, which are stable in air, and easily soluble in water.

A. Oppenheim² did not obtain tellurium arsenate by fusing together a mixture of arsenic, tellurium, sodium carbonate, and charcoal; but R. F. Weinland and H. Prause found that telluric acid unites with the alkali arsenates, forming complex salts. The rubidium and potassium salts could not be obtained, but by evaporating over sulphuric acid a mixture of a mol of telluric acid, and 4 mols of ammonium dihydroarsenate, dissolved in as little water as possible at ordinary temp. and mixed with enough ammonia to give a soln. neutral to litmus, triclinic prisms of **ammonium telluratoarsenate**, $2(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot \text{TeO}_3 \cdot 4\text{H}_2\text{O}$, were obtained, with the axial

ratios $a : b : c = 0.7241 : 1 : 0.7468$, and $\alpha = 90^\circ 34'$; $\beta = 94^\circ 7'$; and $\gamma = 92^\circ 17'$, isomorphous with the corresponding phosphate. By working with a more dil. soln., and one mol. of ammonia, crystals of **ammonium telluratotriarsenate**, $4(\text{NH}_4)_2\text{O} \cdot 3\text{As}_2\text{O}_5 \cdot 2\text{TeO}_3 \cdot 11\text{H}_2\text{O}$, were obtained isomorphous with the corresponding phosphate. Six-sided plates of **sodium telluratoarsenate**, $2\text{Na}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 2\text{TeO}_3 \cdot 9\text{H}_2\text{O}$, were obtained as in the case of the ammonium salt.

According to H. Moser,³ soln. of chromic salts with soln. of potassium dihydroarsenate give an apple-green precipitate of **chromic arsenate**. C. Lefèvre reported **chromic pyroarsenate**, $\text{Cr}_4(\text{As}_2\text{O}_7)_8$, to be formed by melting chromic oxide with potassium or sodium dihydroarsenate. The green, prismatic crystals are not attacked by hot conc. acids. He also prepared **potassium chromic triorthoarsenate**, $\text{K}_3\text{Cr}_2(\text{AsO}_4)_3$, by adding chromic oxide to a molten mixture of potassium dihydroarsenate with 20 per cent. of potassium chloride. Green rhombic crystals of **sodium chromic triorthoarsenate**, $\text{Na}_3\text{Cr}_2(\text{AsO}_4)_3$, were produced in a similar way.

Some **arsenatochromates**, described by C. Friedheim, and N. Tarugi may be taken to be salts of heteropoly-acids, 6. 40, 50. They are formed by the action of arsenic acid on soln. of potassium or ammonium dichromate. They are considered to be condensation products of arsenic and chromic acids. They differ from what are usually regarded as double salts (i) in possessing a small proportion of water of crystallization; (ii) in not being formed directly from their components; and (iii) in not being resolved by water into their components. W. Meyerhofer, however, showed that the formation of these compounds takes place under conditions precisely analogous to those which generally hold for the formation of double salts usually regarded as molecular compounds. C. Friedheim said that the presence of free arsenic acid seems to be necessary for their formation. Two series of compounds have been prepared. These are typified by $2\text{R}'_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 4\text{CrO}_3$ and $3\text{R}'_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 8\text{CrO}_3$, which, according to the co-ordination theory, can be represented by the formulæ: $\text{R}'_3[\text{As}(\text{CrO}_4)_4]$ and $\text{R}'_2\text{H}[\text{AsO}_2(\text{CrO}_4)_2]$ respectively. C. Friedheim preferred to represent $\text{R}'_3[\text{As}(\text{CrO}_4)_4]$ by $(\text{NH}_4\text{O} \cdot \text{CrO}_2 \cdot \text{O})_2 = \text{AsO} - \text{O} \cdot \text{CrO}_2 \cdot \text{O} \cdot \text{CrO}_2 \cdot \text{ONH}_4$ rather than by $(\text{NH}_4)_2\text{O} = \text{AsO} - (\text{OCr}(\text{NH}_4\text{O})_2 = \text{AsO} - \text{O} - \text{CrO}_2 \cdot \text{O} \cdot \text{CrO}_2 \cdot \text{O} \cdot \text{CrO}_2 \cdot \text{O} \cdot \text{CrO}_2 \cdot \text{ONH}_4$, because it has not been possible to replace the hydroxyl associated directly with the arsenic by another radicle. He represented the formation of the $\text{R}'_2\text{H}[\text{AsO}_2(\text{CrO}_4)_2]$ series by the formula for the potassium salt:

and preferred the structure here indicated to $\text{HO}-\text{AsO} = (\text{O} \cdot \text{CrO}_2 \cdot \text{OK})_2$, because (i) arsenic acid and potassium chromate always form the dichromate; (ii) a mol. of potassium hydroxide acting on a mol. of the arsenatochromate produces potassium dichromate and dihydroarsenate; and (iii) the preparation of $(\text{HO})_2 = \text{AsO} - \text{O} \cdot \text{CrO}_2 \cdot \text{OK}$, analogous to a well-defined molybdate, is not possible.

C. Friedheim reported **ammonium arsenatotetrachromate**, $(\text{NH}_4)_3[\text{As}(\text{CrO}_4)_4]$, or $3(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 8\text{CrO}_3$, to be formed by crystallization from a soln. containing a mol. of chromic acid, and a mol. of ammonium dihydroarsenate over sulphuric acid. The salt loses no water at 100° ; water begins to come off at 120° ; reduction begins at 130° ; no ammonia is lost at 200° ; and the salt detonates at 238° . When recrystallized from water, the salt is hydrolyzed: $2(\text{NH}_4)_3[\text{As}(\text{CrO}_4)_4] + \text{H}_2\text{O} = (\text{NH}_4)_2\text{Cr}_2\text{O}_7 + 2(\text{NH}_4)_2\text{H}[\text{AsO}_2(\text{CrO}_4)_2] + 2\text{CrO}_3$. C. Friedheim also obtained **ammonium hydroarsenatodioxydichromate**, $(\text{NH}_4)_2\text{H}[\text{AsO}_2(\text{CrO}_4)_2]$, or $2(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 4\text{CrO}_3 \cdot \text{H}_2\text{O}$, from the mother-liquor obtained in the preparation of the preceding salt; and by crystallization from a soln. of two mols. of arsenic acid and a mol. of ammonium dichromate; if the chromate is substituted for the dichromate, no arsenatochromate is formed. The evaporation of the soln. over sulphuric

acid yields dark red, prismatic crystals of sp. gr. 1.848 at 24°. The salt is not altered at 150°, but at 175° decomposition sets in and a residue of chromic oxide and arsenate is formed. By evaporating a soln. of one or two mols of arsenic acid and a mol of potassium dichromate in a similar manner, dark red crystals of **potassium arsenatodioxydichromate**, $K_2H[AsO_2(CrO_4)_2]$, are produced. The sp. gr. is 2.254 at 24°. There may be a mol. of water of crystallization since the salt loses 0.54 per cent. of water at 55°; 0.67 at 120°; 0.83 per cent. at 140°; 1.09 per cent. at 180°; and 2.06 per cent. at 200°. It melts at 280°, giving off oxygen. When recrystallized from water, the salt is hydrolyzed: $(NH_4)_2H[AsO_2(CrO_4)_2] + H_2O = H_3AsO_4 + (NH_4)_2Cr_2O_7$, but if enough arsenic acid is present the decomposition does not occur; equimolar parts of this salt and potassium hydroxide form a mixture of potassium dichromate and dihydroarsenate; and with three times as much alkali, potassium chromate and dihydroarsenate are formed. The corresponding **sodium arsenatodioxydichromate**, $Na_2H[AsO_2(CrO_4)_2]$, has not been crystallized from aq. soln., although the aq. soln., if treated with potassium chloride, furnishes the potassium salt. A. Rosenheim and S. Thon also prepared **sodium dihydrochromiarsenate**, $NaH_2[Cr(AsO_4)_2] \cdot H_2O$; and **potassium dihydrochromiarsenate**, $KH_2[Cr(AsO_4)_2] \cdot nH_2O$, as a *heptahydrate*, and a *dodecahydrate*.

E. Schweizer found that when an aq. soln. of arsenic trioxide is added to a soln. of potassium dichromate, the liquid acquires a fine green colour, and in a few minutes coagulates to a jelly which, dried at 100°, has the composition $4K_2O \cdot 3CrO_3 \cdot 3As_2O_3 \cdot 20H_2O$. If the liquids be mixed in the reverse order, the green colour is produced, but no precipitate. N. Tarugi ascribed the formula $[Cr(OH)_4 : AsO_4]_2Cr(OH)_4 \cdot 4K_2HASO_4 \cdot 12H_2O$, **potassium trichromatododecahydroxyhexarsenate**, to the compound obtained at ordinary temp. After heating to 60°, it has the constitution $(CrO_3 : AsO_4)_2CrO_3 \cdot 4K_2HASO_4 \cdot 10H_2O$, whilst by heating at 120° the $10H_2O$ is expelled; these constitutions are assigned on the basis of determinations of water of crystallization. The compound of the composition $K_3Cr_3As_6O_{30}H_4$, obtained at 120°, is a green powder which, when boiled with potash, yields a pale green substance of the composition $K_4Cr_2As_2O_{16} \cdot 12H_2O$, to which the constitution $(K_2AsO_4 \cdot CrO_2 \cdot O)_2CrO_2$ is assigned; when boiled with potassium hydroarsenite soln., it yields a substance of the composition $K_2As_2Cr_2O_{22} \cdot 24H_2O$, and the constitution $[Cr(K_2AsO_4) : KAsO_4 \cdot O]_2Cr(KAsO_4) \cdot 24H_2O$. This, on boiling with potash, yields the compound $[Cr(HO)_2(K_2AsO_4) \cdot O]_2Cr(HO)_2$, which on heating at 150° is converted into a compound of the constitution $[CrO(K_2AsO_4) \cdot O]_2CrO$; on treating the latter with potassium hydroarsenite, it yields a substance of the constitution $[Cr(K_2AsO_4) : AsO_4]_2Cr_2$, which is readily oxidized by potassium ferricyanide with formation of chromium arsenite, $AsO_3 : Cr \cdot AsO_4 : Cr : AsO_4 \cdot Cr : AsO_4$, as a dark green powder.

J. J. Berzelius⁴ found that arsenic acid behaves like phosphoric acid towards molybdenum oxide; and by treating a soln. of molybdenum tetrachloride with sodium hydroarsenate, he obtained what is supposed to have been the secondary salt, **molybdenum bishydroarsenate**, $Mo(HAsO_4)_2 \cdot nH_2O$; and by dissolving molybdenum tetrahydroxide in an excess of arsenic acid, a soln. of what is supposed to have been **molybdenum quaterdihydroarsenate**, $Mo(H_2AsO_4)_4$. This soln. has a great inclination to turn blue; and, with ammonia, a deep red soln. is formed which gradually becomes colourless. G. Denigès reported a **molybdosic arsenate**, $[4MoO_3 \cdot MoO_2]_2 \cdot H_3AsO_4 \cdot 4H_2O$, in sapphire-blue, hexagonal plates, to be formed by the action of sodium molybdate on sodium hydroarsenate.

A. Miolati and R. Pizzighelli measured the sp. electrical conductivity of soln. of arsenic acid (0.0456 gm. H_3AsO_4 per c.c.) and of molybdic acid (0.02972 gm. MoO_3 per c.c.); so that 1 c.c. of the MoO_3 soln. represents 0.643 mol of MoO_3 . The results per mol of H_3AsO_4 are shown in Fig. 31. There are definite breaks corresponding with $As_2O_5 : MoO_3 = 1 : 5$ and $1 : 20$.

FIG. 31.—Electrical Conductivities of Mixed Solutions of Molybdic and Arsenic Acids.

A series of arsenatomolybdates has been prepared analogous to the phosphatomolybdates, with the ratio As : Mo : 1 : 1 ; 1 : 2 ; 2 : 5 ; 1 : 3 ; 1 : 8 ; 1 : 9 ; and 1 : 12—with a possible 1 : 2½. They are represented by the co-ordination formulæ :

$R_3[AsO_3(MoO_4)] \cdot nH_2O$	Arsenatomolybdates
$R_2[AsO_3(MoO_4)_2] \cdot nH_2O$	Arsenatodimolybdates
$R_2[AsO(MoO_4)_3] \cdot nH_2O$	Arsenatotrimolybdates
$R_3[(AsO_2)_2(MoO_4)]_6 \cdot nH_2O$	Arsenatohemipentamolybdates
$R_5[AsO(Mo_2O_7)]_4 \cdot nH_2O$	Arsenatoctomolybdates
$R_{12}[(AsO)_2(Mo_2O_7)]_9 \cdot nH_2O$	Arsenatoenneamolybdates
$R_7[As(Mo_2O_7)]_6 \cdot nH_2O$	Arsenatododecamolybdates

L. Forsén regards the arsenatomolybdic acids as members of three general series, (i) the *ortho-arsenatomolybdic acids* of the type $H_3[AsOMo_3O_{12}]$; (ii) the *meta-arsenatomolybdic acids* of the type $H_3[AsOMo_{12}O_{42}H_6]$; and the (iii) *leucoarsenatomolybdic acids* of the type $AsO(Mo_3O_{12}H_5)H_3$, illustrated by the sodium salts with the graphic formula :

H. Seyberth described a salt which he obtained by boiling a soln. of molybdic and arsenic acids and an ammonium salt ; he represented it by the formula $(NH_4)_2O \cdot As_2O_5 \cdot 7MoO_3 \cdot H_2O$ —but gave no analysis. C. Friedheim and J. Meschoirer regarded it as the primary salt of the $H_3[AsO(MoO_4)_3]$ -acid, namely, $(NH_4)H_2[AsO(MoO_4)_3] \cdot H_2O$ —*vide infra*. C. Friedheim and J. Meschoirer also reported another *ammonium diarsenatoheptamolybdate*, $7(NH_4)_2O \cdot 2As_2O_5 \cdot 14MoO_3 \cdot 28H_2O$, to be formed as white amorphous powder by the action of 2 mols of ammonium dihydroarsenate, on a mol of $(NH_4)_3Mo_7O_{24}$; but they regard it as a mixture of 2 mols of ammonium arsenatotrimolybdate with ammonium molybdate, $(NH_4)_2Mo_7O_{24}$. They also reported a white amorphous powder to be precipitated when 3 mols of $(NH_4)_6Mo_7O_{24}$ were added to a soln. of 14 mols of ammonium dihydroarsenate ; and its composition corresponds with $7(NH_4)_2O \cdot 2As_2O_5 \cdot 26MoO_3 \cdot 47H_2O$. A white microcrystalline powder, with the composition $6(NH_4)_2O \cdot As_2O_5 \cdot 15MoO_3 \cdot 3H_2O$, was obtained by the action of a mol of ammonia on a mol of ammonium dihydroarsenatotrimolybdate. By treating $(NH_4)_6Mo_7O_{24}$ with arsenic acid, a white amorphous powder with the composition $9(NH_4)_2O \cdot 2As_2O_5 \cdot 24MoO_3 \cdot 40H_2O$, was obtained.

According to C. Friedheim and J. Meschoirer, a mol of molybdic acid readily dissolves in a soln. containing a mol of ammonium dihydroarsenate. On evaporating the soln., the 1 : 2 compound separates out—*vide infra*—and the filtrate furnishes white prismatic crystals of **ammonium dihydroarsenatomolybdate**, $(NH_4)_2H_2[AsO_3(MoO_4)] \cdot \frac{1}{2}H_2O$. It is also obtained in a similar way from a soln. of equimolar parts of arsenic acid and ammonium molybdate. C. Friedheim and F. Mach obtained silky needles of **potassium dihydroarsenatomolybdate**, $KH_2[AsO_3(MoO_4)] \cdot 1\frac{1}{2}H_2O$, by evaporating a soln. of equimolar parts of arsenic acid, potassium dihydroarsenate, and molybdic acid ; and quadratic prisms of **sodium dihydroarsenatomolybdate**, $NaH_2[AsO_3(MoO_4)] \cdot 3H_2O$, were obtained in a similar way. C. Friedheim represented the constitution of these salts, $(HO)_2=AsO-O \cdot MoO_2 \cdot ONa$. The free acid is unknown. The alkali salts at a bright red-heat give off arsenic trioxide, and molybdenum dioxide.

As indicated above, C. Friedheim and J. Meschoirer obtained **ammonium hydroarsenatodimolybdate**, $(NH_4)_2H[AsO_2(MoO_4)_2] \cdot 1\frac{1}{2}H_2O$, by evaporating a soln. of equimolar parts of molybdic acid and ammonium dihydroarsenate ; it was also obtained by the action of arsenic acid on a soln. of ammonium molybdate ; and of molybdic acid on a soln. of ammonium hydroarsenate. C. Friedheim and F. Mach obtained **potassium hydroarsenatodimolybdate**, $K_2H[AsO_4(MoO_4)_2] \cdot nH_2O$, as a dihydrate, from a soln. of equimolar parts of molybdic acid and potassium dihydroarsenate ; and as a *hemihydrate*, from a soln. of a mol of molybdic

acid and 2 mols of potassium hydroarsenate—the first crop of crystals are those of the arsenatotrimolybdate. C. Friedheim represented the constitution by either $\text{HO}(\text{KO})=\text{AsO}-\text{O}.\text{MoO}_2.\text{OK}$, or $\text{HO}-\text{AsO}=(\text{O}.\text{MoO}_2.\text{OK})_2$. The potassium salt is decomposed by water, forming the arsenatoctomolybdate, etc.

C. Friedheim prepared **potassium hexahydroarsenatohemipentamolybdate**, $\text{K}_4\text{H}_6[(\text{AsO}_2)_2(\text{MoO}_4)_5].n\text{H}_2\text{O}$, where n ranged from 7 to 18; and also **potassium arsenatohemipentamolybdate**, $\text{K}_{10}[(\text{AsO}_2)_2(\text{MoO}_4)_5].19\text{H}_2\text{O}$, as white powders by evaporating a soln. of equimolar proportions of molybdic acid and potassium dihydroarsenate. The second salt is found in the second crop of crystals. It is also obtained as a precipitate on mixing 2 mols of arsenic acid and a mol of potassium molybdate; or a mol of molybdic acid and 2 mols of potassium dihydroarsenate.

C. Friedheim also found **ammonium tetrahydroarsenatohemipentamolybdate**, $(\text{NH}_4)_4\text{H}_4[(\text{AsO}_2)_2(\text{MoO}_4)_5].7\text{H}_2\text{O}$, as an amorphous white powder, among the crystals obtained by the evaporation of a soln. of 2 mols of molybdic acid, and ammonium hydroarsenate; and **ammonium dihydroarsenatohemipentamolybdate**, $(\text{NH}_4)_6\text{H}_2[(\text{AsO}_2)_2(\text{MoO}_4)_5].4\text{H}_2\text{O}$. These products have not been definitely established as chemical individuals.

H. Seyberth first prepared a **hydroarsenatotrimolybdic acid**, $\text{H}_3[\text{AsO}(\text{MoO}_4)_3].n\text{H}_2\text{O}$, by the action of aqua regia on the ammonium salt; J. H. Debray, by the action of aqua regia on ammonium arsenatodecamolybdate; C. Friedheim and F. Mach, from a soln. of one mol of arsenic acid, and 3 mols of molybdic acid, or from a soln. of arsenic acid sat. with molybdic acid; and O. Pufahl, by the action of sulphuric acid on a mixture of barium molybdate and arsenic acid in the theoretical proportions. O. Pufahl obtained the *hemitrihydrate* by slowly cooling a hot sat. soln. of the acid in nitric acid of sp. gr. 1.4. A. Scheibe said that the 4-sided prisms are probably monoclinic. O. Pufahl, and C. Friedheim said that when crystallized from water or dil. nitric acid (1:2), the *hemipentadecahydrate* is formed in tabular crystals which, according to A. Scheibe, belong to the trigonal system, and have the axial ratio $a:c=1:0.8535$. The sp. gr. is 2.493 at 19.8°. The general properties of the two hydrates are otherwise similar. The crystals become matte and opaque; they lose all the water of crystallization in 8 hrs. at 150°; and in 8 days over sulphuric acid, all but one mol. The acid readily melts in its water of crystallization; and after heating to redness it forms a compact greenish-grey mass containing some arsenic trioxide. It forms a colourless soln. in water at ordinary temp.; the soln. sat. at 18.8° has a sp. gr. 2.21. The soln. has an acid reaction, and soon becomes yellow, especially on a water-bath. The acid is easily soluble in alcohol, and the soln. gradually becomes green owing to the reduction of the molybdic acid. The acid is insoluble in carbon disulphide, chloroform, and hydrocarbons. When treated with ether, the acid forms a thick, green liquid. The acid is coloured blue or green by many organic substances. Conc. or 50 per cent. sulphuric acid decomposes hydroarsenatotrimolybdic acid with the separation of molybdic acid, and when heated, a colourless soln. is produced. Boiling hydrochloric acid decomposes the acid, and nitric acid is without action. A conc. soln. of potassium or sodium carbonate gives a white precipitate which dissolves when warmed; alkalis give a white, gelatinous precipitate soluble in acids and alkalies; a caesium or rubidium salt gives sparingly soluble crystalline precipitates; silver nitrate, a white precipitate easily soluble in nitric acid; magnesium salt in the presence of ammonia, a precipitate of ammonium magnesium arsenate and ammonium arsenatomolybdate; mercurous nitrate, a yellowish-white precipitate insoluble in excess, but freely soluble in nitric acid; lead nitrate, a sparingly soluble precipitate easily soluble in nitric acid; thalious nitrate, a similar result to that with lead nitrate; and thallic salts, a microcrystalline precipitate. No definite *mercurous or mercuric arsenatotrimolybdates* have been prepared by O. Pufahl.

C. Friedheim considers that the acid is better represented by the formula $(\text{HO})_2=\text{AsO}-\text{O}.\text{MoO}_2.\text{O}.\text{MoO}_2.\text{O}.\text{MoO}_2.\text{OH}$, than by $\text{AsO}(\text{O}.\text{MoO}_2.\text{OH})_3$, because it

agrees better with the properties of the salts, and with the tendency of the acid to polymerization. The aq. soln. gives reactions characteristic of both the constituent acids; and the acid is therefore dissociated in aq. soln. If an alkali is added to the soln., a salt of the acid is not formed at first, but with the excess of molybdic acid it forms an acid molybdate, and the molybdic acid then condenses with the arsenic acid. There are three series of salts: (i) primary, $\text{RH}_2[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$; (ii) secondary, $\text{R}_2\text{H}[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$; and (iii) tertiary, $\text{R}_3[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$. C. Friedheim reported that there are two isomeric forms of the tertiary acid. J. H. Debray reported a salt $4(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 6\text{MoO}_3 \cdot n\text{H}_2\text{O}$, to be formed by adding ammonia to an aq. soln. of arsenatrimolybdic acid, but he gave no analysis. O. Pufahl could not confirm the existence of the alleged salt; he always obtained the secondary salt, $(\text{NH}_4)_2\text{H}[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$.

The primary salts were produced by J. H. Debray, and O. Pufahl by adding the calculated quantity of hydroxide, carbonate, nitrate, or acetate to the acid; by J. H. Debray, by mixing theoretical quantities of arsenic and molybdic acids and alkali carbonate, and by adding the theoretical quantity of the acid to the tertiary salt; and C. Friedheim, by mixing 3 or 4 mols of molybdic acid with 2 mols of potassium hydroarsenate, or by evaporating a soln. of 3 mols of molybdic acid with a mol of alkali dihydroarsenate. These salts are crystalline, stable in air, and are usually very soluble in water; and, added O. Pufahl, a soln. of the salt gives precipitates with mercurous nitrate, thallos salts, and thallic salts. A. Scheibe and O. Pufahl said the monoclinic crystals of the magnesium, zinc, cadmium, manganese, cobalt, and nickel salts are isomorphous. C. Friedheim found that the potassium salt loses oxygen but no molybdic acid when heated; he therefore argued that the molybdic acid must be united directly with the alkali.

O. Pufahl, J. H. Debray, and C. Friedheim and J. Meschoirer prepared **ammonium dihydroarsenatotrimolybdate**, $(\text{NH}_4)_2\text{H}_2[\text{AsO}(\text{MoO}_4)_3] \cdot \text{H}_2\text{O}$; and A. Scheibe showed that the tetragonal crystals have the axial ratio $a : c = 1 : 1.0379$. O. Pufahl obtained tetragonal crystals of **lithium dihydroarsenatotrimolybdate**, $\text{LiH}_2[\text{AsO}(\text{MoO}_4)_3] \cdot 6\text{H}_2\text{O}$. J. H. Debray, O. Pufahl, and C. Friedheim and F. Mach prepared colourless cubic crystals of **sodium dihydroarsenatotrimolybdate**, $\text{NaH}_2[\text{AsO}(\text{MoO}_4)_3] \cdot 5\text{H}_2\text{O}$, which A. Scheibe referred to the tetragonal system. C. Friedheim and F. Mach obtained **potassium dihydroarsenatotrimolybdate**, $\text{KH}_2[\text{AsO}(\text{MoO}_4)_3] \cdot 1\frac{1}{2}\text{H}_2\text{O}$, crystals which A. Scheibe referred to the tetragonal system. O. Pufahl also prepared cubic and octahedral crystals of **rubidium dihydroarsenatotrimolybdate**, $\text{RbH}_2[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$, which were sparingly soluble in water; similarly also hexagonal crystals of **cæsium dihydroarsenatotrimolybdate**, $\text{CsH}_2[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$. O. Pufahl obtained pale blue, rhombic, bipyramidal crystals of **copper dihydroarsenatotrimolybdate**, $\text{Cu}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 15\text{H}_2\text{O}$, which, according to A. Scheibe, had the axial ratios $a : b : c = 0.788 : 1 : -$. O. Pufahl prepared the salts of the three alkaline earths by dissolving the carbonates in the acid. According to A. Scheibe, **calcium dihydroarsenatotrimolybdate**, $\text{Ca}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 8\text{H}_2\text{O}$, furnishes rhombic crystals with the axial ratios $a : b : c = 0.967 : 1 : 0.747$; the rhombic crystals of **strontium dihydroarsenatotrimolybdate**, $\text{Sr}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 3\text{H}_2\text{O}$, are isomorphous with the calcium and barium salts; and **barium dihydroarsenatotrimolybdate**, $\text{Ba}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 8\text{H}_2\text{O}$. They are all sparingly soluble in water. The monoclinic crystals of **magnesium dihydroarsenatotrimolybdate**, $\text{Mg}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 11\text{H}_2\text{O}$, made by O. Pufahl, were found by A. Scheibe to have the axial ratios $a : b : c = 1.1286 : 1 : 1.0303$, and $\beta = 120^\circ 16'$; similarly the isomorphous crystals of **zinc dihydroarsenatotrimolybdate**, $\text{Zn}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 11\text{H}_2\text{O}$, have $a : b : c = - : 1 : 0.9117$, and $\beta = 119^\circ 29'$; those of the **cadmium dihydroarsenatotrimolybdate**, $\text{Cd}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 11\text{H}_2\text{O}$, $a : b : c = - : 1 : 0.9189$, and $\beta = 119^\circ 44'$. Those of **manganese dihydroarsenatotrimolybdate**, $\text{Mn}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 11\text{H}_2\text{O}$, $a : b : c = 1.12242 : 1 : 1.03199$, and $\beta = 119^\circ 54'$; those of **cobalt dihydroarsenatotrimolybdate**, $\text{Co}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 11\text{H}_2\text{O}$, $a : b : c = 1.12895 : 1 : 1.03039$, and $\beta = 119^\circ 41'$; and those of **nickel dihydroarsenatotrimolybdate**, $\text{Ni}\{\text{H}_2[\text{AsO}(\text{MoO}_4)_3]\}_2 \cdot 11\text{H}_2\text{O}$.

According to O. Pufahl, the only known salt is **ammonium hydroarsenatotrimolybdate**, $(\text{NH}_4)_2\text{H}[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$, which he obtained as a *hemipentahydrate*, by pouring a dil. soln. of the acid into an excess of 10 per cent. ammonia; and the *hemihydrate* which C. Friedheim and J. Meschoirer obtained by evaporating a mixture of ammonium arsenate and molybdate—the first crop of

crystals were those of the arsenatoctomolybdate. The doubly refracting crystals are sparingly soluble in water and cannot be recrystallized from aq. soln.

The tertiary salts were obtained by O. Pufahl from a mixture of the acid with 3 mols of base; and by C. Friedheim, from a mol of potassium or ammonium orthoarsenate and 3 mols of molybdic acid. The condensation is supposed to proceed:

C. Friedheim also obtained a series of tertiary salts which he supposed to be isomeric with those of O. Pufahl by the action of one or two mols of molybdic acid on two mols of potassium dihydroarsenate; of equimolar parts of molybdic acid and sodium or potassium hydroarsenate; of a soln. of a mol of sodium or ammonium dihydroarsenate on one or two mols of $\text{Na}_6\text{Mo}_7\text{O}_{24}$, or $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$, respectively—in the last case the first crop of crystals is mixed with those of ammonium molybdate, $(\text{NH}_4)_2\text{Mo}_2\text{O}_7$.

C. Friedheim and J. Meschoirer obtained **ammonium arsenatotrimolybdate**, $(\text{NH}_4)_3[\text{AsO}(\text{MoO}_4)_3] \cdot 4\text{H}_2\text{O}$, as a white crystalline powder by the action of 3 mols of molybdic acid on a mol of ammonium orthoarsenate; and the isomeric form, $(\text{NH}_4)_3[\text{AsO}(\text{MoO}_4)_3] \cdot 8\text{H}_2\text{O}$, as a white amorphous powder, by the action of ammonium dihydroarsenate on $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$. O. Pufahl obtained a soln. of **lithium arsenatotrimolybdate**, $\text{Li}_3[\text{AsO}(\text{MoO}_4)_3]$, but could not crystallize the syrupy liquid. O. Pufahl, and C. Friedheim and J. Meschoirer obtained **sodium arsenatotrimolybdate**, $\text{Na}_3[\text{AsO}(\text{MoO}_4)_3] \cdot n\text{H}_2\text{O}$, from the theoretical proportions of the acid and sodium carbonate; and by evaporating a soln. of equimolar parts of acid sodium molybdate and arsenic acid. C. Friedheim and J. Meschoirer obtained the isomeric form by the action of 2 mols of sodium hydroarsenate on 2 mols of molybdic acid, or of a mol of sodium dihydroarsenate on one or 2 mols of $\text{Na}_6\text{Mo}_7\text{O}_{24}$. O. Pufahl obtained **potassium arsenatotrimolybdate**, $\text{K}_3[\text{AsO}(\text{MoO}_4)_3] \cdot 4\text{H}_2\text{O}$, by the action of potassium carbonate on the theoretical proportion of the acid, and C. Friedheim and F. Mach, by the action of potassium orthoarsenate on 3 mols of molybdic acid. They also obtained the isomeric form with a high proportion of water of crystallization, $25\text{H}_2\text{O} - 44\text{H}_2\text{O}$, by evaporating a soln. of the arsenatodimolybdate in hot water, and by evaporating a soln. of equimolar parts of molybdic acid and potassium hydroarsenate. O. Pufahl could not crystallize the soln. of **copper arsenatotrimolybdate**, $\text{Cu}_3[\text{AsO}(\text{MoO}_4)_3]_2$. He obtained a microcrystalline powder of sparingly soluble **calcium, strontium, and barium arsenatotrimolybdates**, $\text{Ca}[\text{AsO}(\text{MoO}_4)_3]_2$.

O. W. Gibbs, O. Pufahl, and C. Friedheim and J. Meschoirer reported salts of the hypothetical *hydroarsenatoctomolybdic acid*, $\text{H}_5[\text{AsO}(\text{Mo}_2\text{O}_7)_4] \cdot n\text{H}_2\text{O}$. They obtained **ammonium arsenatoctomolybdate**, $(\text{NH}_4)_5[\text{AsO}(\text{Mo}_2\text{O}_7)_4] \cdot n\text{H}_2\text{O}$, where n may be 5, 9, or 12, by precipitation from a mixture of soln. of equimolar parts of ammonium dihydroarsenate and $3(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$; and by the action of dil. aq. ammonia on hydroarsenatotrimolybdic acid. C. Friedheim and F. Mach also obtained **potassium hydroarsenatoctomolybdate**, $\text{K}_5[\text{AsO}(\text{Mo}_2\text{O}_7)_4] \cdot 3\frac{1}{2}\text{H}_2\text{O}$, from a hot soln. of equimolar parts of potassium dihydroarsenate and molybdic acid; by the action of water on potassium arsenatomolybdate; and when 2 mols of molybdic acid are mixed with a mol of potassium hydroarsenate.

O. Pufahl prepared **hydroarsenatoenneamolybdic acid**, $\text{H}_{12}[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$, by decomposing barium molybdate by sulphuric acid in the presence of arsenic acid; J. H. Debray, by the action of aqua regia on ammonium arsenatododecamolybdate. J. H. Debray without publishing the analysis assigned the formula $\text{As}_2\text{O}_5 \cdot 20\text{MoO}_3 \cdot 27\text{H}_2\text{O}$ to the product. C. Friedheim and F. Mach obtained the acid from a sat. soln. of molybdic acid in one of hydroarsenatotrimolybdic acid; and from a soln. of 4 to 9 mols of molybdic acid in one of potassium dihydroarsenate. If the aq. soln. of the acid be crystallized at ordinary temp. it forms the red *docosihydrate*; and if below 8° , the yellow *dotricontahydrate*. C. Friedheim represented the composition by $\text{AsO}(\text{O.MoO}_2 \cdot \text{O.MoO}_2 \cdot \text{O.MoO}_2 \cdot \text{OH})_3$, but the acid has a higher basicity than this, namely, $\text{H}_{12}[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 22$ (or 32) H_2O . F. Kehrman

and E. Böhm called it *arsenatoluteomolybdic acid*. A. Scheibe said the red crystals of the lower hydrate are triclinic with the axial ratios $a : b : c = 0.9448 : 1 : 1.1382$, and $\alpha = 86^\circ 2' 10''$, $\beta = 87^\circ 21' 20''$, and $\gamma = 122^\circ 44' 20''$. The sp. gr. is 3.088 at 19.8° . These crystals are stable in air, but when kept over conc. sulphuric acid, they rapidly decompose, forming a brown powder; if dried at 100° – 110° , the acid loses 22 mols. of water, and O. Pufahl said that when heated to 150° – 160° , it still retains 3 mols. of water of constitution, which are expelled at 300° . The salt is easily decomposed by moisture; and when treated with water, two-thirds of the molybdic acid remains undissolved. The sat. soln. at 18.3° has a sp. gr. 2.450. It is soluble in alcohol, but insoluble in carbon disulphide, chloroform, and the hydrocarbons. The higher hydrate forms yellow triclinic crystals which, according to A. Scheibe, have the axial ratios $a : b : c = 0.88 : 1 : 0.84$, and $\alpha = 100^\circ 30'$, $\beta = 101^\circ 36'$, and $\gamma = 79^\circ 33'$. The sp. gr. is 2.822 at 19.8° . When the crystals are heated, they melt to a red liquid, which forms an orange-yellow mass; if heated further, a brick-red powder is formed; and when completely dehydrated, the product is greyish-green. When the acid is kept, it soon decomposes into hydroarsenatotrimolybdic and molybdic acids. If hot water be poured over the crystals the colour becomes red, and when recrystallized from water at ordinary temp., the red crystals of the lower hydrate are formed. When the very conc. soln. is warmed over 40° , it decomposes into molybdic acid, which is precipitated, and soluble hydroarsenatotrimolybdic acid. It also gradually decomposes at ordinary temp. in sunlight. The aq. soln. gives the reactions characteristic of molybdic acid. Hydrochloric, and sulphuric acids decompose this compound into its components, which form a colourless soln. The compound is freely soluble in cold nitric acid, and when evaporated, crystals of the hydrodiarsenatoctodecamolybdic acid are formed. At 40° , the soln. in nitric acid decomposes like the aq. soln. The acid decomposes carbonates, nitrates, and acetates, but with the latter, some molybdic acid separates; and with solid chlorides, particularly in the presence of nitric acid, diarsenatoctodecamolybdates are formed. It behaves towards ether and many organic substances very like hydroarsenatotrimolybdic acid; and, as shown by F. Kehrmann and E. Böhm, it gives coloured reactions with alkaloids and organic bases. Alkali carbonates give no precipitate with an aq. soln. of the acid; aq. ammonia gives a precipitate soluble in excess; silver nitrate, and lead, mercurous, and thalious salts give yellow precipitates; copper, barium, zinc, cadmium, mercuric, and thallic salts are without action; stannic, stannous, and arsenious chlorides give no precipitate, but the last two salts give a blue coloration.

O. Pufahl found that when equimolar parts of the acid and potassium carbonate are mixed together, **potassium decahydroarsenatoenneamolybdate**, $K_2H_{10}[(AsO)_2(Mo_2O_7)_9].20H_2O$, is formed together with the hexahydro-salt. C. Friedheim represented the formula $(HO.MoO_2.MoO_2.O.MoO_2.O)_2AsO(O.MoO_2.O.MoO_2.MoO_2.OK)$; and he prepared the salt by boiling with a soln. of potassium hydroarsenate an excess of molybdic acid; the first crop of crystals is the dihydroarsenatotrimolybdate, the second crop the hexahydro-salt, and the third crop contains the required salt. The sulphur-yellow crystals were found by A. Scheibe to be trigonal, and to have the axial ratio $a : c = 1.1.2066$. When heated, it gives off molybdic acid. The salt is soluble in water, and decomposes when evaporated, forming the hexahydro-salt and the red acid. Nitric acid converts it into potassium tetrahydroarsenatoctodecamolybdate. This is the only decahydroarsenatoenneamolybdate so far reported.

According to O. Pufahl, when a mol of the acid is mixed with one of ammonium carbonate, colourless crystals of **ammonium octohydroarsenatoenneamolybdate**, $(NH_4)_4H_8[(AsO)_2(Mo_2O_7)_9].14H_2O$, are formed. A. Scheibe gave for the axial angles of the triclinic crystals $a : b : c = 0.604 : 1 : 0.974$, and $\alpha = 120^\circ 22'$, $\beta = 129^\circ 39'$, and $\gamma = 120^\circ 9'$. This is the only octohydroarsenatoenneamolybdate so far reported.

O. Pufahl prepared a series of salts of the **hexahydroarsenatoenneamolybdates**, $R_6H_6[(AsO)_2(Mo_2O_7)_9].nH_2O$, by treating the acid with the carbonates, or hydroxides

of the alkalis or alkaline earth metals, copper, zinc, cadmium, manganese, cobalt, or nickel; F. Kehrman and E. Böhm, by treating the soln. of the acid in water and nitric acid with a chloride of the metal; and C. Friedheim, by saturating soln. of some of the previous compounds or of the arsenates with molybdic acid. The salts usually crystallize readily; and are generally soluble in water. The aq. soln. of the potassium salt is converted by nitric acid into the tetrahydrododecamolybdates. The zinc, nickel, and cobalt salts were found by A. Scheibe to be isomorphous; probably the salts of magnesium, cadmium, and manganese should be included in the list; but not so with the salts of the alkaline earths. F. Kehrman and E. Böhm found that the reactions of this acid are like those of the corresponding phosphatoenneamolybdate (*q.v.*).

F. Kehrman obtained orange-yellow prisms of the unstable **ammonium hexahydroarsenatoctodecamolybdate**, $(\text{NH}_4)_6\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 11\text{H}_2\text{O}$. The salt is easily soluble in water, and alcohol. O. Pufahl obtained **lithium hexahydroarsenatoctodecamolybdate**, $\text{Li}_6\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 3\text{H}_2\text{O}$, in honey-yellow crystals, which A. Scheibe found to belong to the monoclinic system, and to have the axial ratios $a : b : c = 1.2982 : 1 : 0.0381$, and $\beta = 101^\circ 28'$. The sat. aq. soln. has a sp. gr. 2.481 at 15° . O. Pufahl, and C. Friedheim prepared **sodium hexahydroarsenatoctodecamolybdate**, $\text{Na}_6\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$. Usually the salt has 21 mols. of water of crystallization; but if a cold sat. soln. be allowed to stand for some weeks, it has $27\text{H}_2\text{O}$. The sulphur-yellow *hencicosihydrate* was found by A. Scheibe to furnish monoclinic crystals with the axial ratios $a : b : c = 1.7144 : 1 : 1.7282$, and $\beta = 100^\circ 28'$. It loses 18 mols. of water when dried at 175° . The colourless crystals of the *heptacosihydrate* were found by A. Scheibe to be hexagonal crystals with the axial ratio $a : c = 1 : 0.7475$, and to be isomorphous with the potassium salt. O. Pufahl, and C. Friedheim prepared **potassium hexahydroarsenatoctodecamolybdate**, $\text{K}_6\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 23\text{H}_2\text{O}$. F. Kehrman and E. Böhm obtained it by double decomposition between potassium chloride and the ammonium salt. A. Scheibe found the hexagonal crystals have the axial ratio $a : c = 1 : 0.7573$, and are isomorphous with the sodium salt. O. Pufahl made orange-yellow, probably triclinic, crystals of what is probably **rubidium hexahydroarsenatoctodecamolybdate**, $\text{Rb}_6\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$; and similarly, yellow columns and plates of **caesium hexahydroarsenatoctodecamolybdate**, $\text{Cs}_6\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$. O. Pufahl made grass-green crystals of **copper hexahydroarsenatoctodecamolybdate**, $\text{Cu}_2\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$, or $3\text{Cu}(\text{OH})_2 \cdot \text{As}_2\text{O}_5 \cdot 18\text{MoO}_3 \cdot n\text{H}_2\text{O}$, where n is 28 or 38. A. Scheibe gave $a : c = 1 : 1.6355$ for the axial ratio of the hexagonal crystals. O. Pufahl made yellow triclinic crystals of **calcium hexahydroarsenatoctodecamolybdate**, $\text{Ca}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 29\text{H}_2\text{O}$, which A. Scheibe found to have the axial ratios $a : b : c = 0.576 : 1 : 1.0764$, and $\alpha = 95^\circ 12' 40''$, $\beta = 96^\circ 7' 48''$, and $\gamma = 90^\circ 32' 40''$. The sat. aq. soln. had a sp. gr. 2.163 at 18° . The isomorphous crystals of **strontium hexahydroarsenatoctodecamolybdate**, $\text{Sr}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 29\text{H}_2\text{O}$, had the axial ratios $a : b : c = 0.5837 : 1 : 1.074$, and $\alpha = 95^\circ 46' 18''$, $\beta = 96^\circ 3' 56''$, and $\gamma = 89^\circ 48' 20''$. Small impure crystals of **barium hexahydroarsenatoctodecamolybdate**, $\text{Ba}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$, were also prepared. Needle-like, triclinic crystals of **magnesium hexahydroarsenatoctodecamolybdate**, $\text{Mg}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 33\text{H}_2\text{O}$; yellow triclinic crystals of **zinc hexahydroarsenatoctodecamolybdate**, $\text{Zn}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 34\text{H}_2\text{O}$; and the triclinic crystals of **cadmium hexahydroarsenatoctodecamolybdate**, $\text{Cd}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 33\text{H}_2\text{O}$; triclinic needles of **manganese hexahydroarsenatoctodecamolybdate**, $\text{Mn}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 33\text{H}_2\text{O}$; triclinic crystals of **cobalt hexahydroarsenatoctodecamolybdate**, $\text{Co}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 30\text{H}_2\text{O}$; and yellowish-green triclinic crystals of **nickel hexahydroarsenatoctodecamolybdate**, $\text{Ni}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 34\text{H}_2\text{O}$, with $a : b : c = 0.7763 : 1 : 0.6571$, and $\alpha = 90^\circ 29'$, $\beta = 116^\circ 40'$, and $\gamma = 84^\circ 53'$, were prepared by O. Pufahl and examined by A. Scheibe. F. Kehrman also reported **mercurous hexahydroarsenatoctodecamolybdate**, $\text{Hg}'_2\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$; **mercuric hexahydroarsenatoctodecamolybdate**, $\text{Hg}''_2\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$; and **lead hexahydroarsenatoctodecamolybdate**, $\text{Pb}_3\text{H}_6[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot n\text{H}_2\text{O}$. O. Pufahl also made the mercurous salt.

According to O. Pufahl, **silver arsenatoctodecamolybdate**, $\text{Ag}_{12}[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 22\text{H}_2\text{O}$, is produced as a yellowish-white precipitate, when the theoretical amount of silver nitrate is added to a dil. soln. of sodium hexahydroarsenatoenneamolybdate. The amorphous precipitate furnishes microscopic needles in a few days. The salt is sparingly soluble in water, and freely soluble in aq. ammonia and in dil. nitric acid. C. Friedheim regarded it as a double salt, $(3\text{Ag}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 6\text{MoO}_3) \cdot 3(\text{Ag}_2\text{Mo}_4\text{O}_{13})$. O. Pufahl prepared **thallous arsenatoctodecamolybdate**, $\text{Tl}_{12}[(\text{AsO})_2(\text{Mo}_2\text{O}_7)_9] \cdot 6\text{H}_2\text{O}$, by treating the acid with a soln. of thallous nitrate.

The salt is decomposed by water, and it is easily soluble in nitric acid. The salt melts at a dull red-heat.

O. Pufahl reported $7Ag_2O \cdot 2As_2O_5 \cdot 36MoO_3 \cdot 30H_2O$ to be formed by mixing a conc. soln. of hydroarsenatoenemolybdc acid with a hot sat. soln. of nitric acid of sp. gr. 1.3. The orange-yellow precipitate was washed with dil. nitric acid (1 : 10), and dried on a porous tile. The rhombic crystals melt at a red-heat. Their properties are like those of the last-named silver salt, and the salt may be a mixture.

F. L. Sonnenschein prepared the ammonium salt of the unknown *hydroarsenato-dodecamolybdc acid*, $H_7[As(Mo_2O_7)_6] \cdot 4H_2O$. C. Friedheim represented the constitution $AsO(O.MoO_2.O.MoO_2.O.MoO_2.O.MoO_2.OH)_3$. O. Pufahl made **ammonium tetrahydroarsenatododecamolybdate**, $(NH_4)_2H_4[As(Mo_2O_7)_6] \cdot 10H_2O$, by adding ammonium nitrate to a soln. of ammonium molybdate and arsenic acid in nitric acid at $60^\circ-70^\circ$; if the temp. be 100° , as recommended by F. L. Sonnenschein, O. Pufahl found that some molybdc acid is precipitated. It was also made by adding ammonium nitrate to a hot nitric acid soln. of any of the diarsenatoctodecamolybdates. J. H. Debray assigned to the ammonium salt the formula $3(NH_4)_2O \cdot As_2O_5 \cdot 20MoO_3$, but he did not give the analysis. The lemon-yellow powder consists of minute, rhombic dodecahedral crystals. The salt loses 10 mols. of water at 110° , and all is lost at $140^\circ-150^\circ$; the dehydrated salt takes up 12 mols. of water from the air. H. Struve found that when heated in a glass tube, ammonia and arsenic trioxide are volatilized. O. Pufahl said that the salt is decomposed by water especially if boiled; and is freely soluble in aq. ammonia, in hot sulphuric acid, and in boiling arsenic acid. The salt is less soluble in a soln. of molybdc acid; in nitric acid; and a conc. soln. of ammonium nitrate. Aqua regia, said J. H. Debray, transforms it into hydroarsenatotrimolybdc and hydrodiarsenatoctodecamolybdc acids. According to H. Struve, when the salt is treated with zinc and sulphuric acid, arsine is evolved. J. H. Debray prepared **potassium tetrahydroarsenatododecamolybdate**, $K_3H_4[As(Mo_2O_7)_6] \cdot 10H_2O$, but he assigned to it the formula $3K_2O \cdot As_2O_5 \cdot 20MoO_3 \cdot nH_2O$. O. Pufahl's analysis agrees with the tetrahydro-salt, and he obtained it by warming a soln. of $(NH_4)_6Mo_7O_{24}$ with potash-lye until the ammonia is expelled, and then poured the soln. into an excess of nitric acid containing the theoretical amount of arsenic acid. The properties of the canary-yellow salt resemble those of the ammonium salt.

G. Canneri made a series of complex arsenates, some of them with the general formula $R'_6[(V_2O_6)_m(Mo_2O_7)_n] \cdot pH_2O$. A sat. soln. of ammonium molybdatoarsenate in dil. ammonia, when boiled, filtered, and cooled, to separate the excess of the ammonium salt, yields orange-yellow **ammonium vanadatomolybdatoarsenate**, $6(NH_4)_2O \cdot As_2O_5 \cdot 11MoO_3 \cdot 5V_2O_5 \cdot 50H_2O$; and on evaporating the mother-liquor a red powder of $11(NH_4)_2O \cdot As_2O_5 \cdot 25MoO_3 \cdot 4V_2O_5 \cdot 96H_2O$ was obtained; and when sodium vanadate was used, $5(NH_4)_2O \cdot As_2O_5 \cdot 20MoO_3 \cdot 3V_2O_5 \cdot 50H_2O$, was formed. If sodium vanadatomolybdatoarsenate be treated with barium chloride, **barium vanadatomolybdatoarsenate**, $15BaO \cdot As_2O_5 \cdot 26MoO_3 \cdot 3V_2O_5 \cdot 62H_2O$, separates as a white powder; and if the first part of the above ammonium salts be treated with barium nitrate, $7BaO \cdot As_2O_5 \cdot 33MoO_3 \cdot 4V_2O_5 \cdot 34H_2O$ is formed; and with thallium nitrate in place of barium nitrate, yellow **thallium vanadatomolybdatoarsenate**, $3Tl_2O \cdot As_2O_5 \cdot 32MoO_3 \cdot 5V_2O_5 \cdot 45H_2O$, is formed.

A large number of **arsenatotungstates** have been reported, but in some cases the formulæ assigned to them are based on inexact analyses, and are not therefore to be regarded as being definitely established. Representatives of arsenatotungstates with $As_2O_5 : WO_3 = 1 : 3$; $1 : 6$; $1 : 9$; $1 : 14$; $1 : 17$; $1 : 18$; $1 : 21$; $1 : 22$; $1 : 24$, have been reported. J. Lefort⁵ reported **sodium diarsenatotritungstate**, $3Na_2O \cdot As_2O_5 \cdot 3WO_3 \cdot 20H_2O$, to be formed as a white amorphous powder by mixing conc. soln. of the sodium salts with one part of arsenic acid, and 4 parts of tungstic acid. It is easily soluble in water. J. L. Morris and A. G. Macleod recommended the use of arsenatotungstates in the colorimetric determination of urea. O. W. Gibbs treated the alkali dihydroarsenate with the paratungstate or

the normal tungstate, and obtained a white crystalline powder of **ammonium diarsenatohexatungstate**, $4(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 6\text{WO}_3 \cdot 5\text{H}_2\text{O}$. It is freely soluble in hot water, and on evaporating the aq. soln., a white amorphous mass remains which can be crystallized from nitric acid. He also reported **potassium diarsenatohexatungstate**, $3\text{K}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 6\text{WO}_3 \cdot 3\text{H}_2\text{O}$, as a white powder freely soluble in potash-lye.

According to M. Fremery, no diarsenatoenneatungstates are known, but **hydrodiarsenatoenneatungstic acid**, $\text{As}_2\text{O}_5 \cdot 9\text{WO}_3 \cdot 14\text{H}_2\text{O}$, can be obtained by treating barium tungstate with a sulphuric acid soln. of arsenic acid so that the arsenic and tungstic acids are present in the theoretical proportions. It forms golden-yellow six-sided plates. The acid does not effloresce over sulphuric acid, but it loses all its combined water at a dull red-heat, and is then soluble neither in water nor in aq. ammonia. When exposed to air, the crystals acquire a greenish tinge owing to reduction. The acid dissolves freely in water without decomposition, and the aq. soln. sat. at 16° has a sp. gr. 3.279. Ammonia gives a gelatinous precipitate, but an ammoniacal soln. can be obtained by gradually adding ammonia to a soln. heated nearly to the b.p. When heated in hydrogen chloride, arsenic trichloride is formed; the acid soln. is not reduced by potassium iodide or hydrogen sulphide; magnesium salts precipitate ammonium magnesium arsenate from ammoniacal soln. When the attempt is made to prepare salts of this acid, higher tungstates are formed. Alkali nitrates, for example, as well as ammonium, zinc, and copper salts give a complex with the ratio $\text{As}_2\text{O}_5 : \text{WO}_3 = 1:18$; with nickel salts, 1:15; and with cobalt salts, 1:16. Alkali carbonates do not form salts of the acid. F. Kehrman believed that this acid is really a mixture of the diarsenatoctodecatungstic acid with some other acid which has not been closely investigated, and that the two acids can be separated in the form of their potassium salts. The attempt to prepare the ammonium salt yields what has been regarded as *ammonium diarsenatotetradecatungstate*, $7(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 14\text{WO}_3 \cdot 17\text{H}_2\text{O}$, which may be a complex salt, $(\text{NH}_4)_4\text{W}_5\text{O}_{17} \cdot \text{OAs}(\text{ONH}_4)_2(\text{O} \cdot \text{WO}_3 \cdot \text{WO}_3 \cdot \text{NH}_4) \cdot 8 \cdot 5\text{H}_2\text{O}$.

F. Kehrman obtained **lead diarsenatohexadecatungstates**, $\text{Pb}_5(\text{AsW}_8\text{O}_{29})_2$, and $\text{Pb}_3(\text{AsW}_8\text{O}_{28})_2$, as insoluble white precipitates. F. Kehrman prepared **ammonium diarsenatoheptadecatungstate**, $5(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 17\text{WO}_3 \cdot 8\text{H}_2\text{O}$, by dropping a conc. soln. of ammonium carbonate into a soln. of ammonium diarsenatoctodecatungstate until the liquid is colourless. The white crystals which separate are washed with ice-cold water; they can be recrystallized from the aq. soln. at 60° – 90° . The corresponding **potassium diarsenatoheptadodecatungstate**, $5\text{K}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 17\text{WO}_3 \cdot 22\text{H}_2\text{O}$, was obtained in white crystals by a similar process. The salt is very sparingly soluble in cold water, and is converted by dil. acids into the arsenatoenneatungstate. These two salts are said to be isomorphous with the corresponding phosphates.

F. Kehrman, and M. Fremery prepared what the former called **luteoarsenatotungstic acid**. F. Kehrman first represented the composition by $\text{H}_3\text{AsW}_8\text{O}_{28} \cdot 16\text{H}_2\text{O}$, but this was afterwards corrected to $\text{As}_2\text{O}_5 \cdot 18\text{WO}_3 \cdot 42\text{H}_2\text{O}$, that is, **hydrodiarsenatoctodecatungstic acid**, $\text{H}_{10}[\text{As}_2(\text{OH})_2(\text{W}_2\text{O}_7)_9] \cdot 36\text{H}_2\text{O}$. The acid is obtained by boiling the ammonium salt with aqua regia. The yellow six-sided crystals are soluble in water; alkali chlorides gave no precipitation; barium chloride precipitates the barium salt; copper, mercuric, stannous, stannic, and antimonic chlorides, zinc and cadmium sulphates; and silver and lead nitrates give no precipitate; mercurous nitrate and thallos sulphate give a pale yellow precipitate; and quinoline, aniline, paratoluene, and β -naphthylamine also give a precipitate. Mineral acids are without action; alkali-lye decomposes the acid; and carbonates react: $3\text{R}_2\text{CO}_3 + 3\text{R}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 18\text{WO}_3 = \text{R}_2\text{WO}_4 + 3\text{CO}_2 + 5\text{R}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 17\text{WO}_3$. Yellow alkali salts are formed by boiling sodium tungstate with an excess of arsenic acid; by the action of the hydrodiarsenatoenneatungstic acid on nitrates, and of acids on the diarsenatoheptadecatungstates.

F. Kehrman, and M. Fremery prepared *ammonium luteoarsenatotungstate*, or **ammonium diarsenatoctodecatungstate**, $3(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 18\text{WO}_3 \cdot 14$ or $18\text{H}_2\text{O}$,

that is, $(\text{NH}_4)_6\text{H}_2[\text{As}_2(\text{OH})_2(\text{W}_2\text{O}_7)_9]\cdot 11$ or $15\text{H}_2\text{O}$. M. Fremery made it by boiling sodium tungstate with an excess of arsenic acid; and by adding ammonium nitrate to a soln. of hydrodiarsenatoennecatungstic acid. F. Kehrman employed a modification of the former process. The yellow or yellowish-green crystals are said by C. C. Stuhlmann to be isomorphous with those of the potassium salt, and of the corresponding phosphatotungstate. M. Fremery, and F. Kehrman also prepared **potassium tetrahydrodiarsenatoctodecatungstate**, $\text{K}_6\text{H}_4[\text{As}_2(\text{OH})_2(\text{W}_2\text{O}_7)_9]\cdot 11\text{H}_2\text{O}$, in citron yellow, triclinic crystals which effloresce rapidly in air. F. Kehrman said that the yellow salt obtained by J. Lefort by boiling a soln. of arsenic acid with 4 parts of sodium tungstate is **sodium tetrahydrodiarsenatoctodecatungstate**, $\text{Na}_6\text{H}_4[\text{As}_2(\text{OH})_2(\text{W}_2\text{O}_7)_9]\cdot n\text{H}_2\text{O}$; it is easily soluble in water and alcohol. M. Fremery, and F. Kehrman likewise prepared **copper tetrahydrodiarsenatoctodecatungstate**, $\text{Cu}_3\text{H}_4[\text{As}_2(\text{OH})_2(\text{W}_2\text{O}_7)_9]\cdot 27\text{H}_2\text{O}$. M. Fremery obtained a brown precipitate of unknown composition by treating a soln. of arsenatotungstic acid with silver nitrate; and O. W. Gibbs obtained a complex salt approximating $6\text{Ag}_2\text{O}\cdot\text{As}_2\text{O}_5\cdot 16\text{W}_2\text{O}_7\cdot 11\text{H}_2\text{O}$, which F. Kehrman supposed to be a salt of luteoarsenatotungstic acid, or **silver diarsenatoctodecatungstate**. F. Kehrman could not prepare **zinc and cadmium diarsenatoctodecatungstates** by precipitation. M. Fremery obtained the zinc salt. F. Kehrman prepared yellow crystals of **mercurous diarsenatoctodecatungstate**, $3\text{Hg}_2\text{O}\cdot\text{As}_2\text{O}_5\cdot 18\text{W}_2\text{O}_7\cdot n\text{H}_2\text{O}$, fairly soluble in water; and of **mercuric diarsenatoctodecatungstate**, $3\text{HgO}\cdot\text{As}_2\text{O}_5\cdot 18\text{W}_2\text{O}_7\cdot n\text{H}_2\text{O}$, soluble in water. F. Kehrman also made pale yellow **thallous diarsenatoctodecatungstate**. M. Fremery reported red, monoclinic crystals of what was probably **cobalt diarsenatoctodecatungstate**, although he represented it by the formula $3\text{CoO}\cdot\text{As}_2\text{O}_5\cdot 16\text{W}_2\text{O}_7\cdot 22\text{H}_2\text{O}$; likewise also with the rhombic crystals of **nickel diarsenatoctodecatungstate**, which he represented by $2\text{NiO}\cdot\text{As}_2\text{O}_5\cdot 15\text{W}_2\text{O}_7\cdot 31\text{H}_2\text{O}$. F. Kehrman could not obtain **stannous, stannic, and antimonic diarsenatoctodecatungstates** by precipitation. He found that **lead diarsenatoctodecatungstate** is not formed by precipitation of a salt of lead by the acid. The soln., however, soon decomposes with the separation of a white powder.

F. Kehrman reported **ammonium diarsenatohecticatungstate**, $3(\text{NH}_4)_2\text{O}\cdot\text{As}_2\text{O}_5\cdot 21\text{W}_2\text{O}_7\cdot n\text{H}_2\text{O}$, to be formed by adding a 5 per cent. soln. of ammonium carbonate to 20 grms. of ammonium diarsenatotetracositungstate suspended in 100 c.c. of water, until the precipitate is almost all dissolved. The soln. is acidified with hydrochloric acid, filtered, and treated with ammonium chloride. The white crystalline precipitate is easily soluble in water. It has been analyzed, but not otherwise investigated. According to F. Kehrman, when ammonium diarsenatotetracositungstate is treated with a hot soln. of ammonium carbonate as just indicated, then treated with 5 grms. of dihydrated barium chloride, filtered while hot, and cooled, white, octahedral crystals of **barium arsenatohecticatungstate**, $7\text{BaO}\cdot\text{As}_2\text{O}_5\cdot 22\text{W}_2\text{O}_7\cdot 24\text{H}_2\text{O}$, are formed. They are purified by dissolving in hot water, and salting out with barium chloride. F. Kehrman reported **ammonium diarsenatotetracositungstate**, $3(\text{NH}_4)_2\text{O}\cdot\text{As}_2\text{O}_5\cdot 24\text{W}_2\text{O}_7\cdot 12\text{H}_2\text{O}$, to be formed when a conc. soln. of 8 mols of sodium tungstate is mixed at ordinary temp. with a mol of arsenic acid, and dil. hydrochloric acid added drop by drop with constant stirring. When the liquid is strongly acid, the cold liquid is mixed with solid ammonium chloride and slowly heated to boiling. The precipitate is washed by decantation with a soln. of ammonium chloride acidified with hydrochloric acid. The white, microcrystalline powder is analogous to the corresponding phosphatotungstate.

O. W. Gibbs found that potassium and ammonium arsenates react with a soln. of the arsenitotungstates with the precipitation of crystalline **ammonium arsenitoarsenatotungstate** and potassium arsenitoarsenatotungstate, $10\text{K}_2\text{O}\cdot\text{As}_2\text{O}_3\cdot 4\text{As}_2\text{O}_5\cdot 21\text{W}_2\text{O}_7\cdot 26\text{H}_2\text{O}$, respectively. He also obtained **mercurous arsenitoarsenatotungstate** by adding mercurous nitrate to a soln. of the potassium salt.

G. Canneri prepared some complex arsenatovanadates by the methods indicated in connection with the corresponding molybdatosalts (*q.v.*). Thus, **ammonium**

arsenovanadatotungstate, $18(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 21\text{WO}_3 \cdot 4\text{V}_2\text{O}_5 \cdot 13\text{H}_2\text{O}$, **barium arsenovanadatotungstate**, $6\text{BaO} \cdot \text{As}_2\text{O}_5 \cdot 17\text{WO}_3 \cdot 5 \cdot 5\text{V}_2\text{O}_5 \cdot 40\text{H}_2\text{O}$, and **thallium arsenovanadatotungstate**, $6\text{Tl}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 21\text{WO}_3 \cdot 5\text{V}_2\text{O}_5 \cdot 15\text{H}_2\text{O}$, were obtained, and he concluded that the arsenovanadatotungstates are members of three limiting series represented, respectively, by the compounds (1) $(\text{NH}_4)_6\text{H}[\text{As}(\text{W}_2\text{O}_7)_4(\text{V}_2\text{O}_6)_2] \cdot n\text{H}_2\text{O}$, (2) $(\text{NH}_4)_6\text{H}[\text{As}(\text{W}_2\text{O}_7)_3(\text{V}_2\text{O}_6)_3] \cdot 25\text{H}_2\text{O}$, (3) $(\text{NH}_4)_6\text{H}[\text{As}(\text{W}_2\text{O}_7)_2(\text{V}_2\text{O}_6)_4] \cdot 25\text{H}_2\text{O}$. The colour of these compounds increases in intensity with increasing number of V_2O_6 groups in the complex anion. He did not find the reproducibility of the salt satisfactory when prepared by crystallization, at constant temp., of soln., of various amounts of ammonium tungstate in soln. containing a given ratio of $\text{As}_2\text{O}_5 : \text{NH}_4\text{VO}_3$. The differing compositions of the complexes obtained from soln. containing the ratio $\text{As}_2\text{O}_5 : \text{NH}_4\text{VO}_3 = 3 : 2$ suggest that they are members of a series of mixed crystals of salts of the type (1). From soln. in which the ratio $\text{As}_2\text{O}_5 : \text{NH}_4\text{VO}_3$ was, respectively, 3 : 4 and 1 : 2, salts were obtained approximating in composition to type (2) in the former case, and to both types (2) and (3) in the latter.

C. F. Rammelsberg⁶ found that **uranous arsenate**, $\text{U}_3(\text{AsO}_4)_4$, is precipitated by ammonia from a soln. of the hydroarsenate in hydrochloric acid. It appears as a green precipitate; **uranous hydroarsenate**, $\text{U}(\text{HASO}_4)_2 \cdot 3\text{H}_2\text{O}$, is precipitated by adding sodium hydroarsenate to a soln. of uranium tetrachloride. When heated to redness, arsenic trioxide is evolved, and a little uranium trioxide is formed. It is decomposed by potash-lye, and is soluble in hydrochloric acid. J. Aloy and G. Auber also prepared this arsenate by double decomposition.

A mineral obtained by A. Weisbach from the uranium minerals at the Weisser Hirsh mine, near Schneeberg, Saxony, and named **trögerite**—after R. Tröger—was analyzed by C. Winkler, and found to be hydrated **uranyl orthoarsenate**, $(\text{UO}_2)_3(\text{AsO}_4)_2 \cdot 12\text{H}_2\text{O}$. According to A. Schrauf, it occurs in thin, tabular, monoclinic, lemon-yellow crystals, resembling those of gypsum, and with $a : b : c = 0.71 : 1 : 0.42$, and $\beta = 100^\circ$ nearly, but V. Goldschmidt showed that the crystals are tetragonal with the axial ratio $a : c = 1 : 2.16$. The (010)-cleavage is perfect. According to C. Winkler, the water of crystallization can be expelled by heating without changing the crystalline form. H. Morton and H. C. Bolton found that the absorption spectrum of soln. of uranyl arsenate show bands at $\lambda = 4970, 4820, 4670, 4570, 4370, 4240, \text{ and } 4110$. E. S. Larsen found the indices of refraction of one variety to be $\alpha = 1.585, \beta = 1.630, \text{ and } \gamma = 1.630$, and of another variety $\epsilon = 1.580, \text{ and } \omega = 1.624$. The optical character is negative. When the calcined mineral is moistened with water, it breaks up into shining scales. F. Bordas observed that helium is given off by the mineral at a temp. above 250° .

According to G. Werther, when a soln. of uranyl acetate is treated with sodium hydroarsenate, or arsenic acid, pale yellow, pulverulent **uranyl hydroarsenate**, $(\text{UO}_2)\text{HASO}_4 \cdot 4\text{H}_2\text{O}$, is formed. It loses its water of crystallization at 120° ; and it is insoluble in acetic acid. G. Werther also obtained **uranyl dihydroarsenate**, $(\text{UO}_2)(\text{H}_2\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$, in small, yellow crystals, by evaporating an excess of arsenic acid with uranyl oxide, nitrate, or acetate. The salt loses its water of crystallization at 150° . R. E. O. Puller, and G. Werther said that if uranyl hydroarsenate, or ammonium uranyl arsenate be calcined, pale yellow **uranyl pyroarsenate**, $(\text{UO}_2)_2\text{As}_2\text{O}_7$, is formed. To prevent reduction to a greenish compound, the calcination can be conducted in oxygen, or the mass can be moistened with nitric acid and recalced.

R. E. O. Puller prepared **ammonium uranyl arsenate**, $\text{NH}_4(\text{UO}_2)\text{AsO}_4 \cdot n\text{H}_2\text{O}$, by adding uranyl acetate to a neutral or acetic acid soln. of an arsenate mixed with ammonia or an ammonium salt. The slimy precipitate becomes granular when boiled. The compound is insoluble in water, acetic acid, or aq. ammonia. It is soluble in the mineral acids. Pale yellow **sodium uranyl arsenate**, $\text{Na}(\text{UO}_2)\text{AsO}_4 \cdot 2.5\text{H}_2\text{O}$, is precipitated when sodium orthoarsenate in excess is added to a soln. of uranyl nitrate. C. Winkler prepared **copper uranyl arsenate**,

$\text{Cu}(\text{UO}_2)_2(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$, by mixing a soln. of freshly precipitated copper carbonate in an excess of arsenic acid, with a soln. of uranyl nitrate. In a short time, green, tabular crystals appear. The action is accelerated by warming the soln., but the crystals are then smaller. G. Werther also obtained this salt by boiling a soln. of uranyl arsenate with basic copper acetate. The water of crystallization is expelled by heat. A. G. Bergman measured the vap. press.

FIG. 32.—Vapour Pressure Curve of $\text{Cu}(\text{UO}_2)_2(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$.

of the octohydrate, and the results are summarized in Fig. 32. This salt occurs in grass-green or emerald-green crystals among the uranium minerals of the Weisser Hirsch mine, Schneeberg, and at Zinnwald, Saxony; near Joachimsthal; and at Wheal Gorland, Cornwall. A. Weisbach called the mineral **zeunerite**—after G. Zeuner. It has also been called *copper-uranite*, and *copper uranio-mica*. The mineral was analyzed by C. Winkler. The crystals were examined by G. C. Laube, B. Jezek, and V. Goldschmidt; A. Weisbach said that they belong to the tetragonal system, and have the axial ratio $a : c = 1 : 2.9125$. The (001)-cleavage is perfect, and that on the (100)-face is distinct. The hardness is 2.0–2.5; and the sp. gr. 3.2. E. S. Larsen gave for the indices of refraction $\omega = 1.635$ – 1.643 , and $\epsilon = 1.623$ – 1.651 . The optical character is negative. The mineral is soluble in nitric acid. The mineral, called by A. Weisbach **uranospinite**, occurs in siskin-green crystals among the uranium minerals at Neustädte, Saxony. The analysis by C. Winkler corresponds with **calcium uranyl arsenate**, $(\text{UO}_2)_2\text{Ca}(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$, the arsenic analogue of autumite. A. H. Church said that the mineral may be decahydrated. C. Winkler synthesized the mineral by mixing uranyl nitrate with a soln. of lime in an excess of arsenic acid. The thin tabular crystals were found by A. Weisbach to be rhombic, and to have the axial ratios $a : b : c = 1 : 1 : 2.9136$ approximately. V. Goldschmidt said that the crystals are anomalous being really tetragonal; according to A. Weisbach, the mineral is biaxial, but V. Goldschmidt said the artificial mineral is uniaxial. The (001)-cleavage is perfect. The hardness is 2–3, and the sp. gr. 3.45. E. S. Larsen found the optic axial angle of the rhombic variety to be $2V = 46^\circ$; the indices of refraction $\alpha = 1.560$, $\beta = 1.582$, and $\gamma = 1.587$; and the optical character negative; while for the tetragonal variety, $\omega = 1.586$, and $\epsilon = 1.56$. Another uranium mineral found in the Weisser Hirsch mine at Neustädte, Saxony, was named *Walpurgin* by A. Weisbach. This name has been altered to **walpurgitite**. Its analysis by C. Winkler corresponds with **bismuth uranyl arsenate**, $5\text{Bi}_2\text{O}_3 \cdot 3\text{UO}_3 \cdot 2\text{As}_2\text{O}_5 \cdot 12\text{H}_2\text{O}$; C. F. Rammelsberg wrote this $(\text{UO}_2)_3(\text{AsO}_4)_2 \cdot 2\text{BiAsO}_4 \cdot 8\text{Bi}(\text{OH})_3$; and P. Groth, $\text{Bi}_{10}(\text{UO}_2)_3\text{As}_4\text{O}_{28} \cdot 10\text{H}_2\text{O}$. The mineral occurs in thin scale-like crystals resembling gypsum; the colour is orange-yellow. The crystals were considered by A. Weisbach, and A. Schrauf to belong to the triclinic system. The hardness is 3.5, and the sp. gr. 5.64–5.8. E. S. Larsen found the indices of refraction to be $\alpha = 1.90$, $\beta = 2.00$, and $\gamma = 2.05$; the optic axial angle $2V = 52^\circ$; and the optical character negative. When calcined, the mineral becomes brown, and, on cooling, dark orange-yellow.

§ 23. The Arsenates of the Manganese and Iron Families

Manganous salts, said C. H. Pfaff,¹ are not precipitated by sodium dihydroarsenate. The Grasselli Chemical Co. prepared manganese arsenate heating a mixture of arsenic trioxide and water with a manganese oxide higher than the monoxide. A. Coloriano prepared chestnut-brown needles of **manganese orthoarsenate**, $Mn_3(AsO_4)_2 \cdot H_2O$, by heating sodium orthoarsenate with an excess of manganese sulphate in a sealed tube at 175°. C. W. Scheele treated a manganese salt with alkali hydroarsenate and obtained a white, gelatinous precipitate, which, according to J. H. Debray, becomes crystalline when digested for a long time in the mother-liquor. H. Rose said that the precipitate is a mixture of normal manganese orthoarsenate, and **manganese hydroarsenate**, $MnHASO_4 \cdot H_2O$. By the successive addition of ammonium sulphate, acetic acid, and sodium arsenate to a soln. of a manganous salt, E. O. Kraemer, H. B. Weiser, E. Deiss, and G. Klemp and J. von Gyulay obtained **colloidal manganese arsenate** as an opalescent jelly which slowly crystallized. H. B. Weiser and A. P. Bloxson prepared the hydrogel of **manganese arsenate** by the method used for the zinc salt. F. Flade and co-workers found that glycerol retards the crystallization; and by means of photographs demonstrated the fibrous structure of the gel, and the change of structure which accompanies ageing. A. Coloriano prepared the hydroarsenate, as a white crystalline powder, by treating manganese carbonate with not too much of a soln. of arsenic acid; or by boiling the mixture. M. Amadori partially studied the conditions of equilibrium of the system $MnO-As_2O_5-H_2O$ at 25°, and his results are summarized

in Fig. 33. The *monohydrate* of the hydroarsenate, $\text{MnHAsO}_4 \cdot \text{H}_2\text{O}$, was obtained from soln. containing $\text{Mn} : \text{As}_2\text{O}_5$ in the ratio 3 : 1 ; or by precipitation by alcohol from a soln. of manganese carbonate in a sat. soln. of arsenic acid. The salt is stable in water at 25°. The monohydrate lost its water of hydration at 140°. According to C. W. Scheele, the hydroarsenate loses its combined water and forms the pyroarsenate when calcined ; and, according to C. Lefèvre, it loses all its arsenic when calcined for a long time at bright redness ; when heated in a current of

FIG. 33.—Equilibrium Conditions in the System: $\text{MnO}-\text{As}_2\text{O}_5-\text{H}_2\text{O}$ at 25°.

hydrogen or carbon monoxide, the arsenic volatilizes and manganese oxide remains ; and, according to H. Rose, if heated with sulphur in a current of hydrogen, arsenic volatilizes, and manganese sulphide remains. The salt is insoluble in cold water at ordinary temp.—M. Amadori said that 0.013 grm. is dissolved per 100 c.c. of water—and when treated with hot water, it forms manganic arsenate. J. F. John said that it is soluble in arsenic acid. Boiling potash-lye does not extract all the arsenic. It is soluble in arsenic acid, and in the common mineral acids. F. C. B. Schiefer reported that

manganese dihydroarsenate, $\text{Mn}(\text{H}_2\text{AsO}_4)_2$, crys-

tallizes from a soln. of manganese carbonate in the theoretical quantity of arsenic acid. The rectangular plates deliquesce in air. M. Amadori found the *monohydrate*, $\text{Mn}(\text{H}_2\text{AsO}_4)_2 \cdot \text{H}_2\text{O}$, is deposited in microscopic, rose-red crystals from soln. containing an excess of arsenic acid. It is readily hydrolyzed by water, and is stable only in an excess of arsenic acid. Microcrystals of the acidic salt, **manganese heptahydrotriarsenate**, $\text{Mn}(\text{H}_2\text{AsO}_4)_2 \cdot \text{H}_3\text{AsO}_4$, are obtained from soln. containing a large excess of arsenic acid, are readily hydrolyzed by water, and are stable only in the presence of an excess of arsenic acid.

Some basic arsenates occur in nature. Almost simultaneously L. J. Igelström reported a basic arsenate from the Sjömine, Orebro, Sweden, which he called *polyarsenite*, and A. Sjögren one from Pajsberg, Sweden, which he called **sarkinite**—from $\sigma\alpha\rho\kappa\nu\sigma$, made of flesh—in allusion to the blood-red colour and greasy lustre of the mineral. G. Flink and A. Hamburg proved that the two minerals are of the same species. The analyses reported by L. J. Igelström, and A. Sjögren correspond with $(\text{MnO})_4\text{As}_2\text{O}_5 \cdot \text{H}_2\text{O}$, while G. Flink and A. Hamburg represent it as a **manganese hydroxyarsenate**, $\text{Mn}=\text{O}_2=\text{AsO}-\text{O}-\text{MnOH}$ —*vide* adamite. It can also be represented as *manganyl hydroarsenite*, $(\text{MnO})_2\text{HAsO}_3$. According to G. Flink and A. Hamburg, the crystals are monoclinic with the axial ratios $a : b : c = 2.0017 : 1 : 1.5154$, and $\beta = 62^\circ 13\frac{1}{2}'$. The prismatic cleavage is distinct. The optical axial angle $2E = c. 83^\circ$; the pleochroism is very feeble; the optical character is negative; and the birefringence strong. G. Flink gave $2E = 99^\circ 45'$ for light of wave-length $535\mu\mu$; $108^\circ 45'$ for $589\mu\mu$; and $113^\circ 30'$ for $671\mu\mu$; the indices of refraction are $\alpha = 1.8085$; $\beta = 1.8065$; and $\gamma = 1.7930$; E. S. Larsen gave $\alpha = 1.780$, $\beta = 1.795$, and $\gamma = 1.802$. The hardness is 4 to 5; and the sp. gr. 4.17 to 4.19. G. Flink gave 4.178 at 15°. The mineral is easily soluble in nitric and hydrochloric acids. L. J. Igelström described a yellow or reddish-yellow mineral from Pajsberg, Sweden, which resembled chondrodite in many respects, but contained an arsenate; he called it *chondrarsenite*. The analysis and general properties were found by H. Sjögren to be so like those of sarkinite that he thought it probable that chondrarsenite is more or less weathered sarkinite. L. J. Igelström described a sulphur-yellow mineral occurring in masses or grains near chondrarsenite. He called it **xanthoarsenite**—from $\xi\alpha\nu\theta\omicron\varsigma$, yellow—in allusion to the colour. The analysis approximates $5(\text{Mn}, \text{Fe}, \text{Mg}, \text{Ca})\text{O} \cdot \text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$; W. C. Brögger favoured $(\text{Mn}, \text{Fe}, \text{Mg}, \text{Ca})_5(\text{OH})_4(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$, by analogy with cornwallite, $\text{Cu}(\text{OH})_4(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$; and P. Groth favoured $(\text{Mn}, \text{Mg}, \text{Fe}, \text{Ca})(\text{AsO}_4)_2(\text{MnOH})_4 \cdot 2\text{H}_2\text{O}$ —in the

idealized case this corresponds with **manganese tetrahydroxydiarsenate**, $(\text{MnOH})_2 : \text{AsO}_4 \cdot \text{Mn} \cdot \text{AsO}_4 : (\text{MnOH})_2 \cdot 2\text{H}_2\text{O}$. The crystals were found by E. Bertrand to be optically biaxial. L. J. Igelström reported a brownish-red, or garnet-red mineral occurring with the manganese minerals at Nordmark, Sweden. He called it *aimafibrite*, and it is now called *hemafibrite* or *hæmafibrite*—from *αἷμα*, blood, and *fibra*, fibre—in allusion to the blood-red colour, and the fibrous structure. Analyses reported by A. Sjögren, H. Sjögren, and L. J. Igelström agree with the formula $\text{Mn}_3\text{As}_2\text{H}_{10}\text{O}_{16}$, or, according to H. Sjögren, with $\text{Mn}_3(\text{AsO}_4)_2 \cdot 3\text{MnO} \cdot 5\text{H}_2\text{O}$, because the water is easily expelled by heat. P. Groth regarded it as **manganese trihydroxyarsenate**, $(\text{MnOH})_3\text{AsO}_4 \cdot \text{H}_2\text{O}$. The prismatic crystals are commonly aggregated into spherical radiating groups with a fibrous structure. H. Sjögren said that the crystals are rhombic, with the axial ratios $a : b : c = 0.5261 : 1 : 1.1510$; the (010)-cleavage is distinct, the (110)-cleavage less so. E. Bertrand found that the optic axial angle $2E = c. 70^\circ$; the optical character is negative. According to A. Sjögren, the hardness is about 3; and the sp. gr. 3.50–3.65. E. S. Larsen gave for the indices of refraction $\alpha = 1.87$, $\beta = 1.88$, and $\gamma = 1.93$. The mineral becomes black or brownish-black when exposed to air, it readily fuses; and dissolves in hydrochloric acid. The brownish-red mineral, found by A. Sjögren along with the manganese arsenates at Nordmark, Sweden, was named *allaktite*, or **allactite**—from *ἀλλάττειν*, to change—in allusion to its strong pleochroism. The analyses reported by A. and H. Sjögren correspond with $\text{Mn}_3\text{O}_6(\text{AsO})_2 \cdot 4\text{Mn}(\text{OH})_2$, which they represented $3\text{MnO} \cdot \text{As}_2\text{O}_5 \cdot 4\text{MnO} \cdot 4\text{H}_2\text{O}$. It can be regarded as **manganese octohydroxydiarsenate**, $(\text{HO})(\text{MnOH})_3\text{As} \cdot \text{O} \cdot \text{Mn} \cdot \text{O} \cdot \text{As}(\text{O} \cdot \text{MnOH})_3(\text{OH})$. G. Aminoff emphasized its relationship to pharmacolite. The water is expelled only at dull redness. The small, prismatic or tabular crystals were found by H. Sjögren to belong to the monoclinic system, and to have the axial ratios $a : b : c = 0.61278 : 1 : 0.33385$, and $\beta = 84^\circ 16\frac{3}{4}'$. G. Aminoff gave $0.8206 : 1 : 0.4508$, and $\beta = 95^\circ 37'$. J. A. Krenner gave for the optic axial angles $2H_a = 12^\circ 22'$ for red light, $9^\circ 2'$ for yellow light, 0° for green light, and $11^\circ 36'$ for blue light; while $2V_a = 10^\circ 12'$ for red light, and $7^\circ 34'$ for yellow light. H. Sjögren found the optical character is negative, and the index of refraction $\beta = 1.778$ for red light, 1.786 for yellow light, and 1.795 for violet light. G. Aminoff gave $\alpha = 1.75$; $\beta = 1.779$; and $\gamma = 1.78$; and E. S. Larsen, $\alpha = 1.761$; $\beta = 1.786$; and $\gamma = 1.787$. The birefringence is strong. The (101)-cleavage is distinct, and the (100)-cleavage less so. J. A. Kenner, and C. F. Rammelsberg said that there is no physical or chemical support for H. Sjögren's suggestion that this mineral is isomorphous with vivianite. The hardness is 4.5, and the sp. gr. 3.83–3.85. Allactite is easily soluble in hydrochloric acid, and less soluble in sulphuric and nitric acids.

As indicated above, if manganese hydroarsenate be heated to redness, **manganese pyroarsenate**, $\text{Mn}_2\text{As}_2\text{O}_7$, is formed; and as F. J. Otto showed, the same result is obtained when ammonium manganese arsenate is similarly treated. C. Lefèvre found that the pyroarsenate is produced when manganese oxide or carbonate is dissolved in molten potassium dihydroarsenate. If over 8 or 9 per cent. of manganese oxide be added, potassium manganese arsenate is formed. The colourless, tabular crystals were found by H. Stallo to have a sp. gr. 3.683–3.693 at 23° ; he obtained 3.662 at 25° . The salt melts to a dark red glass. Cold water is without action on the salt, but it is decomposed by hot water. A. Coloriano reported the formation of monoclinic or triclinic prismatic crystals of the *dihydrate* of **manganese tetrarsenate**, $\text{Mn}_5\text{As}_4\text{O}_{15} \cdot 2\text{H}_2\text{O}$, or $\text{Mn}_5\text{H}_2(\text{AsO}_4)_4 \cdot \text{H}_2\text{O}$, by heating a gram of manganic arsenate with 24 c.c. of water in a sealed tube at 150° ; if the heating be continued for a longer time, monoclinic prisms of the *pentahydrate* are formed. M. Amadori could not confirm the existence of this salt.

O. T. Christensen prepared **manganic arsenate**, $\text{MnAsO}_4 \cdot \text{H}_2\text{O}$, as a dark grey powder, by decomposing the acetate with phosphoric acid, or, more conveniently, by adding a conc. soln. of manganese nitrate to a hot aq. soln. of arsenic acid. It forms the pyroarsenate when heated to redness. It is insoluble in nitric acid,

but is slowly dissolved by hydrochloric acid; and is decomposed by alkalis and ammonium sulphide. E. Deiss obtained a similar compound in rose-red crystals by evaporating a soln. of manganic acetate in a cold, conc. soln. of arsenic acid; and by the action of potassium permanganate on manganous dihydroarsenate, and arsenic acid: $\text{KMnO}_4 + 4\text{Mn}(\text{H}_2\text{AsO}_4)_2 + 8\text{H}_3\text{AsO}_4 = \text{KH}_2\text{AsO}_4 + 4\text{H}_2\text{O} + 5\text{H}_6[\text{Mn}(\text{AsO}_4)_3]$. He showed that the crystallized salt is **triarsenomanganic acid**, $\text{H}_6[\text{Mn}(\text{AsO}_4)_3] \cdot 3\text{H}_2\text{O}$, which forms a stable, violet-red, crystalline powder; it can be recrystallized from acetic acid soln. The violet-coloured soln. observed by L. C. A. Barreswil to be formed when a soln. of a manganese salt containing arsenate or phosphate is oxidized, was shown to contain, in the former case, triarsenomanganic acid. When triarsenomanganic acid is rapidly heated over a bunsen burner, the compound is decomposed, but not so readily if the sample be first dried in vacuo over sulphuric acid. A conc. soln. of arsenic acid dissolves a little of the acid, forming a violet soln., and when warmed or diluted with water, it deposits O. T. Christensen's salt, $\text{MnAsO}_4 \cdot \text{H}_2\text{O}$. When the crystals are treated for a long time with water, manganic arsenate, soluble in nitric acid, is formed: $\text{H}_6[\text{Mn}(\text{AsO}_4)_3] = \text{MnAsO}_4 + 2\text{H}_3\text{AsO}_4$. Alcohol slowly decomposes triarsenomanganic acid; acetic acid has no action, but an aq. soln. decomposes it with the liberation of arsenic acid; conc. hydrochloric acid of sp. gr. 1.12, dissolves it quickly with decomposition, the dil. acid acts more slowly; phosphoric acid of sp. gr. 1.7 dissolves it, forming a bluish-violet soln.; conc. sulphuric acid gives a bluish-violet soln., dil. sulphuric acid acts slowly, forming an olive-green soln.; fuming nitric acid of sp. gr. 1.52 has no perceptible action, but ordinary nitric acid becomes yellow, and a small quantity of arsenic acid passes into soln.; dil. nitric acid of sp. gr. 1.2–1.3 acts like dil. sulphuric acid; a 30 per cent. soln. of perchloric acid forms a green liquid.

A. Hamberg described a greenish-brown mineral from the Harstig mine, Pajsberg, Sweden, which he named **flinkite**—after G. Flink. Its composition corresponds with $4\text{MnO} \cdot \text{Mn}_2\text{O}_3 \cdot \text{AsO}_5 \cdot 4\text{H}_2\text{O}$, and this can be represented graphically as a **manganese tetrahydroxydimanganiansenate**, $(\text{HO})_2\text{Mn}-\text{O}-\text{AsO}=(\text{O} \cdot \text{MnOH})_2$, where the tervalent manganese can be partly replaced by tervalent iron or aluminium, and the bivalent manganese by calcium or magnesium. Flinkite occurs in minute tabular crystals, or in groups of feather-like aggregates. The rhombic crystals have the axial ratios $a : b : c = 0.41306 : 1 : 0.73862$. The optic axial angle is large; and the optical character positive. E. S. Larsen gave for the indices of refraction $\alpha = 1.783$, $\beta = 1.801$, and $\gamma = 1.834$; the pleochroism shows: α , pale brownish-green; β , yellowish-green; and γ , orange-brown. A. Hamburg gave orange-brown for a , yellowish to brownish-green for b , and yellowish-green for c . The hardness is 4.0–4.5, and the sp. gr. 3.87. Flinkite is not far removed from the mineral **synadelphite**—from $\sigma\upsilon\nu$, with; $\acute{\alpha}\delta\epsilon\lambda\phi\acute{\omicron}\varsigma$, brother—so-named because of its close relation with other species. Synadelphite occurs at the Moss mine, Nordmark, Sweden. It was described by H. Sjögren. The analyses approximate $(\text{Al}, \text{Fe}, \text{Mn})_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 5(\text{Ca}, \text{Mg}, \text{Mn})(\text{OH})_2$, and the idealized mineral with $\text{Mn}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 5\text{Mn}(\text{OH})_2$, that is, **manganese decahydroxydimanganidiarsenate**, $(\text{MnOH}) \cdot \text{O} \cdot \text{Mn}(\text{OH}) \cdot \text{O} \cdot \text{Mn} \cdot \{ \text{O} \cdot \text{As}(\text{OH})_2(\text{O} \cdot \text{MnOH})_2 \}_2$. The black or brownish-black prismatic crystals are monoclinic with the axial ratios $a : b : c = 0.8582 : 1 : 0.9192$, and $\beta = 90^\circ$. The crystals are feebly pleochroic; the optic axial angle is small; the optical character is positive; the hardness is 4.5; and the sp. gr. 3.45–3.50. E. S. Larsen gave for the indices of refraction $\alpha = 1.86$, $\beta = 1.87$, and $\gamma = 1.90$. The mineral is fusible; and it dissolves readily in acids, giving off chlorine with hydrochloric acid. L. J. Igelström described a brownish-red or garnet-red mineral from Nordmark, Sweden, which he called *amatolite*, that is, *hematolite*, or **hæmatolite**—from $\acute{\alpha}\mu\alpha$, blood—in allusion to the colour. A little later, H. Sjögren described what was apparently the same mineral as *diadelphite*—from $\delta\iota\varsigma$, twice, and $\acute{\alpha}\delta\epsilon\lambda\phi\acute{\omicron}\varsigma$, brother—in allusion to its relationship with allactite. L. J. Igelström's analysis corresponds with $2(3\text{MnO} \cdot \text{As}_2\text{O}_3) \cdot 8\text{MnO}(\text{OH}) \cdot 6\text{H}_2\text{O}$; and H. Sjögren's analysis,

with $(\text{Al,Fe,Mn})_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 8\text{Mn}(\text{OH})_2$, or, in the idealized case, with $\text{Mn}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 8\text{Mn}(\text{OH})_2$, *i.e.* **manganese hexahydroxymanganiarsenate**, $(\text{HO})_2\text{Mn} \cdot \text{O} \cdot \text{As}(\text{O} \cdot \text{MnOH})_4 \cdot \text{H}_2\text{O}$. H. Sjögren found that the trigonal crystals have the rhombohedral habit, and the axial ratio $a : c = 1 : 0.8885$. E. Bertrand, and J. Lorenzen referred the crystals to the monoclinic system. According to H. Sjögren, the (0001)-cleavage is perfect; the optic axial angle is small; the optical character is negative; optical anomalies are sometimes very marked; the refractive indices are $\omega = 1.723$, and $\epsilon = 1.740$. E. S. Larsen gave $\omega = 1.733$, and $\epsilon = 1.714$. The hardness is 3.5; and the sp. gr. 3.30–3.40. The mineral is freely soluble in acids. W. F. Foshag and co-workers found what they called **chlorophoenicite** at Franklin Furnace, New Jersey. The mineral is pale green by daylight, purplish-red in artificial light; and in general appearance it resembles willemite. The composition is $\text{R}_3(\text{AsO}_4)_2 \cdot 7\text{R}(\text{OH})_2$, *i.e.* $10\text{RO} \cdot \text{As}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, where R denotes bivalent Mn, Zn, Ca, Mg, and Fe, corresponding with **zinc manganese tetradecahydroxyarsenate**. The monoclinic crystals have the indices of refraction $\alpha = 1.682$, $\beta = 1.690$, and $\gamma = 1.697$; and the axial ratios $a : b : c = 2.357 : 1 : 2.153$, and $\beta = 105^\circ 34'$. The cleavage is parallel to the front pinacoid (100). The sp. gr. is 3.55, and the hardness 3.0–3.5. C. Palache and E. V. Shannon obtained a pink mineral which they called **holdenite**—after A. F. Holden. The rhombic crystals from Franklin, New Jersey, approximate $12\text{RO} \cdot \text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, where R is chiefly manganese and zinc in the ratio 2 : 1.

F. J. Otto obtained a flocculent precipitate of manganese arsenate which soon passes into crystalline **ammonium manganese arsenate**, $(\text{NH}_4)\text{MnAsO}_4 \cdot 6\text{H}_2\text{O}$, by adding an ammoniacal soln. of manganese chloride to a soln. of arsenic acid or ammonium arsenate. This salt is washed with water freed from air by boiling. The reddish crystalline powder is permanent in air, and when heated it furnishes manganese pyroarsenate. With potash-lye, it gives off ammonia, forming potassium arsenate, and manganese hydroarsenate. It is insoluble in water, and alcohol, but soluble in acids. C. Lefèvre saturated with manganese carbonate a molten mixture of potassium dihydroarsenate with less than 80 per cent. potassium chloride, and obtained small, red, transparent, prismatic crystals of **potassium manganese arsenate**, KMnAsO_4 . If more potassium chloride is employed, the product contains a chloro-compound, and if potassium orthoarsenate or hydroarsenate are used, the crystals are not so good. The product in the analogous case with the sodium salt is a mass of colourless lamellæ of **sodium manganese hexarsenate**, $\text{Na}_3\text{Mn}_2\text{As}_6\text{O}_{21}$. When molten sodium hydroarsenate, or a mixture of the orthoarsenate and chloride, is treated with manganese oxide, red, transparent dendritic crystals of **sodium manganese diorthoarsenate**, $\text{Na}_3\text{AsO}_4 \cdot \text{NaMnAsO}_4$, are formed. A. E. Nordenskjöld described a colourless or white mineral from the Harstig mine, Pajsberg, Sweden, which he called **brandtite**—after G. Brandt. The analysis agrees closely with normal dihydrated **calcium manganese arsenate**, $\text{Ca}_2\text{Mn}(\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$. The prismatic crystals are triclinic, and they were examined by G. Lindström; P. Groth gave for the axial ratios $a : b : c = 2.20 : 1 : 1.44$, and $\alpha = 89^\circ$, $\beta = 90^\circ 30'$, and $\gamma = 89^\circ 20'$; on the other hand, E. S. Larsen, and G. Aminoff said that the crystals are monoclinic. The latter gave for the axial ratios $a : b : c = 0.8720 : 1 : 0.4475$, and $\beta = 99^\circ 37'$; and they have the indices of refraction $\alpha = 1.107$, and $\gamma = 1.729$ while the birefringence is 0.020. E. S. Larsen gave $\alpha = 1.709$, $\beta = 1.711$, and $\gamma = 1.724$; he also found the optic axial angle to be $2V = 23^\circ$; and the optical character positive. The crystals may be united in radiated groups, and in rounded or reniform aggregates. Twinning occurs about the (001)-plane. The hardness is 5.0–5.5; and the sp. gr. 3.671–3.672. The mineral is easily fusible; and it is soluble in nitric and hydrochloric acids.

H. Kühn² described a mineral from Långban, Sweden, which he called **berzeliite**—after J. J. Berzelius. It was called *magnesian pharmacolite* by J. D. Dana; *chaux arsenatée anhydre*, by P. A. Dufrenoy; *kühnite*, by H. J. Brookes and W. H. Miller; and *pyrrharsenite*—from *πυρρός*, fire—in allusion to its fiery

red colour, by L. J. Igelström. The mineral was analyzed by H. Kühn, G. Flink, A. G. Högbom, L. J. Igelström, A. H. Church, and H. Sjögren. L. J. Igelström, and A. G. Högbom used the formula $(\text{Ca}, \text{Mg}, \text{Mn})_{10} \text{As}_6 \text{O}_{25}$, which is like that given by H. Kühn. G. Aminoff regarded it as a normal orthoarsenate, $\text{R}_3(\text{AsO}_4)_2$; and W. T. Schaller represented it by $(\text{Ca}, \text{Mg}, \text{Mn})_3(\text{AsO}_4)_2$. The analyses show 5.68–19.18 per cent. MnO ; 18.35–20.73 per cent. CaO ; and 3.50–16.12 per cent. MgO ; while in the case of a sample described by H. Sjögren, 5.14 per cent. of soda and potash—hence the name *soda-berzeliiite*. Some samples also contain up to 6.54 per cent. of antimony pentoxide along with the 50.0 to 60.00 per cent. of arsenic pentoxide. The mineral may therefore be regarded as a **calcium magnesium manganese arsenate**, $(\text{Ca}, \text{Mg}, \text{Mn})_3(\text{AsO}_4)_2$, in agreement with C. F. Rammelsberg's $\text{R}_3\text{As}_2\text{O}_8$. The mineral usually occurs massive, but G. Flink also described cubic crystals in trapezohedra. E. S. Larsen gave 1.727 for the index of refraction. The colour is various shades of yellow and yellowish-red. The hardness is 5; and G. Flink gave 4.07–4.09 for the sp. gr. The mineral can be easily fused; and it is soluble in nitric acid. L. J. Igelström, and E. Bertrand said that the mineral is normally isotropic, but doubly refracting patches may be found in the isotropic crystals. The doubly refracting variety was regarded by W. Lindgren as a distinct species, and called *pseudoberzeliiite*. This variety was analyzed by L. W. McCay; W. T. Schaller represented it by $(\text{Ca}, \text{Mg}, \text{Mn})_3(\text{AsO}_4)_2$. E. Bertrand held this mineral to be rhombic; the optic axial angle $2E=c. 140^\circ$. The double refraction is positive. Pyrrharsenite is regarded as a variety of berzeliiite, in which antimony pentoxide replaces part of the arsenic pentoxide. It was analyzed by L. J. Igelström, and A. G. Högbom. G. Flink described a **magnesium manganese tetrahydroxyarsenate**, $\text{MgO} \cdot 4\text{MnO} \cdot \text{As}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, or, according to G. K. Almström, $\text{Mn}_3(\text{AsO}_4)_2 \cdot \text{Mn}(\text{OH})_2 \cdot \text{Mg}(\text{OH})_2 \cdot 4\text{H}_2\text{O}$, or $\text{MgMn}_4(\text{AsO}_5)_2 \cdot 6\text{H}_2\text{O}$, from Langban, Sweden. G. Flink called the mineral **acrochordite**—from *ἀκροχόρδαν*, a wart—in allusion to the warty excrescences on the crystals. The reddish-brown or yellowish-brown crystals belong to the mineral system; the sp. gr. is 3.194; and the hardness 3.5. W. Foshag and R. B. Gage described a mineral, which they called **chlorophoenicite**—from *χλωρός*, green; *φονικός*, blood-red—in allusion to the colour. It was found at Franklin Furnace, New Jersey. The composition corresponds with **zinc manganese hydroxyarsenate**, $\text{R}_3(\text{AsO}_4)_2 \cdot 7\text{R}(\text{OH})_2$, where R is mainly $\text{Mn} : \text{Zn} = 6 : 4$. The indices of refraction are $\alpha = 1.682$, $\beta = 1.690$, and $\gamma = 1.697$. C. Palache and E. V. Shannon described a pink, red, or yellowish-red mineral which they called **holdenite**—after A. F. Holden—the composition of which approximated to **zinc manganese arsenate**, $4\text{ZnO} \cdot 8\text{MnO} \cdot \text{As}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$. The rhombic crystals have the axial ratios $a : b : c = 0.3802 : 1 : 0.2755$. The sp. gr. is 4.07; and the hardness is 4. The optical character is positive; the optical axial angle $2V = 30^\circ 21'$; and the indices of refraction $\alpha = 1.769$, $\beta = 1.770$, and $\gamma = 1.785$.

C. H. Lundström found a brown mineral among the manganese ores of Långban, Sweden. He named it *karynite*, *korginite*, or **caryinite**—from *καρύινος*, nut-brown. The analysis corresponds with the formula used by W. T. Schaller, $(\text{Pb}, \text{Ca}, \text{Mg}, \text{Mn})_3(\text{AsO}_4)_2$; H. Sjögren added that if the contained water be regarded as basic, the general formula is $\text{R}_{10}\text{As}_6\text{O}_{25}$, otherwise the formula is $\text{R}_3(\text{AsO}_4)_2$ —**calcium magnesium lead manganese orthoarsenate**. The mineral occurs massive, and in crystals which are biaxial, and may be monoclinic—E. S. Larsen said rhombic. A. des Cloizeaux gave $2E = 41^\circ 58' - 47^\circ 0'$ for the optic axial angle; the optical character is positive; the hardness is 3.0–3.5; and the sp. gr. 4.25. E. S. Larsen gave for the indices of refraction, $\alpha = 1.776$, $\beta = 1.780$, and $\gamma = 1.805$.

A mineral from Orebro, Sweden, was named *chloroarsenian* by L. J. Igelström. It was only qualitatively analyzed, and it may be related with caryinite. Another complex mineral, incompletely investigated, was called **arseniopleite**—from *πλεῖον*, more, because it adds one more to the number of arsenical minerals—by L. J. Igelström. He obtained it from Grythytt, Sweden. His analysis corresponds with $9\text{R}'\text{O} \cdot \text{R}_2''\text{O}_5 \cdot 3\text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, on

the assumption that some of the manganese is trivalent, and can be replaced in part by ferric-iron. The mineral is also represented $(Ca, Mg, Pb, Mn)(Mn, Fe)(OH)_6(AsO_4)_6$. It occurs in brownish-red cleavable masses. According to E. Bertrand, the crystals are probably triclinic; optically uniaxial, and positive. E. S. Larsen gave $\omega=1.794$ and $\epsilon=1.803$ for the indices of refraction. The mineral is soluble in hydrochloric acid. Another basic calcium manganese arsenate containing 0.2 per cent. PbO , and 2.7 per cent. MgO , was called **retzian**—after A. J. Retzian—by H. Sjögren. It occurs at Nordmark, Sweden. The prismatic or tabular, chocolate-brown or chestnut-brown crystals are rhombic, with the axial ratios $a : b : c = 0.4414 : 1 : 0.7269$. The optic axial angle is large. The mineral is strongly pleochroic—brown-red and wine-red. The hardness is 4, and the sp. gr. 4.15. It is soluble in acids. A mineral called **rhodoarsenian** was obtained by L. J. Igelström from Örebro, Sweden. Its composition approximates $(Mn, Ca, Mg)_{20}O \cdot As_2O_5 \cdot 10H_2O$. It occurs in rose-red spherules embedded in arseniopleite. Its hardness is 4. It blackens when heated, and is soluble in hydrochloric acid. He also obtained a mineral which he called **elfstorpite** from the same locality. It is supposed to be a hydrated manganese arsenate. Similarly also with **pleurasite**—from $\pi\lambda\epsilon\upsilon\rho\acute{\alpha}$, side—in allusion to its occurrence in bluish-black bands on the side of arseniopleite. The composition of these three manganese arsenates is unknown.

R. Chenevix³ reported a white precipitate of **ferrous orthoarsenate**, $Fe_3(AsO_4)_2 \cdot 6H_2O$, to be formed when ammonium arsenate is added to a soln. of ferrous sulphate; and G. C. Wittstein obtained it by the reaction: $4Na_2HASO_4 + 4FeSO_4 = Fe_3(AsO_4)_2 + Fe(H_2AsO_4)_2 + 4Na_2SO_4$. G. Klemp and J. von Gyulay obtained **colloidal ferrous arsenate** by the successive addition of ammonium sulphate, acetic acid, and sodium arsenate to a soln. of a ferrous salt. The opalescent jelly slowly crystallizes. A. Breithaupt and C. F. Plattner found a mineral which he called **symple-site**—from $\sigma\upsilon\nu$, together; and $\pi\lambda\eta\sigma\acute{\iota}\zeta\epsilon\upsilon\nu$, to bring—in allusion to its relation to other minerals. It occurs at Lobenstein, Voigtland; Hüttenberg, Carinthia; at Pisek, Bohemia; and Felsőbánya; etc. Analyses reported by A. L. Parsons, E. Boricky, and C. F. Rammelsberg correspond with the *octohydrate*, $Fe_3(AsO_4)_2 \cdot 8H_2O$; A. Breithaupt and C. F. Plattner obtained about 3 per cent. less than this proportion of water. T. L. Walker and A. L. Parsons described a related mineral from Cobalt, Ontario. Symple-site occurs in small prismatic or tabular crystals, or in crystal aggregates which are coloured pale indigo inclined to celadon-green; and they are sometimes mountain-green or leek-green. According to J. A. Krenner, the monoclinic crystals have the axial ratios $a : b : c = 0.7806 : 1 : 0.6812$, and $\beta = 72^\circ 43'$. The (010)-cleavage is perfect. The crystals are said to be isomorphous with vivianite. The optic axial angle for yellow light is $2E = 107^\circ 28'$. The optical character is negative. E. S. Larsen gave $2V = 86\frac{1}{2}^\circ$; and, for the indices of refraction, $\alpha = 1.635$, $\beta = 1.668$, and $\gamma = 1.702$. The pleochroism for a is bluish-green to blue; for b , colourless to greenish-yellow; and for c , yellowish-green to oil-green. F. Ulrich studied the optical properties of the mineral. The hardness is 2.5–3; and the sp. gr. 2.957—C. Vrba gave 2.889. The mineral melts easily before the blowpipe. J. J. Berzelius said that the precipitated arsenate dissolves sparingly in aq. ammonia, forming a liquid which turns green when exposed to air; and G. C. Wittstein said that the ammoniacal soln. is greenish-yellow, and does not become turbid when exposed to air for several hours; the salt does not dissolve in a soln. of ammonium arsenate, or other ammonium salt soln. According to G. C. Wittstein, if the precipitated ferrous arsenate be washed and dried in air, it forms a grass-green mass with a composition corresponding with *ferrosic arsenate*, $6FeO \cdot 3Fe_2O_3 \cdot 4As_2O_5 \cdot 32H_2O$; most of the water is expelled at 100° , and the product is then greyish-green. At a red-heat, the compound loses all its water, but no arsenic. It is insoluble in water, but dissolves in hydrochloric acid, forming a yellow liquid. H. B. Weiser and A. P. Bloxson prepared the **hydrogel of ferrous arsenate** by the method used for the zinc salt.

According to C. W. Scheele, iron dissolves in a soln. of arsenic acid, and N. W. Fischer added that if the acid acts on the metal for several weeks, out of contact with air, what is possibly *ferrous hydroarsenate* is deposited in asbestos-like threads united in spherical masses; black needles of arsenic also appear. As

indicated in the above equation, G. C. Wittstein considered that the mother-liquor remaining after the precipitation of ferrous orthoarsenate contained **ferrous dihydroarsenate**, $\text{Fe}(\text{H}_2\text{AsO}_4)_2$. W. Duncan reported the formation of **ferrous ammonium arsenate**.

W. Duncan obtained anhydrous **ferric orthoarsenate**, FeAsO_4 , by heating the hydrate at 100° ; and B. Jezek and A. Simek observed that black, prismatic crystals of anhydrous ferric arsenate collected on the clay balls used in Deacon's process for chlorine at Hruschau, Silesia. The crystals are monoclinic, with the axial ratios $a : b : c = 0.6155 : 1 : 0.3221$, and $\beta = 77^\circ 8'$. The (001)-cleavage is perfect; the sp. gr. is 4.32; and the mean refractive index is 1.78 for Na-light. N. H. Hartshorne measured the viscosity of soln. of ferric oxide in arsenic acid, for soln. with 2.6 to 23.13 per cent. As_2O_5 , at 25° . Within this range, the results showed the existence of $\text{FeAsO}_4 \cdot n\text{H}_2\text{O}$, where n is not far from 3. This salt carries some adsorbed arsenic acid. Ferric trihydrodiarsenate was also formed—*vide infra*. No basic salts were observed. G. C. Wittstein, and H. Rose found that a yellowish-white precipitate of the *tetrahydrate*, $\text{FeAsO}_4 \cdot 4\text{H}_2\text{O}$, gradually separated from a soln. of ferrous dihydroarsenate when exposed to air. G. Franceschi represented the reactions with ferric chloride and the potassium arsenates by the equations: $2\text{K}_3\text{AsO}_4 + 2\text{FeCl}_3 = 2\text{Fe}(\text{AsO}_4)_2 + 6\text{KCl}$; $3\text{K}_2\text{HASO}_4 + 2\text{FeCl}_3 = \text{Fe}_2(\text{HASO}_4)_3 + 6\text{KCl}$; and $3\text{KH}_2\text{AsO}_4 + 2\text{FeCl}_3 = \text{Fe}_2(\text{HASO}_4)_3 + 3\text{KCl} + 3\text{HCl}$. P. Kotschoubey reported the *hemipentahydrate*, $\text{FeAsO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, to be formed when the precipitation is made in the presence of acetic acid and sodium acetate, and the product dried at 100° ; but H. Salkowsky could not confirm this. A. Verneuil and L. Bourgeois prepared the *dihydrate*, $\text{FeAsO}_4 \cdot 2\text{H}_2\text{O}$, by heating iron wire and a conc. soln. of arsenic acid in a sealed tube at 150° for 8 days. The wire is then covered with bluish-green crystals of the dihydrate. H. Metzke found that ferric arsenate is formed under varying conditions by the action of a mol of ammonium ferric alum on 2 to 4 mols of sodium hydroarsenate. The appearance of the precipitate varies with the proportion of the salts employed; when a small quantity of the arsenate is added to the alum soln., a white precipitate is obtained, whilst on adding the alum soln. to the arsenate the precipitate is brownish; when the two salts are employed in equal proportions, a yellow precipitate is formed. The white precipitate turns yellow and finally brownish when washed with water. According to the conditions under which they are formed, the precipitates contain small quantities of ammonium and sodium arsenates. In the presence of a large excess either of disodium arsenate or of iron ammonium alum, a mixture is obtained consisting mainly of the basic ferric arsenate, $3\text{Fe}_2\text{O}_3 \cdot 2\text{As}_2\text{O}_3 \cdot 16$ or $17\text{H}_2\text{O}$ —it is thought to be a mixture of basic salts. H. Metzke prepared the *hemihydrate* by heating precipitated ferric dihydroarsenate—*vide infra*—with arsenic acid, hydrogen dioxide, and water in a sealed tube at 170° for 14 days. Yellowish-green, rhombic crystals of the hemihydrate mixed with the dihydrate are formed. Crystals of the *monohydrate* are produced from normal ferric arsenate treated in a similar manner. W. Duncan represented the air-dried salt as $\text{FeAsO}_4 \cdot \text{H}_2\text{O}$, and said that it becomes anhydrous at 100° . They represented the hydrated salt by the formula $\text{AsO}_2(\text{FeO})(\text{HO})_2$, the acidic character being shown by its effervescence with sodium hydrocarbonate. The *dihydrate* is formed by heating ferric arsenate with water and arsenic acid in a sealed tube at 80° for 4 days; and by the evaporation of a soln. of ferric arsenate acidified with hydrochloric acid. D. N. Chakravasti and N. R. Dhar discussed the viscosity of colloidal soln. of ferric arsenate. W. Ipatieff and co-workers heated ferric arsenate with water and hydrogen and obtained successively scorodite, ferric arsenite, arsine, ferrous arsenite, arsenic, and arsenious acid. H. B. Weiser discussed *colloidal ferric arsenate*. The dihydrate occurs in nature as the mineral **scorodite**—from *σκόροδος*, garlic—which was so named by A. Breithaupt in allusion to its odour before the blowpipe flame. J. L. Bournon called it *cupromartial arsenate*; R. J. Haüy, *cuivre arseniaté ferrifère*; and F. S. Beudant, scorodite and *néoctèse*.

Analyses were reported by A. Damour, J. J. Berzelius, J. B. J. D. Boussingault, R. Hermann, J. H. C. Martens, A. Raimondi, J. da Costa Sena, and A. Hague. The results agree with the formula $\text{FeAsO}_4 \cdot 2\text{H}_2\text{O}$. It has been reported from many localities—Schwarzenberg, Saxony; Dernbach, Nassau; Hüttenberg, Carinthia; Nerchinsk, Siberia; Chanteloube, Limoges; Minas Graes, Brazil; Popayan, Peru; Edenville, New York; in Utah, and Nevada, Victoria, Australia, etc. M. Piazza found it in the tungsten ores of Cerva, Portugal. A. Hague found a deposit of ferric arsenate—scorodite—from a hot spring in the Yellowstone National Park. J. H. C. Martens, and R. P. D. Graham also described some American deposits. M. Lippmann called a variety with cobalt, *cobalt-scorodite*. R. L. Codazzi called a variety *loaisite*. E. Hussak observed scorodite to be produced by the decomposition of auriferous arsenical pyrites; and it is formed likewise in nature by the decomposition of other arsenical earths. The mineral *jogynait*, discussed by N. von Kokscharoff, is a variety of scorodite. It occurs earthy and amorphous, when R. Hermann called it *arsenical sinter*, or *iron-sinter*; it also occurs in irregular groups of crystals, and in octahedral, prismatic, or tabular crystals. The colour is pale leek-green, or liver-brown. According to G. vom Rath, the rhombic crystals have the axial ratios $a : b : c = 0.86578 : 1 : 0.95414$; and P. Groth gave $0.8687 : 1 : 0.9536$; and R. P. D. Graham, $0.8785 : 1 : 0.0550$. The (120)-cleavage is imperfect; and traces of cleavage appear on the (100)- and (010)-faces. E. F. Tschirva studied the crystals of scorodite. A. des Cloizeaux gave for the optic axial angles with red light, $2H_a = 76^\circ 43\frac{1}{2}'$, and $2E = 130^\circ 58'$; with yellow light, $2H_a = 76^\circ 5'$, and $2E = 129^\circ 32'$; and with blue light, $2H_a = 72^\circ 44'$, and $2E = 122^\circ 25'$. When the temp. was raised from 17° to 76.5° , $2E$ for red light altered from $115^\circ 43'$ to $116^\circ 56'$. The optical character is positive. A. Verneuil and L. Bourgeois found the artificial crystals were crystallographically and optically like the natural crystals. The hardness is 3.5–4.0; and the sp. gr. 3.1–3.3. A. Damour gave 3.11; J. J. Berzelius, 3.18; J. H. C. Martens, 2.70–2.86; R. P. D. Graham, 3.235; J. da Costa Sena, 3.2; and A. Verneuil and L. Bourgeois, 3.28 for the artificial crystals. J. H. C. Martens found the index of refraction 1.775, and the birefringence, strong. Scorodite can be easily fused; and it is soluble in hydrochloric acid. It is altered to limonite when weathered. E. S. Larsen gave 1.775 for the index of refraction; and R. P. D. Graham, 1.76. In opposition to J. J. Berzelius, H. Rose said that ferric arsenate is completely decomposed by potash-lye. Red or yellow soln. were obtained by J. J. Berzelius, G. C. Wittstein, and J. W. Döbereiner by treating the arsenate with aq. ammonia; and H. Rose said that the ammoniacal soln. becomes blue when acidified. G. Lunge observed that ferric arsenate dissolves in conc. arsenic acid, and is re-precipitated by diluting and warming the soln.

According to H. Metzke, ferric orthoarsenate is a bright yellow powder insoluble in water. It is slowly decomposed by cold water, more quickly by hot water, and is soluble in hydrochloric, sulphuric, nitric, dil. arsenic, and phosphoric acids; the soln. in the last two acids decompose when boiled and diluted. Neutral and acid ferric arsenate are quickly and completely dissolved by conc. ammonia, yielding a blood-red soln.; the basic ferric arsenates, however, are not. Yellow ammoniacal soln. are obtained in the presence of large quantities of disodium arsenate and ammonium chloride. These arsenates are not decomposed by a soln. of silver nitrate, are quickly decomposed by soln. of ammonium and sodium acetates, and give the reaction of ferric salts with potassium ferrocyanide and thiocyanate only in strongly acid soln., and never in ammoniacal soln. Cold conc. potassium hydroxide precipitates ferric hydroxide from the neutral ferric arsenate, but only an incomplete decomposition takes place when a hydrochloric acid soln. of the arsenate is boiled with potassium hydroxide.

According to C. H. Pfaff, a soln. of ferric chloride gives a white precipitate when treated with sodium hydroarsenate. The precipitate was examined by J. J. Berzelius, R. Chenevix, R. Brandes, J. W. Döbereiner, and G. C. Wittstein.

Analyses by J. J. Berzelius, and R. Chenevix correspond with **ferric hydroarsenate**, $\text{Fe}_2(\text{HAsO}_4)_3 \cdot 4\frac{1}{2}\text{H}_2\text{O}$. H. Metzke obtained the salt by dissolving ferric orthoarsenate in a soln. of arsenic acid and precipitating the filtered soln. with alcohol. The white precipitate is quickly washed with 98 per cent. alcohol, and dried by press. between folds of bibulous paper. It dissolves in acids, forming a yellow soln., and in ammonia, a red soln. The white acid compound obtained by the action of sodium hydroarsenate on iron ammonium alum is quickly decomposed when washed with water, dil. alcohol, or glycerol: it is not altered, however, by strong alcohol or ether, but these solvents do not wash out the impurities in the mother-liquor, so that it cannot be obtained pure. H. Metzke obtained **ferric dihydroarsenate**, $\text{Fe}(\text{H}_2\text{AsO}_4)_3 \cdot 5\text{H}_2\text{O}$, by dissolving 4 grms. of artificial pharmacosiderite in syrupy arsenic acid (11.5 grms. As_2O_5), and heating the soln. White, pulverulent ferric hydroarsenate is deposited. In 24 hrs., the precipitate was washed with alcohol, and dried. It is decomposed by water and is readily dissolved by acids, forming a yellow soln., and in aq. ammonia, forming a red soln.

L. Dede found that when arsenic acid is added to a soln. of ferric chloride there is a considerable increase in the sp. conductivity of the soln.; an increase also occurs with the further addition of the acid soln. until equivalent proportions of acid and salt are mixed. It is therefore assumed that the complex **trichloroarsenato-ferric acid**, $\text{H}_3[\text{Fe}(\text{AsO}_4)\text{Cl}_3]$, is formed; neither the acid nor its salts could be isolated. Still further additions of arsenic acid had no appreciable effect on the conductivity, but the three chlorine atoms are replaced by another arsenato-group so as to form **ferric trihydrodiarsenate**, or **diarsenato-ferric acid**, $\text{H}_3[\text{Fe}(\text{AsO}_4)_2] \cdot 2\frac{1}{2}\text{H}_2\text{O}$. The acid was readily isolated. N. H. Hartshorne also prepared this salt—*vide supra*.

J. J. Berzelius reported a basic salt, $16\text{Fe}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 24\text{H}_2\text{O}$, to be formed by boiling one of the orthoarsenates with potash-lye; but H. Metzke showed that this product is probably a mixture. H. Metzke, however, prepared $4\text{Fe}_2\text{O}_3 \cdot 3\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ with $n=15.4, 20.5$, and 33.5 , and contaminated with small quantities of sodium and ammonium salts by heating ferric orthoarsenate with water in a sealed tube at 200° ; or by boiling the orthoarsenate with a soln. of ammonium acetate acidified with acetic acid; or by oxidizing with hydrogen dioxide the white precipitate obtained by mixing molar proportions of soln. of ferrous sulphate and sodium dihydroarsenate. The analysis $4\text{Fe}_2\text{O}_3 \cdot 3\text{As}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, can be represented by $\text{Fe}(\text{AsO}_4)_3 \cdot (\text{FeOH})_3 \cdot m\text{H}_2\text{O}$, that is, **ferric trihydroxytriarsenate**, $\text{Fe}(\text{AsO}_4 : \text{FeOH})_3 \cdot m\text{H}_2\text{O}$. A related product occurs in nature in various parts of Cornwall, and Cumberland; Saxony; Bohemia; Hungary; Dept. du Var, France; Australia; Utah, U.S.A.; etc. It was probably the *fer mineralisé par l'acide arsenique* of J. L. Proust; the arsenicated iron ore of R. Kirwan; the *Olivenerz* or the *arseniksaures Eisen in Würfelnkrystallen*, of M. H. Klaproth; the *Wurfelerz* or *cube ore*, of D. G. L. Lenz and D. L. G. Karsten. J. F. L. Hausmann called it **pharmacosiderite**—from *φάρμακόν*, poison; and *σίδηρος*, iron. C. Vrba and A. d'Achiardi discussed the formation of the mineral in nature from arsenical pyrites. The mineral commonly occurs in cubes, and tetrahedra, and rarely granular. The colour varies from grass-green, emerald-green, olive-green, honey-yellow, to yellowish-brown—sometimes being hyacinth—red and blackish-brown. J. J. Berzelius' analysis corresponds with $4\text{Fe}_2\text{O}_3 \cdot 3\text{As}_2\text{O}_5 \cdot 15\text{H}_2\text{O}$, which P. Groth represented $\text{Fe}(\text{AsO}_4)_3 \cdot (\text{FeOH})_3 \cdot 6\text{H}_2\text{O}$. E. G. J. Hartley represented his analysis by $2\text{FeAsO}_4 \cdot \text{Fe}\{\text{O}(\text{H},\text{K})\}_3 \cdot 5\text{H}_2\text{O}$. A. Kalecsinsky found some thallium in pharmacosiderite from Ujbanya, Hungary. The hardness is 2.5, and the sp. gr. is nearly 3.0. C. Vrba found 2.873 for the sp. gr., and E. G. J. Hartley, 2.789. The last-named observed that when heated, the mineral lost 0.84–1.60 per cent. of water in dry air; 9.82 per cent. at 100° ; 14.51 per cent. at 136° ; and 19.53 per cent. at a red-heat. The crystals are pyroelectric. The mineral was found by E. Bertrand to show an anomalous double refraction, and P. Gaubert gave for the index of refraction 1.676. The general properties are like those of

scorodite. Pharmacosiderite passes into psilomelane, limonite, and hæmatite when weathered.

A mineral called *pitchy iron ore*, *iron-sinter*, or *arsenical iron-sinter* was described by D. L. G. Karsten,⁴ R. J. Häuy, and C. A. S. Hofmann. J. F. L. Hausmann called it *püttizite*; F. S. Beudant, *sideretine*; and later J. F. L. Hausmann called it *pitticite*. Analyses by F. Stromeyer, C. M. Kersten, C. F. Rammelsberg, A. H. Church, A. Frenzel, F. A. Genth, F. Kovar, E. W. Benecke and E. Cohen, etc., show that the mineral is rather indefinite, for the composition varies so much that a satisfactory guess at the idealized mineral has not been made. It appears to be a basic ferric arsenate—some varieties contain sulphates, others also contain lime—*e.g.* the mineral described by P. P. Pilipenko. W. F. Foshag and H. G. Clinton regard it as a mixture of colloidal arsenate and sulphate of iron. E. S. Larsen found the index of refraction is near 1.635. The so-called iron sinter may be pitticite or impure scorodite.

L. J. Curtman⁵ found that when ammonium hydroarsenate is added to a strong acid soln. of ferric chloride it furnished a white crystalline precipitate of **ferric ammonium arsenate**, $(\text{NH}_4)_2\text{H}_2\text{AsO}_4 \cdot \text{FeAsO}_4$. This salt readily hydrolyzes in the presence of water; it dissolves in mineral acids and in ammonia. A basic salt is precipitated from the ammoniacal soln. or by the addition of alcohol. A **ferric potassium arsenate** is formed in a similar way. C. Lefèvre dissolved about 7 per cent. of ferric oxide in molten potassium metarsenate, and obtained colourless, transparent, rhombic prisms of **potassium ferric pyroarsenate**, KFeAs_2O_7 ; with sodium metarsenate, greenish, transparent prisms of **sodium ferric pyroarsenate**, $\text{NaFeAs}_2\text{O}_7$, were formed. He also obtained greenish lamellæ of **potassium ferric triorthoarsenate**, $\text{K}_3\text{Fe}_2(\text{AsO}_4)_3$, by using a larger proportion of ferric oxide; and green, transparent monoclinic prisms of **sodium ferric triorthoarsenate**, $\text{Na}_3\text{Fe}_2(\text{AsO}_4)_3$, were similarly obtained. A. Rosenheim and S. Thon prepared **sodium dihydroferriarsenate**, $\text{NaH}_2[\text{Fe}(\text{AsO}_4)_2] \cdot \text{H}_2\text{O}$, and **potassium dihydroferriarsenate**, $\text{KH}_2[\text{Fe}(\text{AsO}_4)_2]$. The triclinic crystals of $\text{CuFe}_4\text{As}_4\text{O}_{17}$ obtained by A. Arzruni and E. Schütz in the brick-work of a furnace making chlorine by Deacon's process may be *copper ferric oxytetraarsenate*. The rare mineral named **cheneviseite**—after R. Chenevix—occurs with the arsenical pyrites in Cornwall, and Utah. Analyses by R. Chenevix, F. Pisani, G. S. Mackenzie, and W. F. Hillebrand agree approximately with **copper ferryl arsenate**, $\text{Cu}(\text{FeO})\text{AsO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$. It occurs in dark green or greenish-yellow compact masses of hardness 3.5–4.5; and sp. gr. 3.93. E. S. Larsen found that the index of refraction approximates 1.88.

G. A. Koenig⁶ described a basic arsenate from the Jesus-Maria mine, Mazapil, Mexico, and called it **mazapilite**. The analysis corresponds with $\text{Ca}_3\text{Fe}_2(\text{AsO}_4)_4 \cdot (\text{FeO} \cdot \text{OH})_2 \cdot 5\text{H}_2\text{O}$, which P. Groth represented as **calcium ferric hexahydroxy-tetraarsenate**, $\text{Fe}_4\text{Ca}_3(\text{AsO}_4)_4(\text{OH})_6 \cdot 3\text{H}_2\text{O}$; that is

The slender prismatic crystals are black or deep brownish-red, but in thin splinters, by transmitted light, they are blood-red. The rhombic crystals have the axial ratios $a : b : c = 0.8617 : 1 : 0.9980$; A. des Cloizeaux gave $0.57735 : 1 : 0.56443$. According to G. A. Koenig, the hardness is 4.5; and the sp. gr. 3.567–3.562. E. S. Larsen gave for the index of refraction $\omega = 1.898$, and $\epsilon = 1.815$; the optical character is negative. About a mol. of water is lost at 360° , and the remainder at a red-heat. Mazapilite is soluble in warm hydrochloric acid. E. S. Larsen compared the properties of the mineral with those of arsenosiderite. J. Barthoux obtained a related mineral from Jebel Debar, Algeria. He named it **dussertite**. Its analysis corresponds with **calcium triferric enneahydroxydiarsenate**, $\text{Ca}_3\text{Fe}_3(\text{OH})_9(\text{AsO}_4)_2$. The minute, green crystals are flattened parallel to the base and are either trigonal or hexagonal; they are optically uniaxial and negative; the indices of refraction, ω and ϵ , are between 1.80 and 1.88; and $\omega - \epsilon = 0.012$. Thin sections are

yellowish-green and slightly pleochroic. The hardness is 3·5; and the sp. gr. 3·75. 0·3 per cent. of water is lost at 120°; 9·3 per cent. at 700°; and 9·8 per cent. at 1000°. Dussertite is soluble in dil. hydrochloric acid. The related mineral occurs at Mâcon, France, and at Schneeberg, Saxony. It was called by P. A. Dufrénoy ⁷ **arsenosiderite**, which E. F. Glocker changed to *arsenocrocite*—from *κρόκη*, a fibre—because the term arsenosiderite had been employed by him for löllingite. Analyses were made by P. A. Dufrénoy, etc. C. F. Rammelsberg used the formula $2\text{Ca}_3(\text{AsO}_4)_2 \cdot 6\text{FeAsO}_4 \cdot 8\text{Fe}(\text{OH})_3$; and A. H. Church, $2\text{Ca}_3(\text{AsO}_4)_2 \cdot 2\text{FeAsO}_4 \cdot 6\text{Fe}(\text{OH})_3$. P. Groth regarded it as **calcium tetraferrie ennea-hydroxyarsenate**, $\text{Fe}_4\text{Ca}_4(\text{OH})_9\text{AsO}_4$. The yellowish-brown mineral occurs in fibrous concretions, and the crystals belong to the tetragonal or hexagonal system. A. Lacroix said the crystals are uniaxial, negative, and strongly pleochroic. The hardness is 1–2. The sp. gr. given by P. A. Dufrénoy is 3·520; by C. F. Rammelsberg, 3·88; and by A. H. Church, 3·36. It resembles scorodite in many respects. E. S. Larsen gave for the indices of refraction $\omega=1\cdot870$, and $\epsilon=1\cdot792$. J. B. Tyrrel and R. P. D. Graham described a yellowish-brown mineral from the Yukon Territory, Canada, and called it **yukonite**. Its composition approximates $(\text{Ca}_3\text{Fe}_2''')(\text{AsO}_4)_2 \cdot 2\text{Fe}(\text{OH})_3 \cdot 5\text{H}_2\text{O}$. The sp. gr. was 2·65, and when soaked in water, 2·86; and the hardness 2–3. Half the water is lost at 100°, or in vacuo, and the remainder at a red-heat. A. Rosenheim and S. Thon prepared **barium hexahydroferriarsenate**, $\text{Ba}_3\text{H}_6[\text{Fe}(\text{AsO}_4)_3]_2$.

The mineral called *carmine spar* by F. Sandberger,⁸ and **carminite**, by J. D. Dana, occurs in clusters of carmine-red or brick-red needles at Norhausen, Germany. Other occurrences were noted by A. Russell, and W. F. Petterd. The analysis by R. Müller corresponds with **lead ferric dodecarsenate**, $\text{Pb}_3(\text{AsO}_4)_2 \cdot 10\text{FeAsO}_4$, the prismatic crystals belong to the rhombic system. The hardness is 2·0–2·5; and the sp. gr. 4·105. A. Russell found the refractive index to be over 1·74; and the double refraction is strong and positive. The mineral is soluble in nitric acid. L. J. Igelström described a yellow mineral from Sjö mine, Orebro, Sweden. He called it **sjogrufovite**. The analysis corresponds with $2(\text{RO})_3 \cdot 2\text{As}_2\text{O}_5 \cdot \text{R}_2\text{O}_3 \cdot 6\text{H}_2\text{O}$, or **(calcium) manganese ferric triarsenate**, $\text{FeMn}_3(\text{AsO}_4)_3 \cdot 3\text{H}_2\text{O}$. It contains about 3·61 per cent. of calcium oxide, and 1·74 per cent. of lead oxide. It resembles arseniolepte in many ways. It is magnetic; it oxidizes rapidly in air; and is readily soluble in cold hydrochloric acid. A. Frenzel found rhombohedral crystals of a blackish, reddish, or yellowish-brown mineral at Schneeberg, Saxony, which he called **miriquidite**, and which was regarded as a lead ferric phosphato-arsenate, but it was not quantitatively analyzed. The rhombohedral crystals have a hardness of 4.

In 1872, F. E. Bruckmann⁹ described *Koboldblüthe*, or *cobalt bloom*, as a blood-red mineral. J. G. Wallerius applied the term *Koboltblomma*, or *flos cobalti*, to the *cobaltic minera colore rubra* when crystalline, and *Koboltbeslag*, when earthy. A. Cronstedt called the same mineral *ochra cobalti rubra*, *red cobalti*, or *cobalt ochre*; T. Bergman, *cobaltum acido arsenico mineralisatum*; J. J. N. Huot, *rudoise*; and F. S. Beudant, *erythrine*, hence the usual term **erythrite**—from *έρυθρός*, red. This mineral is supposed by G. la Valle, L. Buchrucker, etc., to be a decomposition product of smaltite. It has been reported from Schneeberg, Saxony; Wolfach and Wittichen, Baden; Riechelsdorf, Hesse; Saalfeld, Thuringia; Modum, Norway; St. Just, Cornwall; Alston, Cumberland; Killarney, Ireland; Allemont, Dauphiné; Messina, Sicily; in California, and Pennsylvania; and in several other localities. It occurs as a pulverulent incrustation, in prismatic crystals, and in globular and reniform shapes with a columnar structure, sometimes stellate. The colour is crimson, and peach-red; pearl-grey or greenish-grey; and there is a green variety at Platten, Bohemia, which sometimes has red and green on the same crystal. Analyses have been reported by C. M. Kersten, J. F. Vogel, C. F. Rammelsberg, F. Petersen, A. Laugier, and C. F. Bucholz. The results are in agreement with what is required for **cobalt orthoarsenate**, $\text{Co}_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$.

H. B. Weiser and A. P. Bloxson prepared the **hydrogel of cobalt arsenate** by the method used for the zinc salt. The earthy variety of cobalt bloom—*Kobaltbeschlag*—was considered by C. M. Kersten to be a mixture of erythrite and arsenolite (1 : 1). Lavendulite (*q.v.*) has been regarded as a cupriferous erythrite. L. Gmelin obtained this arsenate as a precipitate, the colour of the peach-blossom, by adding sodium arsenate to a soln. of a cobalt salt. It dries to a dark horny mass. O. Ducru obtained the octohydrate by treating an aq. soln. of a cobalt salt with ammonia orthoarsenate, which may or may not contain ammonium chloride, but not free ammonia. The pale rose-red precipitate consists of microscopic needles. A. de Schulten obtained crystals of erythrite by allowing a soln. of heptahydrated sodium hydroarsenate (2 grms. per litre) slowly to drop into a soln. of anhydrous cobalt sulphate (2 grms. per 3 litres) heated on a water-bath for 40 days. G. Klemp and J. von Gyulay prepared **colloidal cobalt arsenate** by the successive addition of ammonium sulphate, acetic acid, and an excess of sodium arsenate to a soln. of a cobaltous salt. The opalescent jelly crystallizes when allowed to stand for some time.

The prismatic crystals of erythrite may be vertically striated. According to A. Brezina, they belong to the monoclinic system and have the axial ratios $a : b : c = 0.75 : 1 : 0.70$, and $\beta = c. 75^\circ$; A. des Cloizeaux gave $0.7937 : 1 : 0.7356$, and $\beta = 105^\circ 9'$. The (010)-cleavage is perfect; and the (100)- and ($\bar{1}01$)-cleavages indistinct. The crystals are isomorphous with vivianite. A. des Cloizeaux gave for the optic axial angle for red, yellow, and blue light, respectively $2H = 104^\circ 41'$, $104^\circ 31'$, and $102^\circ 21'$. The optical character is positive. P. Gaubert gave for the indices of refraction $\alpha = 1.6263$, $\beta = 1.6614$, and $\gamma = 1.6986$ for Na-light; the birefringence $\gamma - \alpha = 0.0723$. E. S. Larsen gave $\alpha = 1.629$, $\beta = 1.663$, and $\gamma = 1.701$. The pleochroism is shown by the pale red colour of a , pale violet of b , and red of c . G. Lincio, and F. Ulrich studied the optical properties of the mineral. The hardness is 1.5 to 2.5, being smallest on the (010)-face. The sp. gr. given by C. M. Kersten is 2.912. A. de Schulten gave 3.178 for artificial erythrite. Erythrite dissolves in hydrochloric acid, forming a blue soln. which when diluted is rose-red. The mineral is decomposed by potash-lye leaving a black residue. J. Lemberg found that bromine-water slowly oxidizes the mineral; and J. R. Müller investigated the action of an aq. soln. of carbon dioxide. O. Ducru reported the formation of three amines by the action of arsenic acid, or an arsenate on soln. of cobalt salts containing ammonium salts and free ammonia. The composition depends on the proportion of ammonia, but is not affected by the proportion of ammonium salts. The amines are to be regarded as being formed by the substitution of water of crystallization by ammonia. If the mother-liquor contains 15 c.c. of 20 per cent. ammonia per litre, rhombic plates or needles of **cobalt monaminorthoarsenate**, $\text{Co}_3(\text{AsO}_4)_2(\text{NH}_3) \cdot 7\text{H}_2\text{O}$, are formed; with 60 c.c. of 20 per cent. ammonia, **cobalt diamminorthoarsenate**, $\text{Co}_3(\text{AsO}_4)_2(\text{NH}_3)_2 \cdot 6\text{H}_2\text{O}$, is formed; and with 350 c.c. of 20 per cent. ammonia, **cobalt triaminorthoarsenate**, $\text{Co}_3(\text{AsO}_4)_2(\text{NH}_3)_3 \cdot 5\text{H}_2\text{O}$.

A basic arsenate of cobalt was once used commercially under the name *chaux métallique*. It was made by adding potassium carbonate to a soln. of smaltite in nitric acid so long as white ferric arsenate was precipitated, and more alkali carbonate was added to the filtrate to precipitate the basic cobalt arsenate. A reddish powder was also made by roasting cobalt arsenide. J. G. Gentile obtained **cobalt oxyarsenate**, $\text{CoO} \cdot \text{Co}_3(\text{AsO}_4)_2$, by precipitating a soln. of cobalt arsenate in nitric acid by the addition of sodium carbonate, and fusing the product. The cold crystalline mass contained deep blue, prismatic crystals, soluble in acids. When powdered, the product is rose-red. It was used as a pigment. A. Coloriano prepared dichroic—blue and reddish-violet—rhombic, prismatic crystals of the *monohydrate*, $\text{Co} = \text{O}_2 = \text{AsO} - \text{O} - \text{CoOH}$, by heating a mixture of sodium orthoarsenate with an excess of cobalt nitrate soln. in a sealed tube at 150° .

According to C. M. Kersten, the evaporation in vacuo of a soln. of cobalt

hydroxide or cobalt orthoarsenate, dissolved in an excess of arsenic acid, furnished peach-coloured needles arranged in stellated groups. This product is supposed to be an acidic arsenate. A. Coloriano heated a mixture of cobalt carbonate and an excess of arsenic acid in a sealed tube at 235° , and obtained rose-red needles of $5\text{CoO}\cdot 2\text{As}_2\text{O}_5\cdot 3\text{H}_2\text{O}$, or **cobalt dihydrotetrarsenate**, $\text{Co}_3(\text{AsO}_4)_2\cdot 2\text{CoHASO}_4\cdot 2\text{H}_2\text{O}$. The product is insoluble in water, and is dehydrated by heat. C. Lefèvre obtained **cobalt pyroarsenate**, $\text{Co}_2\text{As}_2\text{O}_7$, in violet crystals by dissolving cobalt oxide in molten potassium metarsenate; and H. Goguel obtained the *dihydrate*, $\text{Co}_2\text{As}_2\text{O}_7\cdot 2\text{H}_2\text{O}$, or $\text{H}_2(\text{CoOH})_2\text{As}_2\text{O}_7$, in monoclinic crystals.

C. Lefèvre obtained blue, prismatic crystals of **potassium cobalt arsenate**, KCoAsO_4 , by dissolving cobalt oxide in one of the molten potassium arsenates mixed with the alkali chloride; he also obtained blue prismatic crystals of **sodium cobalt arsenate**, NaCoAsO_4 , in an analogous way; and violet plates of **sodium cobalt hexarsenate**, $\text{Na}_4\text{Co}_4\text{As}_6\text{O}_{21}$, from cobalt oxide and molten sodium metarsenate. A. Rosenheim and S. Thon could not prepare **cobaltarsenates** like the ferriarsenates. A mineral obtained by A. Lévy from Schneeberg, Saxony, was called **roselite**—after G. Rose. It occurs in small crystals and in spherical aggregates coloured light or dark rose-red. Analyses were reported by C. Winkler, and A. Weisbach. A. Schrauf represented the results by formulæ ranging from $\text{Ca}_6\text{Mg}_2\text{Co}_4\text{As}_8\text{O}_{32}\cdot 10\text{--}12\text{H}_2\text{O}$ and $\text{Ca}_7\text{Mg}_2\text{Co}_3\text{As}_8\text{O}_{32}\cdot 10\text{H}_2\text{O}$; which can be generalized into $\text{R}_3(\text{AsO}_4)_2\cdot 3\text{H}_2\text{O}$, or $\text{R}_3(\text{AsO}_4)_2\cdot 2\text{H}_2\text{O}$, that is, $(\text{Ca}, \text{Mg}, \text{Co})_3(\text{AsO}_4)_2\cdot 2\text{H}_2\text{O}$, or **calcium magnesium cobalt arsenate**. A. Schrauf gave for the axial ratios of the triclinic crystals $a : b : c = 0.45360 : 1 : 0.55604$, and $\alpha = 90^{\circ} 34'$, $\beta = 91^{\circ}$, and $\gamma = 89^{\circ} 20'$; and P. Groth gave $2.2046 : 1 : 1.4463$, and $\alpha = 89^{\circ} 0'$, $\beta = 90^{\circ} 34'$, and $\gamma = 98^{\circ} 21'$. E. S. Larsen said that the optic axial angle is moderate; the optical character, positive; the index of refraction, 1.725; the birefringence, 0.01; and the pleochroism b —pale rose-red, and c colourless. The hardness is 3.5; and the sp. gr. reported by A. Schrauf is 3.506–3.738; and by C. Winkler, and A. Weisbach, 3.460–3.561. The mineral is soluble in hydrochloric acid giving a blue conc. soln., or a red dil. soln.

C. Bergemann¹⁰ described what he called *Nickelerz* as a sulphur-yellow mineral from Johanngeorgenstadt. The analysis corresponds with normal **nickel orthoarsenate**, $\text{Ni}_3(\text{AsO}_4)_2$. M. Adam called it **xanthiosite**—from *ξανθός*, yellow—in allusion to the colour. The anhydrous salt was made by A. Girard by heating the hydrate, or by the action of nitric acid on the hydrate; and by O. Ducru, by heating one of the amines—*vide infra*. Xanthiosite is amorphous; its hardness is 4; and its sp. gr. 4.982. It is attacked by acids very slowly. R. Tupputi obtained the *dihydrate*, $\text{Ni}_3(\text{AsO}_4)_2\cdot 2\text{H}_2\text{O}$, by double decomposition with an alkali arsenate and a nickel salt; A. Coloriano obtained it as a by-product in the preparation of nickel dihydrotetraorthoarsenate—*vide infra*—from which it can be separated mechanically since the dihydrate is specifically heavier. The product appears as an apple-green powder, or in hexagonal plates. According to J. L. Proust, and R. Tupputi, when the dihydrate is heated, it gives off at first nothing but water, becoming first hyacinth-red; at a red-heat, it becomes pale yellow; and at a higher temp. it exhibits no further change unless it be in the presence of a reducing agent. J. W. Döbereiner observed that when heated with sulphur it gives off sulphur dioxide, then yellow arsenic sulphide, then the red sulphide, and leaves behind nickel sulphide. J. J. Berzelius reported it to be insoluble in water; soluble in arsenic acid, and in the stronger mineral acids; and freely soluble in aq. ammonia. When potassium hydroxide is added to the ammoniacal soln., potassium niccolate is precipitated free from arsenic unless some ferric salt is also present. The salt is decomposed by fused potassium hydroxide. If it be dissolved in an acidic soln. of cobalt arsenate, and a small proportion of potash-lye be added, cobalt arsenate is precipitated.

The *octohydrate*, $\text{Ni}_3(\text{AsO}_4)_2\cdot 8\text{H}_2\text{O}$, occurs in nature, as the mineral named **annabergite** by H. J. Brookes and W. H. Miller. It appears as an apple-green

earth. or capillary crystals. It was called *ochra niccoli* and *niccolium calciforme* by A. Cronstedt, and it has been variously called nickel bloom, nickel ochre, and nickel green. Annabergite occurs at Annaberg and Schneeberg, Saxony; Kamsdorf, Thuringia; Allemont, Dauphiné; in Connecticut, Colorado, and Nevada; etc. Analyses, made by P. Berthier, F. Stromeyer, L. Buchrucker, A. Sachs, J. S. Newberry, C. M. Kersten, and F. A. Genth, are in agreement with the above formula. In some cases a little nickel is replaced by calcium, magnesium, or ferrous-iron. O. Ducru obtained the octohydrate, in microscopic needles, by precipitation by ammonium orthoarsenate from a soln. of nickelous chloride and an ammonium salt, but no free ammonia; and A. de Schulten obtained artificial annabergite by a method similar to that employed for erythrite. He said that the crystals are monoclinic like those of erythrite. F. Ulrich studied the optical properties of the crystals. E. S. Larsen gave 82° for the optic axial angle; the optical character is positive; and the indices of refraction $\alpha=1.622$, $\beta=1.658$, and $\gamma=1.687$. The sp. gr. was 3.300. Annabergite is soluble in acids. According to O. Ducru, a soln. containing a mixture of nickel and ammonium salts and free ammonia when treated with arsenic acid or a soluble arsenate, produces in the cold or on gently warming a gelatinous greenish-white precipitate which deepens in colour and becomes crystalline when the mixture is heated on the water-bath. The crystals are anisotropic and belong to the monoclinic system; they vary in composition according to the amount of ammonia present. When the soln. contains no free ammonia, the octohydrate is produced; with 1.38 per cent. of ammonia, **nickel monamminorthoarsenate**, $\text{Ni}_3(\text{AsO}_4)_2 \cdot (\text{NH}_3) \cdot 7\text{H}_2\text{O}$; with 6.9 per cent. of ammonia, **nickel diamminorthoarsenate**, $\text{Ni}_3(\text{AsO}_4)_2(\text{NH}_3)_2 \cdot 6\text{H}_2\text{O}$; and with more conc. soln., **nickel triamminorthoarsenate**, $\text{Ni}_3(\text{AsO}_4)_2(\text{NH}_3)_3 \cdot 5\text{H}_2\text{O}$. When heated to dull redness, all these salts yield the anhydrous arsenate, but at 150° , $\text{Ni}_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$ yields $\text{Ni}_3(\text{AsO}_4)_2 \cdot 1\frac{1}{2}\text{H}_2\text{O}$; $\text{Ni}_3(\text{AsO}_4)_2 \cdot 7\text{H}_2\text{O} \cdot \text{NH}_3$ yields $\text{Ni}_3(\text{AsO}_4)_2 \cdot \text{H}_2\text{O} \cdot \frac{3}{4}\text{NH}_3$; $\text{Ni}_3(\text{AsO}_4)_2 \cdot 6\text{H}_2\text{O} \cdot 2\text{NH}_3$ yields $\text{Ni}_3(\text{AsO}_4)_2 \cdot \frac{1}{2}\text{H}_2\text{O} \cdot \frac{3}{4}\text{NH}_3$; and $\text{Ni}_3(\text{AsO}_4)_2 \cdot 5\text{H}_2\text{O} \cdot 3\text{NH}_3$ yields $\text{Ni}_3(\text{AsO}_4)_2 \cdot \frac{1}{2}\text{H}_2\text{O} \cdot \frac{1}{2}\text{NH}_3$.

C. Bergemann reported a green or brownish-green nickel ore from Johann-georgenstadt whose composition corresponded with **nickel dioxyarsenate**, $2\text{NiO} \cdot \text{Ni}_3(\text{AsO}_4)_2$, or $\text{Ni}_4\{\text{AsO}(\text{O} \cdot \text{NiO})\}_2$. M. Adam called it **aerugite**. Its hardness is 4. It dissolves in acids very slowly, and resembles xanthosite in many respects. J. F. L. Hausmann obtained monoclinic crystals approximating **nickel oxyarsenate**, $\text{NiO} \cdot \text{Ni}_3(\text{AsO}_4)_2$, as a furnace product by the oxidation of smaltite at a high temp. A. Coloriano prepared **nickel hydroxyarsenate**, $(\text{NiOH})\text{Ni}_3(\text{AsO}_4)_2$, by heating a conc. soln. of sodium arsenate and an excess of nickel nitrate in a sealed tube at 235° – 260° . The pale green stellate groups of needle-like crystals belong to the hexagonal system. They are insoluble in water, and only slightly attacked by acids. He also heated nickel with an excess of a conc. soln. of arsenic acid in a sealed tube at 160° , and obtained pale green, rhombic prisms of **nickel hydroarsenate**, $\text{NiHAsO}_4 \cdot \text{H}_2\text{O}$. They are soluble in water, are decomposed by acids with difficulty; and lose their water at a high temp. When the filtrate from a soln. of nickel carbonate in an excess of arsenic acid is heated to 235° in a sealed tube, pale green needles of **nickel dihydrotetraorthoarsenate**, $5\text{NiO} \cdot 2\text{As}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or $\text{Ni}_3(\text{AsO}_4)_2 \cdot 2\text{NiHAsO}_4 \cdot 2\text{H}_2\text{O}$, are formed. They are insoluble in water; and only slightly attacked by acids.

M. F. Heddle described a mineral resembling annabergite, but with about one-third the nickel replaced by calcium, forming **calcium nickel arsenate**, $(\text{Ni}, \text{Ca})_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$. It was obtained from Creetown, Scotland. J. H. Ferber described a **magnesium nickel arsenate**, $(\text{Ni}, \text{Mg})_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$, with a little ferrous and cobaltous oxides in place of the nickel oxide. It was obtained from Sierra Cabrera, Spain, and hence J. D. Dana called it **cabrerite**; it also occurs in the zinc mines of Laurium, Greece. It results from the oxidation of the arsenides of nickel and cobalt. Analyses were reported by J. H. Ferber, A. Frenzel, A. Sachs, and A. Damour and A. des Cloizeaux. A. de Schulten synthesized the crystals of

cabrerite by a method analogous to that employed for erythrite, and annabergite. Cabrerite appears in apple-green monoclinic crystals, and in masses with a fibrous, concentric, or radiated structure. It appears also reniform and granular. A. Sachs gave for the axial ratios $a : b : c = 0.82386 : 1 : 0.77677$ and $\beta = 106^\circ 29'$. A. Damour and A. des Cloizeaux found the optic axial angle for red light to be $2H = 105^\circ 30'$ to $112^\circ 20'$. E. S. Larsen found that $2V$ is nearly 90° . The optical character is negative. E. S. Larsen obtained for the indices of refraction $\alpha = 1.620$, $\beta = 1.654$, and $\gamma = 1.689$. F. Ulrich studied the optical properties of the mineral. The hardness is 2; and the sp. gr. by A. des Cloizeaux and A. Damour, 3.11; by A. Sachs, 3.0104; by A. Frenzel, 2.92; and by J. H. Ferber, 2.96. A. de Schulten gave 2.288 for the artificial crystals. It loses all its water between 100° and 400° . D. Forbes described what he called a hydrous dibasic arsenate of nickel and cobalt occurring at Atacama. G. A. Kenngott called it **forbesite**. The colour is greyish-white, and the mineral has a fibro-crystalline structure. D. Forbes' analysis corresponds with $2(\text{Ni}, \text{Co})\text{O} \cdot \text{As}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$, in agreement with **cobalt nickel hydroarsenate**, $(\text{Ni}, \text{Co})(\text{HASO}_4)_4 \cdot \text{H}_2\text{O}$. The hardness is 2.5; and the sp. gr. 3.086.

§ 24. The Arsenates of the Platinum Family

Very little is known about these compounds. According to T. Thomson,¹ sodium arsenate gives a yellowish-white precipitate of *rhodium arsenate* when added to a hot aq. soln. of sodium chlororhodate; J. J. Berzelius, a pale yellow precipitate of *palladious arsenate* from a neutral soln. of palladious nitrate; T. Thomson, a brown precipitate of *iridium arsenate* from a hot soln. of iridium chloride; and a pale brown precipitate of *platinic arsenate* from a soln. of platinic nitrate. D. Tivoli obtained platinic arsenate in red crystals by adding potassium chloroplatinate to a soln. of platinum hydroxyarsenide in aqua regia.

§ 25. The Fluorides of Arsenic

Arsenic was found by H. Moissan¹ to unite directly with fluorine at ordinary temp. and the mass became incandescent. The product of the reaction is a mixture of the two fluorides of arsenic— AsF_3 and AsF_5 . J. B. A. Dumas, in 1826, discovered **arsenic trifluoride**, AsF_3 , while studying the action of a mixture of sulphuric acid and calcium fluoride on arsenic trioxide. H. Moissan found that this process is usually the most convenient; he prepared the liquid by heating a mixture of 2 kgrms. of sulphuric acid, and a kilogram of a powdered mixture of equal weights of precalcined calcium fluoride and dry arsenic trioxide in a 4-litre glass retort. The trifluoride is condensed in a lead receiver cooled by ice-water, and rectified by distillation on a water-bath at 65° . The liquid is best preserved in a platinum bottle. O. Unverdorben employed a platinum or lead retort. R. W. E. MacIvor also used this process. The trifluoride is formed in a number of reactions; H. Moissan obtained it by the action of gaseous or liquid fluorine on arsenic trichloride; by the action of iodine pentafluoride on arsenic; and by the action of silver fluoride or lead fluoride on arsenic. P. Lebeau obtained it by the action of fluorine on the arsenides of the alkalis or alkaline earths; J. B. A. Dumas, by the action of anhydrous hydrogen fluoride on arsenic trioxide; and R. W. E. MacIvor, by the action of ammonium fluoride on arsenic tribromide.

At ordinary temp., arsenic trifluoride is a colourless, mobile liquid, which fumes in air. It has not a garlic odour, but smells like silicon tetrafluoride. It evaporates from the skin like ether, but leaves a painful burn like hydrofluoric acid. O. Unverdorben gave 2.73 for the sp. gr.; R. W. E. MacIvor, 2.66; H. Moissan, 2.734; and T. E. Thorpe, 2.6659 at $0^\circ/4^\circ$, and 2.4497 at the b.p. O. Masson, and J. A. Groshans studied the mol. vols. of the family of halides. H. Moissan found that the liquid forms a crystalline mass at -8.5° . O. Unverdorben gave 63° for the b.p.; R. W. E. MacIvor, $64^\circ-66^\circ$; H. Moissan, 63° at 752 mm.; and T. E. Thorpe, 64° at 760 mm. According to T. E. Thorpe, the thermal expansion between 0° and 65° is given by $v=1+0.001443\theta+0.00297\theta^2$, when v is the vol. at 0° . When the gas is heated in a glass vessel, it decomposes and attacks the glass: $4\text{AsF}_3+3\text{SiO}_2=3\text{SiF}_4+2\text{As}_2\text{O}_3$. H. Moissan said that the liquid is a bad conductor of electricity, but it can be electrolyzed, giving a deposit of arsenic at the cathode, and at the cathode evolving a gas which attacks platinum. Liquid arsenic trifluoride reddens blue litmus, but only when a trace of moisture is present. O. Unverdorben said that it mixes with **water** with a small rise of temp., forming a clear liquid which attacks zinc and tin slightly, and glass readily. J. B. A. Dumas found that the trifluoride is immediately decomposed by water, forming hydrofluoric acid and arsenic trioxide; and J. J. Berzelius thought that the arsenic trioxide reacts with the hydrofluoric acid, forming *hydrofluarsenic acid*, which reacts with bases to form salts—*fluoarsenates*. H. Moissan found that arsenic trifluoride reacts with **bromine**, forming a crystalline substance; and the liquid dissolves **iodine**, forming a purple-red soln. It does not react in the cold with **sulphur chloride**; but with **thionyl-chloride**, H. Moissan and P. Lebeau symbolized the reaction: $2\text{AsF}_3+3\text{SOCl}_2=3\text{SOF}_2+2\text{AsCl}_3$. O. Unverdorben found that arsenic trifluoride unites with **ammonia**, forming a white powder; ammonium carbonate can be used in place of ammonia. A. Besson also made this compound by vaporizing the trifluoride in an atm. of ammonia and showed that it is **arsenic triamminotrifluoride**, $\text{As}(\text{NH}_3)_3\text{F}_3$. O. Unverdorben represented its composition by $2\text{AsF}_3.5\text{NH}_3$, and said that it can be sublimed without decomposition, that it can be dissolved in boiling water, and recrystallized from the soln. on cooling. A. Besson, however, found that the compound is decomposed by water. According to A. Besson, **phosphine** reacts: $\text{AsF}_3+\text{PH}_3=3\text{HF}+\text{AsP}$. R. W. E. MacIvor, and H. Moissan found that with **phosphorus trichloride** there is a simple exchange of halogens: $\text{PCl}_3+\text{AsF}_3=\text{AsCl}_3+\text{PF}_3$; T. E. Thorpe observed an analogous reaction with **phosphorus pentachloride**: $3\text{PCl}_5+5\text{AsF}_3=5\text{AsCl}_3+3\text{PF}_5$; with **thiophosphoryl**

chloride, T. E. Thorpe and J. W. Rodger observed a similar reaction: $\text{PSCl}_3 + \text{AsF}_3 = \text{AsCl}_3 + \text{PSF}_3$. H. Moissan said that arsenic trifluoride does not react with **carbon tetrachloride** in the cold. O. Unverdorben said that the trifluoride may be mixed with more or less decomposition with **alcohol**, and **ether**; and somewhat less readily with fixed and volatile **oils**. He also said that the trifluoride can be kept in **glass** vessels in which it slowly develops silicon fluoride—*vide supra*—it may also be evaporated without decomposition in glass vessels to which air has not access, but when exposed to air, the moisture reacts so that arsenic trioxide is left behind. At a dull red-heat, it acts on glass: $3\text{SiO}_2 + 4\text{AsF}_3 = 3\text{SiF}_4 + 2\text{As}_2\text{O}_3$; H. Moissan represented the reaction with **silicon tetrachloride**: $3\text{SiCl}_4 + 4\text{AsF}_3 = 4\text{AsCl}_3 + 3\text{SiF}_4$; and O. Ruff and K. Albert found that it reacts vigorously with **silico-chloroform** at ordinary temp. There are two simultaneous reactions one of which involves a simple exchange of halogens: $\text{AsF}_3 + \text{SiHCl}_3 = \text{AsCl}_3 + \text{SiHF}_3$, and the other reaction is symbolized: $4\text{AsF}_3 + 3\text{SiHCl}_3 = 3\text{SiF}_4 + 2\text{AsCl}_3 + 2\text{As} + 3\text{HCl}$. O. Unverdorben said that arsenic trifluoride has scarcely any action on **zinc** and **tin**, or on **calcium carbonate**.

H. Moissan found that arsenic trifluoride absorbs fluorine and becomes warm; and O. Ruff and H. Graf prepared **arsenic pentafluoride**, AsF_5 , by the action of bromine and antimony pentafluoride on arsenic trifluoride: $2\text{SbF}_5 + \text{AsF}_3 + \text{Br}_2 = 2\text{SbBrF}_4 + \text{AsF}_5$, in a platinum vessel, or in a well-dried glass vessel using dried reagents. The apparatus should be in one piece. 0.2 mol of well-cooled pentafluoride and 0.1 mol of arsenic trifluoride are mixed at -20° with 0.25 mol of bromine. The retort is cooled by liquid air until it is fitted with a reflux condenser, etc. The retort is then warmed for half an hour on a water-bath at 55° . The arsenic pentafluoride collected in the well-cooled receiver is mixed with some bromine. To remove the bromine, the gas is passed over molten sulphur.

At ordinary temp., arsenic pentafluoride is a colourless gas with a vap. density in agreement with a mol. wt. 172.3–173—when the calculated value is 170.25. At -53° and 760 mm. it forms a pale yellow liquid, and at -80° , it freezes to a white solid. The gas gives a dense white fume when exposed to **air**. It dissolves in **water** and alkali-lye with the development of heat. It reacts with **iodine** in the cold; and slowly reacts with **sulphur** in the cold. O. Ruff found that **arsenic nitrosyl hexafluoride**, $\text{AsF}_5 \cdot \text{NOF}$, is obtained by passing **nitrosyl fluoride** through cooled arsenic trichloride until absorption is complete, the product being finally kept over fused sodium hydroxide in a vacuum for some time to absorb traces of nitrosyl chloride. The compound forms a white, crystalline mass, and is remarkably stable; it is unaffected in dry air even at a high temp., but decomposes in moist air; it is split up by water, by alkali, and by conc. hydrochloric acid, but is unacted on by phosphorus trichloride, carbon tetrachloride, silicon, copper, and lead. On warming gently with antimony pentafluoride, arsenic pentafluoride, and antimony nitrosyl hexafluoride are formed; with **phosphorus** it produces a little phosphorus trifluoride; and it dissolves in **arsenic trifluoride** developing a little heat—the gas escapes from the liquid when warmed. The gas is absorbed by **alcohol**, **ether**, and **benzene** with warming; **turpentine** vapour gives a black cloud in contact with the gas; dry **paper**, and **sugar** are not altered, but they are rapidly carbonized if moist; and **paraffin**, and **wax** are gradually blackened. In the cold, the gas does not react with **silicon**, but when heated, arsenic and silicon tetrafluoride are formed; when heated with dry **glass**, silicon tetrafluoride and probably arsenic pentoxide are produced. There is no reaction with **copper** in the cold, but the metal is blackened if heated; **zinc**, **mercury**, **lead**, **bismuth**, and **iron** form fluorides; **tungsten** is not attacked.

J. C. G. de Marignac prepared **potassium hexafluoroarsenate**, $\text{KF} \cdot \text{AsF}_5 \cdot \frac{1}{2} \text{H}_2\text{O}$, in small rhombic crystals, by evaporating a soln. of potassium arsenate in hydrofluoric acid. The axial ratios of the crystals are $a : b : c = 0.8401 : 1 : 2.5172$. The crystals are fairly stable when dry; they are decomposed by water, forming an oxyfluoride (*vide infra*); and they melt when heated, giving off water and hydrogen

fluoride. If a soln. of this salt, or of the oxyfluoride, in an excess of hydrofluoric acid and potassium fluoride, be evaporated, rhombic crystals of **potassium heptafluoroarsenate**, $2\text{KF} \cdot \text{AsF}_5 \cdot \text{H}_2\text{O}$, are formed; they have the axial ratios $a : b : c = 0.8847 : 1 : 0.6453$; and are stable in dry air. The corresponding **ammonium hexafluoroarsenate** was only obtained as a gum-like mass. H. von Helmont found that arsenic trioxide readily dissolves in a boiling soln. of ammonium fluoride, but on cooling the arsenic trioxide separates from the soln.

A compound of **arsenic oxyfluoride** or **arsenyl fluoride**, AsOF_3 , with potassium arsenate was reported by J. C. G. de Marignac, but the oxyfluoride itself has not been prepared. If potassium hexafluoroarsenate be crystallized from its aq. soln., or if potassium arsenate be dissolved in a dil. soln. of hydrofluoric acid, and the soln. crystallized, rhombic plates of **potassium oxytetrafluoroarsenate**, $\text{KF} \cdot \text{AsOF}_3 \cdot \text{H}_2\text{O}$, are formed. By repeatedly crystallizing potassium heptafluoroarsenate from its aq. soln., or by crystallizing a soln. of the oxytetrafluoroarsenate from dil. hydrofluoric acid, a crystalline mass of **potassium oxydodecafluoroarsenate**, $4\text{KF} \cdot \text{AsF}_5 \cdot \text{AsOF}_3 \cdot 3\text{H}_2\text{O}$, is produced. The right to the recognition of this product as a chemical individual has not been established.

§ 26. The Chlorides of Arsenic

In 1648, J. R. Glauber¹ described the preparation of *butyrum arsenici*—*butter of arsenic*—by heating in a retort a powdered mixture of one part of white arsenic, two parts of common salt, and four parts of vitriol calcined white. A thick oil was collected in the receiver. N. Lemery obtained it by distilling a mixture of equal parts of white arsenic and corrosive sublimate. J. H. Pott, and T. Bergman found that white arsenic does not give so good results as arsenic itself. J. Davy's analysis showed that butter of arsenic is really **arsenic trichloride**, AsCl_3 . It is doubtful if *arsenic pentachloride*, AsCl_5 , has ever been isolated, and a similar remark applies to *arsenyl chloride*, AsOCl .

Arsenic trichloride can be obtained by chlorinating arsenic, arsenic tri- or penta-oxide, or arsenic sulphide. 1. *By chlorinating arsenic (q.v.)*.—As previously indicated, powdered arsenic readily burns when projected in chlorine gas. J. B. A. Dumas² recommended making arsenic trichloride by the action of chlorine on arsenic contained in a retort. The neck of the retort was connected with a receiver cooled by a freezing mixture. The product was purified from the excess of chlorine by distillation from pulverized arsenic. B. H. Jacobson found the reaction accelerated if a trace of bromine be present, as well as alkali halide. E. W. Wescott also produced arsenic trichloride by treating arsenic ores with chlorine. Boiling hydrochloric acid slowly converts arsenic into the trichloride, and, as shown by R. Napoli, and A. Ditte and R. Metzner, particularly in the presence of oxygen. The trichloride is formed by the action of arsenic on numerous chlorides; thus M. Chevrier, and G. Oddo and E. Serra

produced it by the action of arsenic on sulphur monochloride; K. Heumann and P. Köchlin, on chlorosulphonic acid or sulphuryl chloride; F. Selmi, ammonium chloride; A. Baudrimont, and B. Reinitzer and H. Goldschmidt, phosphorus pentachloride, or phosphoryl chloride; L. D. l'Hôte, magnesium chloride; O. Ruff and K. Staib, aluminium chloride at 120° ; and F. Selmi, H. Capitaine, and H. Ludwig prepared the trichloride by heating arsenic with six times its weight of mercuric chloride. 2. *By chlorinating arsenic trioxide (q.v.)*.—R. Weber, and C. L. Bloxam said that chlorine converts heated arsenic trioxide into arsenic trichloride and pentoxide. J. Davy made arsenic trichloride by heating a mixture of sulphuric acid and a sat. soln. of arsenic trioxide in conc. hydrochloric acid. Various modifications of this process have been used by W. Wallace and F. Penny, A. Negri, W. Böttger, etc. W. Wallace and F. Penny also passed dry hydrogen chloride over arsenic trioxide; J. B. A. Dumas heated arsenic trioxide with sodium chloride and sulphuric acid, and F. Selmi substituted lead chloride for the sodium chloride. Other chlorinating agents can be used with arsenic trioxide. Thus, H. Prinz, R. C. Smith, and G. Oddo and E. Serra used sulphur monochloride; V. de Luynes, ammonium chloride; A. Michaelis, phosphorus trichloride; L. Hurtzig and A. Geuther, phosphorus pentachloride; B. Reinitzer and H. Goldschmidt, phosphoryl chloride; and G. Rauter, silicon tetrachloride. L. H. Milligan and co-workers found that if carbonyl chloride be passed over a heated mixture of arsenic trioxide with 20 per cent. of carbon, at 200° - 260° , an almost quantitative yield of arsenic trichloride is obtained. G. Oddo and U. Giarchery prepared the trichloride by passing chlorine over a heated mixture of sulphur and arsenic trioxide. 3. *By chlorinating arsenic pentoxide (q.v.)*.—R. Weber showed that chlorine forms arsenic trichloride when passed over strongly heated arsenic pentoxide; and H. Rose, that hydrochloric acid will reduce arsenic acid to the volatile chloride. H. Rose, and J. von Liebig and F. Wöhler obtained a similar result by treating arsenic acid or an alkali arsenate with sodium chloride and sulphuric acid. The reducing action of hydrochloric acid or hydrogen chloride on arsenic acid has been studied by C. R. Fresenius and A. Souchay, K. Röhre, and J. Mayrhofer. E. Fischer showed that the reaction is greatly accelerated in the presence of ferrous chloride; A. Classen and R. Ludwig, in the presence of ferrous sulphate; F. A. Gooch and E. W. Danner, potassium iodide; F. A. Gooch and I. K. Phelps, potassium bromide; W. Böttger, hydrobromic acid; C. Friedheim and P. Michaelis, and L. Duparc and L. Ramadier, methyl alcohol; and W. Böttger, pyrogallol. Under these circumstances arsenic can be completely removed from a soln., and the process is utilized in analytical work for the separation from antimony, and tin—*vide supra*, arsenic trioxide, and arsenic acid. F. Hufschmidt showed that a current of hydrogen chloride through the liquid also favours the volatilization of the trichloride. H. Rose found that arsenic trichloride can be removed from alkali arsenates or arsenic acid by repeatedly heating them with ammonium chloride; L. Hurtzig and A. Geuther, by heating them with phosphorus pentachloride, but not, according to A. Michaelis, with phosphorus trichloride. 4. *By chlorinating arsenic sulphide (q.v.)*.—L. N. Nilson converted arsenic di-, or tri-sulphide into the trichloride by heating it in a current of chlorine. For the action of hydrochloric acid, and hydrogen chloride, *vide infra*, arsenic sulphides. T. Reackher, A. Fyfe, E. R. Schneider, and J. Clark found that the presence of ferric chloride facilitates the chlorination of the sulphide by hydrochloric acid. C. R. Fresenius treated the sulphide with a mixture of ammonium chloride and nitrate; A. Baudrimont chlorinated the heated sulphide with sulphur monochloride; H. Ludwig, with mercuric chloride; and C. F. Rammelsberg, with cuprous chloride, or potassium antimonyl tartrate and hydrochloric acid. R. Napoli's observations on the action of conc. hydrochloric acid on arsine; and T. E. Thorpe's on the action of phosphorus pentachloride, etc., on arsenic trifluoride, have been previously discussed.

Arsenic trichloride, at ordinary temp., is a transparent, colourless, oily liquid, which fumes in air. It was analyzed by J. Davy, J. Mayrhofer, L. N. Nilson,

W. Wallace and F. Penny,³ and K. Heumann and P. Köchlin. The results are in agreement with the empirical formula AsCl_3 . J. B. A. Dumas found the **vapour density** to be 6.301 in agreement with 6.27, calculated for AsCl_3 . H. Henstock discussed the electronic structure of the family of trihalides. According to P. Walden, the mol. wt. calculated from the f.p. of nitrobenzene is 127 instead of 180. L. Kahlenberg and A. T. Lincoln obtained a normal value. J. I. Pierre gave 2.205 for the **specific gravity** of the liquid at 0° ; W. Wallace and F. Penny, 2.1766; H. Becquerel, 2.172; A. Stiefelhagen, 2.205; A. Haagen, 2.1668 at 20° ; and T. E. Thorpe, 2.2050 at $0^\circ/4^\circ$, and 1.91813 at the b.p. E. Rabinowitsch gave 92.4 for the mol. vol.; and O. Masson, and J. A. Groshans studied the mol. vols. of the family of halides. F. M. Jäger found the sp. gr., D , of the liquid at different temp., referred to water at 4° , can be represented by $D=2.20511-0.001856\theta-0.0_527\theta^2$; I. I. Saskowsky found the ratio of the mol. vol. to the at. vols. of the constituent elements to be 1.33. F. M. Jäger's observed results for the sp. gr. are indicated below along with values for the **specific cohesion**, a^2 in sq. mm.; the **surface tension**, σ , in dynes per cm.; and the mol. **surface energy** in ergs per sq. cm.; in an atm. of nitrogen,

	-21.0°	0.0°	20.8°	50.2°	75.7°	110.0°
Sp. gr. . . .	2.245	2.205	2.165	2.105	2.051	1.968
a^2	3.98	3.83	3.71	3.54	3.40	3.21
σ	43.8	41.4	39.4	36.6	34.2	31.0
μ818.4	782.0	754.3	713.9	678.8	632.4

R. Lorenz and W. Herz studied some relationships of the surface tensions of the family of halides. J. B. A. Dumas gave 132° for the **boiling point**; J. I. Pierre, 133.5° at 756.9 mm.; P. Walden, 129° at 752 mm.; F. M. Jäger, 130.5° at 757 mm.; W. Biltz and E. Mienecke, between 130.1° and 130.3° at 758 mm.; A. Haagen, 128° at 754 mm.; G. P. Baxter and co-workers, 129.6° at 760 mm.; C. G. Maier, 121.9° ; and T. E. Thorpe, 130.2° at 760 mm. N. de Kolossowsky gave 6.48 to 7.25 for the **ebulliscope constant**. G. P. Baxter and co-workers found the **vapour pressure** of arsenic trichloride at 0° to be 2.44 mm.; at 25° , 11.65 mm.; at 35° , 19.53 mm.; at 50° , 40.90 mm.; and at 100° , 301 mm. The results at θ° can be represented by $\log p=7.5183-1270(241.2+\theta)^{-1}$ mm. C. G. Maier gave for the vap. press., p , in mm. of mercury:

p	8.7°	27.1°	49.5°	61.1°	83.4°	101.1°	121.0°	122.0°	124.0°
	21.7	29.7	90.4	145.1	270.6	452.2	749.1	776.0	798.9

A. Besson said that the trichloride freezes at -18° with a marked decrease in vol., forming acicular crystals. E. Haase gave -16° for the **melting point** of the solid; F. M. Jäger, -13° ; C. Baskerville and H. H. Bennett, -18° ; and W. Biltz and E. Meinecke, -16° ; W. R. Smith and J. E. Hora, -16.2° —*vide* Fig. 34. J. I. Pierre represented the **thermal expansion** between -14.9° and 130.2° by $v=1+0.00097907\theta+0.0_696695\theta^2+0.0_817772\theta^3$ when the vol. is unity at 0° . T. E. Thorpe gave $v=1+0.000991333\theta+0.0_684914\theta^2+0.0_227551\theta^3$. H. V. Regnault found the **specific heat** of the vapour to be 0.11224; and of the liquid, 0.17604, and the **heat of vaporization**, 69.741 cal. G. P. Baxter and co-workers calculated 7.42 Cals. per mol for the heat of vaporization at 0° ; 7.29 Cals. at 50° ; and 6.68 Cals. at 100° . C. G. Maier gave 7.63 Cals. per mol; and E. Beckmann, 44.51 cal. per gram. N. de Kolossowsky studied the relation between the thermal expansion and the heat of vaporization. C. M. Guldberg estimated 356.0° for the **critical temperature**. J. Thomsen gave 71.39 Cals. for the **heat of formation** of the liquid; M. Berthelot, 69.40 Cals.; and M. Berthelot and W. Louguinine, 74.6 Cals. According to A. Haagen, the **index of refraction** is 1.592 for red light; 1.6123, for green light; and 1.6243, for violet light. A. Stiefelhagen gave for the index of refraction, μ , for the wave-length $\lambda=274\mu$, 1.781; for $\lambda=298$, 1.73023; for $\lambda=394$, 1.64540; for $\lambda=480$, 1.61949; for $\lambda=589$, 1.60395; and for $\lambda=768$, 1.59262. He also

gave $\mu^2=1.82577+0.66457\lambda^2(\lambda^2-(195.71)^2)^{-1}$. A. Haagen found the **specific refraction** to be 0.2732; and the **refraction equivalent**, 49.50. A. K. Macbeth and N. I. Maxwell measured the **absorption of light** by a 0.01*N*-soln. of arsenic trichloride in *N*-HCl, and found the mol. extinction coeff. had a range from 5 to 30 in passing from light of wave-length $\lambda=357$ to $\lambda=227$. K. Natterer examined the **electrical conductivity** of the vapour; and H. Buff found that if the liquid is free from moisture, it is a very bad electrical conductor. P. Walden said that the liquid has a small but appreciable conductivity of about 0.0000124 mho, and he suggested that it ionizes: $\text{AsCl}_3 \rightleftharpoons \text{AsCl}_2^+ + \text{Cl}^-$; or $\text{AsCl}_3 \rightleftharpoons \text{AsCl}^{++} + 2\text{Cl}^-$; or $\text{AsCl}_3 \rightleftharpoons \text{As}^{+++} + 3\text{Cl}^-$. According to L. Kahlenberg and A. T. Lincoln, the conductivity of a soln. of the trichloride in acetic ether is $\mu_{1.8}=0.087$, and $\mu_{4.8}=0.097$; and in nitrobenzene, $\mu_{8.48}=0.026$, and $\mu_{16.9}=0.042$. The soln. in dry benzene has no appreciable conductivity and yet it gives an immediate precipitation of cupric chloride with a soln. of cupric oleate in benzene. This is taken to show that ionization is not a necessary prelude to chemical reactions in soln. G. N. Guam and J. A. Wilkinson found that arsenic halide dissolved in liquid hydrogen sulphide is a conductor. P. Walden gave 0.0511 mho for the sp. conductivity at 0°; and W. Biltz and W. Klemm, 0.0430 for the eq. conductivity. G. Hänsel found the following equilibrium values for the electrode potentials $\text{As} | 0.33N\text{-AsCl}_3$ in 3*N*-NaCl, 0.3 volt; and in 3*N*-HCl, 0.305 volt. W. Finkestein found the **decomposition voltage** of arsenic trichloride in nitrobenzene soln. to be 0.78 volt. P. Walden said that arsenic trichloride is a good ionizing solvent for binary salts, but not for cobalt iodide and strong acids like tribromoacetic acid. He found the **dielectric constant** to be 12.8; and H. Schlundt gave 12.35 at 21°.

According to A. Besson and L. Fournier,⁴ when a mixture of arsenic trichloride and **hydrogen** is submitted to the electric discharge, the brown deposit which forms on the tube has the composition As_{11}Cl , and was thought to be a mixture of arsenic and an unknown *arsenic subchloride*. M. Berthelot showed that when the vap. of arsenic trichloride is mixed with **oxygen**, and passed through a red-hot tube, it decomposes into chlorine and an oxychloride. According to W. Wallace and F. Penny, a mol. of arsenic trichloride requires 9 mols. of **water** for its soln., and the liquid has the sp. gr. 1.53; if another 9 mols. of water be added, the sp. gr. is 1.346; a little water changes arsenic trichloride into the oxychloride (*vide infra*), and with an excess of water, there is finally produced arsenious and hydrochloric acids. If enough water be added some arsenic trioxide may be deposited from the liquid. J. Thomsen gave for the heat of the reaction $\text{AsCl}_3 + \text{Aq.} = \text{H}_3\text{AsO}_3\text{aq.} + 3\text{HCl}_{\text{aq.}}$ +17.6 Cals. A similar soln. is obtained by treating arsenic trioxide with hydrochloric acid. It is assumed that some arsenic chloride is present because more arsenic trioxide is dissolved by the acid than by water. As shown by A. Dupasquier, the liquid is volatile without residue, and hence when arseniferous hydrochloric acid is distilled, the arsenic collects in the distillate. This is the basis of a well-known analytical method of separating arsenic from antimony and tin—*vide supra*, action of hydrochloric acid on arsenic acid, and on arsenic trioxide. H. Moissan found that arsenic trichloride is vigorously attacked by **fluorine**—*vide* arsenic trifluoride. J. V. Janowsky, and J. Mayrhofer found that arsenic trichloride at a low temp. dissolves much **chlorine** which it gives off again at a higher temp., or by the passage of an inert gas like air. B. E. Sloan showed that at -23° , arsenic trichloride dissolves sufficient chlorine to give an at. ratio $\text{As} : \text{Cl} = 1 : 4.45$, and at higher temp. the dissolved chlorine is slowly given off, but there is no evidence of the formation of a pentachloride. A. Besson found that arsenic trichloride carefully purified from excess of chlorine solidifies at -18° with very considerable contraction, and crystallizes in white, nacreous needles. If, however, the chloride is sat. with chlorine at 0°, the product does not solidify above -30° , but at this temp. it freezes with very great contraction. At -30° the arsenic trichloride will absorb a much larger quantity of chlorine, yielding a yellow liquid which does not solidify at -60° . If this liquid, cooled to -50° , is thrown into water, a large vol. of chlorine is liberated,

and the soln. contains arsenious acid and not arsenic acid; it follows that no arsenic pentachloride is formed. If liquid chlorine at -35° is brought in contact with arsenic trichloride at the same temp., and the temp. is allowed to rise slowly, the arsenic trichloride melts, and the two liquids gradually mix by diffusion without any development of heat or any other evidence of combination.

J. B. A. Dumas argued that when a large excess of dry chlorine is brought in contact with powdered arsenic, besides arsenic trichloride there is formed a small quantity of a white crystalline substance which was thought to be arsenic pentachloride, $AsCl_5$. H. Capitaine, however, showed that if the chlorine be very thoroughly dried, the alleged pentachloride is not produced. The white crystals obtained by J. B. A. Dumas were those of arsenic trioxide proceeding from traces of moisture in the inadequately dried gas. H. Rose also obtained nothing but the trichloride when arsenic is treated with an excess of chlorine. Nevertheless, C. Baskerville and H. H. Bennett said that arsenic pentachloride is produced when about 5 c.c. of purified arsenic trichloride, in a dry test-tube, are cooled by solid carbon dioxide loosely packed in a Dewar bulb, and sat. with chlorine. The crystalline trichloride assumes a greenish-yellow colour and becomes liquid. After distilling off the excess of chlorine at $+31^{\circ}$, the residual liquid has the composition $AsCl_5$. Arsenic pentachloride is readily soluble in carbon disulphide and ether at -30° , and either crystallizes from these solvents, or solidifies alone at about -40° in yellow prisms. When heated above -25° , it begins to decompose, and on exposure to the air it evolves fumes of hydrogen chloride. The alleged pentachloride is only a mixture. For A. W. Cronander's complex $AsCl_5 \cdot PCl_5$, *vide infra*.

Results in opposition to those of C. Baskerville and H. H. Bennett, and in agreement with those of A. Besson, and B. E. Sloan were obtained by W. R. Smith and J. E. Hora by measuring the f.p. of mixtures of liquid chlorine and arsenic trichloride, and the results of W. Biltz and E. Meinecke are summarized in Fig. 34. There is no sign of a singular point on the curve as would be anticipated if a definite compound were produced under these conditions. The crystals obtained by freezing a mixture corresponding with the pentachloride consist of arsenic trichloride contaminated with liquid chlorine. The subject was discussed by W. Biltz and K. Jeep, and E. Kordes. A. G. Page observed that the presence of arsenic trichloride shows no signs of the stimulating action observed by some agents on the chlorination of organic compounds.

T. Karantassis studied the interchange of the halogens—chlorine, bromine, and iodine. B. E. Sloan found that iodine readily dissolves in arsenic trichloride, the amount rapidly increasing with rise of temp. The surplus iodine separates out in crystals as the soln. is cooled; 100 parts of the trichloride retain 8.42 parts of iodine at 0° , 11.88 parts at 15° , and 36.89 parts at 90° . There is no evidence of the formation of *arsenic diiodotrichloride*, although F. Gramp claimed to have made red crystals of a compound of the three elements by heating arsenic trichloride with iodine at 100° . W. Wallace and F. Penny found that arsenic trichloride is soluble in conc. hydrochloric acid, and when the soln. is treated with sulphuric acid an oily liquid is precipitated—*vide supra*. W. D. Treadwell and C. Mussler found that 100.3 grms. of arsenic trichloride can be dissolved by a litre of conc. hydrochloric acid at 100° . P. Hautefeuille found that hydriodic acid reacts with arsenic trichloride with the development of heat, forming arsenic triiodide and hydrochloric acid. B. Köhlein said that ethyl iodide behaves similarly; and H. L. Snape found that potassium iodide and arsenic trichloride form arsenic triiodide when heated in a sealed tube at 240° . E. Bamberger and J. Philipp also showed that potassium iodide forms arsenic triiodide when treated with a hydrochloric acid soln. of arsenic trioxide.

FIG. 34.—Freezing Points of Mixtures of Arsenic Trichloride and Chlorine.

According to P. Walden, arsenic trichloride dissolves many inorganic salts; and E. Beckmann found arsenic trichloride can be used as a solvent for the ebullioscopic method of determining mol. wts. He used it for sulphur, etc. The ebullioscopic constant is 7.25. Thus, potassium iodide or **rubidium iodide**, **tetramethylammonium** or **tetraethylammonium iodide**, and **trimethyl thioiodide** dissolve in the cold, and when warmed, the soln. becomes yellow, or violet. The soln. with **mercuric iodide**, or **antimony triiodide**, is colourless; with **cobalt iodide**, violet; with sublimed **ferrous chloride**, yellow; and with **arsenic triiodide**, yellow. According to H. L. Snape, **potassium bromide** heated in a sealed tube with arsenic trichloride at 180°–200° forms some arsenic tribromide: $\text{AsCl}_3 + 3\text{KBr} = 3\text{KCl} + \text{AsBr}_3$. L. Lindet observed that in the presence of hydrochloric acid, **stannous chloride** reduces the trichloride to arsenic, while **gold chloride** is dissolved without decomposition. The reaction with stannous chloride has been discussed in connection with allotropic arsenic. J. Davy said that hot arsenic trichloride copiously dissolves **sulphur**, and deposits the greater part on cooling. G. Vortmann and C. Padberg found that acidic soln. of arsenic trichloride are not altered by boiling with sulphur. L. Ouvrard found that **hydrogen sulphide** reacts with liquid arsenic trichloride, forming a series of thiochlorides (*q.v.*); F. Hurter, that the vap. of the trichloride is not attacked by hydrogen sulphide. According to W. Biltz and E. Keunecke, dry, liquid hydrogen sulphide thiohydrolyzes arsenic trichloride; and, added O. Ruff, the hydrogen sulphide does not act on the boiling liquid, but if a little aluminium chloride be present, hydrogen chloride and arsenic trisulphide are formed; and, working at a high temp., H. Arctowsky obtained the trisulphide in a crystalline form. G. N. Guam and J. A. Wilkinson, and A. W. Ralston and J. A. Wilkinson found the sp. conductivity of a sat. soln. of the arsenic trichloride in liquid hydrogen sulphide to be 11.510×10^7 mhos. N. R. Dhar found that the reaction between a **thiosulphate** and salts of antimony has an induction period dependent on the temp. and conc. of the soln. C. Hugot, and G. Gore observed that liquid **ammonia** reacts with arsenic trichloride. According to J. Persoz, ammonia is rapidly absorbed by arsenic trichloride forming a white or pale yellow solid, which has the composition $\text{AsCl}_3 \cdot 4\text{NH}_3$; H. Rose said $\text{AsCl}_3 \cdot 3\frac{1}{2}\text{NH}_3$, and A. Besson, $\text{AsCl}_3 \cdot 4\text{NH}_3$, *i.e.* **arsenic tetramminotrichloride**. L. Pasteur represented it by the formula $2\text{As}(\text{NH})\text{Cl} \cdot 4\text{NH}_4\text{Cl}$; and C. Hugot suggested this alleged ammine is really a mixture of ammonium chloride and arsenic triamide (*q.v.*). L. Pasteur said that when the ammine is heated, ammonia is first given off, then the undecomposed compound, and finally ammonium chloride; it dissolves in water with the evolution of heat, and the loss of ammonia, and the residue obtained on evaporation contains $\text{As}_4\text{N}_2\text{Cl}_2 \cdot 10\text{O}_7$. H. Rose said that ammonia in the aq. soln. is only partially precipitated by hydrochloroplatinic acid; and, added L. Pasteur, hot water decomposes the ammine into ammonia, ammonium chloride, and arsenic trioxide. J. von Liebig and F. Wöhler said that conc. sulphuric acid expels ammonia from the ammine; and aq. ammonia, said L. Pasteur, converts it into ammonium metarsenite. The tetrammine formed at -20° , when distilled in vacuo at 200° , was found by A. Besson and G. Rosset to pass into **arsenic hemiheptamminotrichloride**, $\text{AsCl}_3 \cdot 3\frac{1}{2}\text{NH}_3$ —*vide* arsenic imides. A. Ferratini found that when arsenic trichloride, in alcoholic soln., is boiled with **hydrazine hydrochloride**, a complex salt, **hydrazine arsenochloride**, is formed, but could not be isolated in a pure state. A. C. Vournazos obtained the complex **sodium arsenooctoazidotrichloride**, $\text{Na}_8[\text{AsCl}_3(\text{N}_3)_8]$. A. Geuther found that **nitrogen peroxide** oxidizes arsenic trichloride, forming arsenic pentoxide, and nitrogen oxychlorides. O. C. M. Davis found that **nitrogen sulphide**, N_4S_4 , does not form a compound with arsenic trichloride. J. Davy showed that warm arsenic trichloride in the cold dissolves **phosphorus**, without becoming luminous, and deposits most of the phosphorus on cooling; O. Ruff said that phosphorus does not react with arsenic trichloride, but if a little aluminium chloride be present, arsenic oxyphosphide, As_4PO_2 , is formed. The reaction was studied by O. Ruff and K. Staib—*vide infra*.

W. Finkelstein found that yellow phosphorus, **antimony**, and **bismuth** precipitate arsenic from a soln. of the trichloride in nitrobenzene. According to A. Besson, and J. V. Janowsky, **phosphine** reacts with the trichloride: $\text{AsCl}_3 + \text{PH}_3 = 3\text{HCl} + \text{AsP}$. A. W. Cronander found that with **phosphorus pentachloride** unstable complex **arsenic phosphotrichloride**, $\text{PCl}_5 \cdot \text{AsCl}_3$, and **arsenic phosphodecachloride**, $\text{AsCl}_5 \cdot \text{PCl}_5$, are produced. A. Geuther observed that **phosphorus trichloride** reduces arsenic trichloride to arsenic (*q.v.*); while T. Karantassis observed that **phosphorus triiodide** reacts with arsenic trichloride by double decomposition, but the reverse reaction does not occur. J. V. Janowsky, R. Engel, and J. Thiele found that the trichloride is reduced to arsenic by **hypophosphorous acid**, and by **phosphorous acid**. J. V. Janowsky found that **arsine** decomposes the trichloride: $\text{AsCl}_3 + \text{AsH}_3 = 3\text{HCl} + 2\text{As}$. W. Wallace and F. Penny, and L. Hurtzig and A. Geuther, noted that the trichloride dissolves **arsenic trioxide**, forming the oxychloride; and L. Ouvrard, that **arsenic trisulphide** converts the trichloride into thiochlorides.

J. Tarible found that **boron bromide** reacts with the trichloride: $\text{AsCl}_3 + \text{BBr}_3 = \text{BCl}_3 + \text{AsBr}_3 + 25 \text{ cal.}$ O. A. Dafert found that **acetylene** does not react to any considerable extent with arsenic trichloride at the ordinary temp. or at the b.p. of the latter; in the presence of anhydrous aluminium chloride at the ordinary temp., however, **arsenic diacetylenotrichloride**, $\text{AsCl}_3 \cdot 2\text{C}_2\text{H}_2$, is formed as a heavy oil of sp. gr. 1.6910 at 15°, and b.p. 250°. F. Oberhauser studied the reaction with **cyanogen bromide**. According to P. Walden, arsenic trichloride dissolves many organic compounds—*e.g.* **hydrocarbons**, **organic acids**, **ketones**, **esters**, **tertiary bases**, etc.—**quinoline** gives a colourless soln.; and **dimethylaniline**, a yellowish-green liquid. H. Schiff, A. R. Leeds, and H. Grossmann prepared complex salts with **aniline**, and with quinoline. V. de Luynes said that absolute **alcohol**, and **ether** mix readily with the trichloride, and the soln. becomes warm. J. Davy found that the trichloride dissolves **turpentine**, **olive oil**, and **resin**. M. Centnerszwer found that the trichloride dissolves in liquid **cyanogen**; J. Davy, that it dissolves ten times its vol. of **carbonyl chloride**, which is again set free on mixing the liquid with water; G. Gustavson, that arsenic trichloride and **carbon tetrabromide** slowly react in a sealed tube at 150°–200° converting about 72 per cent. of the trichloride into tribromide in about 60 days; and P. Miquel, that metal **thiocyanates** react, forming a small proportion of arsenic thiocyanate. For the interchange with **organic halides**, *vide infra*, arsenic triiodide. When arsenic trichloride acts on a Grignard reagent, **magnesium phenyl bromide**, in ethereal soln. in equimolar proportions, the product is triphenyl-arsine if the former is added gradually to the latter. If, however, magnesium phenyl bromide is added to arsenic trichloride, the product is diphenylchloroarsine. O. Ruff and K. Albert observed no change when arsenic trichloride and **silico-chloroform** are heated in a sealed tube at 150°.

A. C. Vournazos observed that the trichloride in boiling toluene soln. reacts with potassium furnishing potassium chloride and arsenic, but no arsenide. According to N. W. Fischer, when the metals **copper**, **zinc**, **cadmium**, **tin**, **lead**, **antimony**, **bismuth**, and **iron** are immersed in arsenic trichloride they acquire a crust of arsenic which prevents further decomposition, and J. B. A. Dumas found that **mercury** slowly decomposes the trichloride at ordinary temp., forming a greyish-brown powder. K. Seubert and A. Schmidt found that at a red-heat, **magnesium** reduces the trichloride to arsenic, and in acid soln., arsenic, arsine, and magnesium hydroxide and chloride are formed. Z. Roussin and R. Commaille also noted the production of arsine. F. Ducelliez examined the action of arsenic trichloride on **cobalt** at different temp. and obtained various arsenides (*q.v.*); A. Granger and G. Didier, and E. Vigouroux observed that when the vap. is passed over heated **nickel**, nickel arsenide is formed. According to L. Kahlenberg and J. V. Steinle, when sodium, magnesium, zinc, or aluminium is immersed in arsenic trichloride there is an immediate plating at ordinary temp., and a vigorous reaction at 100°; with cadmium, iron, cobalt, and nickel, there is a slight plating on standing at ordinary

temp., and a slight reaction at 100°; with lead, and tin, there is an immediate plating at ordinary temp., and a strong reaction at 100°; whilst bismuth and antimony are slightly tarnished after standing at ordinary temp. and there is a slight reaction at 100°; with copper, there is a good plating after standing, and a strong reaction at 100°; with mercury, there is a slight black deposit after standing, and no further reaction at 100°; and with silver, platinum, gold, and molybdenum, there is no plating at ordinary temp., and no reaction at 100°. No effect was observed with acetone soln. of arsenic trichloride and bismuth or antimony.

According to H. L. Wheeler, if sat. soln. of rubidium chloride and of arsenic trioxide in 20 per cent. hydrochloric acid be mixed, and treated with conc. hydrochloric acid, pale yellow trigonal crystals of **rubidium enneachlorodiarsenite**, $3\text{RbCl}\cdot 2\text{AsCl}_3$, are formed having the axial ratio $a:c=1:1\cdot 210$, and $\alpha=88^\circ 56'$. The salt can be recrystallized from 20 per cent. hydrochloric acid, but is hydrolyzed by 15 per cent. acid. 100 parts of hydrochloric acid, of sp. gr. 1.2, dissolve 2.935 parts of the salt. Trigonal crystals of **caesium enneachlorodiarsenite**, $3\text{CsCl}\cdot 2\text{AsCl}_3$, were produced in an analogous way. The axial ratio is $a:c=1:1\cdot 209$, and $\alpha=89^\circ 3'$. 100 parts of hydrochloric acid, of sp. gr. 1.2, dissolve 0.429 part of the salt. E. H. Ducloux used the complex salt in the microdetection of arsenic. O. Ruff and K. Staib found that yellow phosphorus reduces arsenic trichloride in the presence of aluminium chloride, forming a red compound, **aluminium triarsenotrichloride**, $\text{Al}(\text{AsCl})_3$, of sp. gr. 2.85 at 22°. The same substance is produced at 135°–140° by the action of **aluminium** powder on arsenic trichloride in the presence of a little aluminium chloride. Water decomposes the compound into aluminium chloride and black arsenic. Titanium tetrachloride and ammonia also decompose the compound, black arsenic being formed. It is stable in dry air, and when heated above 170° decomposes with formation of aluminium arsenide, arsenic, and arsenic trichloride thus: $\text{AlAs}_3\text{Cl}_3=\text{AlAs}+\text{As}+\text{AsCl}_3$. S. Hilpert and F. Herrmann found that finely-divided, reduced **silver** and arsenic trichloride, when heated in a sealed tube, form **silver arsenochloride**, $7\text{Ag}\cdot 2\text{AsCl}_3$. By analogy with the corresponding bromide (*q.v.*), it is thought that the product is a solid soln. of silver and the compound Ag_3AsCl_3 , or $[\text{Ag}_3\text{As}]\text{Cl}_3$. A substance with similar properties was obtained by the action of arsenic vapour on silver chloride at 500°. An analogous **copper arsenochloride** was likewise prepared.

J. J. Berzelius⁵ reported a brown complex containing mercury, arsenic, and chlorine to be formed along with arsenic trichloride when arsenic is heated with mercurous chloride; and R. Lochmann obtained a series of complexes, $\text{As}(\text{HgCl})_3$; $\text{AsH}(\text{HgCl})_2$; and $\text{AsH}_2(\text{HgCl})$, by the action of arsine on mercuric chloride. A. Partheil and E. Amort reported **arsenic dihydrochloromercuriate**, $\text{AsH}_2(\text{HgCl})$, to be formed when arsine, largely diluted with hydrogen, is passed into a soln. of mercuric chloride in alcohol. The pale yellow precipitate is decomposed by an excess of mercuric chloride, forming mercurous chloride, hydrochloric acid, and arsenic acid. F. Stromeyer observed these products in his study of the action of arsine on mercuric chloride. The next product of the reaction is **arsenic hydrobischloromercuriate**, $\text{AsH}(\text{HgCl})_2$, obtained as a yellow precipitate by A. Partheil and E. Amort, and A. H. Gotthelf, when arsine acts on an aq. or alcoholic soln. of mercuric chloride. It, too, forms mercurous chloride, hydrochloric acid, and arsenic acid by the action of an excess of mercuric chloride. The next product of the action of arsine on mercuric chloride soln. is **arsenic trischloromercuriate**, $\text{As}(\text{HgCl})_3$, or $\text{HgCl}_2\cdot \text{AsHg}_2\text{Cl}$. H. Rose regarded this product as $3\text{HgCl}_2\cdot \text{As}_2\text{Hg}_3$, but P. Lohmann said that this is wrong. E. Soubeiran obtained a similar product by the action of arsine on a 5 per cent. soln. of mercuric chloride; P. Lohmann said that the product is less impure if an alcoholic soln. of mercuric chloride be employed. The reddish-brown product is decomposed into mercury and arsenic trichloride when heated in contact with its mother-liquor; and, according to H. Rose, it is decomposed by water: $2\text{As}(\text{HgCl})_3+3\text{H}_2\text{O}=6\text{Hg}+\text{As}_2\text{O}_3+6\text{HCl}$. P. Lohmann said that light accelerates, and the presence of ammonium chloride

retards the decomposition by water. A. Partheil and E. Amort said that an excess of mercuric chloride soln. decomposes it into arsenic and mercurous chloride. P. Lohmann observed that 20 grms. of the compound were decomposed by a 5 per cent. soln. of mercuric chloride in ten days. H. Rose found that nitric acid converts it into mercurous chloride, etc.

H. Capitaine said that when an intimate mixture of arsenic with three times its weight of mercurous chloride is heated in a sand-bath until most has sublimed, the hard reddish residue has the composition of arsenic trischloromercuriate, $\text{As}(\text{HgCl})_3$, but possibly $\text{AsH}(\text{HgCl})_2$. It slowly blackens in sunlight; when heated it decomposes: $3\text{As}(\text{HgCl})_2 = 6\text{Hg} + \text{As} + 2\text{AsCl}_3$; and water breaks it down: $3\text{As}(\text{HgCl})_2 + 3\text{H}_2\text{O} = 6\text{Hg} + \text{As} + \text{As}_2\text{O}_3 + 6\text{HCl}$. G. Franceschi reported a *pentahydrate*, $\text{As}(\text{HgCl})_3 \cdot 5\text{H}_2\text{O}$, to be formed by the action of arsine on an alcoholic or ethereal soln. of mercuric chloride; it is decomposed by water into arsine, hydrochloric acid, arsenic trichloride, and mercurous oxide. D. Vitali reported a similar product to be formed by the action of nascent arsine on mercuric chloride. H. Capitaine also obtained **arsenic monochloromercuriate**, $\text{As}(\text{HgCl})$, as a brown mass consisting of dendritic crystals as a by-product in the preparation of the bischloromercuriate. The product is decomposed by sunlight; by heat: $3\text{AsHgCl} = 3\text{Hg} + 2\text{As} + \text{AsCl}_3$; and by water: $6\text{AsHgCl} + 3\text{H}_2\text{O} = 6\text{Hg} + \text{As}_2\text{O}_3 + 4\text{As} + 6\text{HCl}$.

According to W. Wallace and F. Penny, and L. Hurtzig and A. Geuther, a mol of boiling arsenic trichloride dissolves a mol of arsenic trioxide, forming **arsenic oxychloride**, or **arsenyl monochloride**, AsOCl . A similar soln. was obtained by passing hydrogen chloride into water with arsenic trioxide in suspension until the solid has disappeared. If the soln. be distilled until it begins to foam, the residue forms a soln. of arsenic trioxide in arsenic trichloride, and beneath this is a brown, viscid mass of the oxychloride. If the temp. of distillation be too high, the residue has the composition $\text{AsOCl} \cdot \text{As}_2\text{O}_3$. Again, if arsenic trichloride be mixed with sufficient water, and allowed to stand a few days, stellate masses of crystals of the *monohydrate*, $\text{AsOCl} \cdot \text{H}_2\text{O}$, are formed. If some ammonium chloride be placed in a soln. of arsenic trichloride in water acidified with hydrochloric acid to prevent the separation of arsenic oxychloride, snow-white needles of **ammonium oxyarsenotrichloride**, $2\text{NH}_4\text{Cl} \cdot \text{AsOCl}$, or $(\text{NH}_4)_2\text{AsOCl}_3$, are formed. These observations need revision.

According to S. Delépine,⁶ the inhalation of air charged with fumes of arsenic trichloride or the direct application of undiluted arsenic trichloride to the skin rapidly causes death by acute arsenic poisoning. The application of the liquid to the skin results immediately in necrosis; this is considerably retarded by washing within one minute of the application, but washing after five minutes has no effect. The arsenic is rapidly absorbed by the tissues, and within a few hours can be recovered from most of the tissues and organs of the body, especially the brain, liver, and kidneys. The symptoms of poisoning by arsenic trichloride include laryngeal obstruction, dyspnoea, and convulsions.

§ 27. The Bromides of Arsenic

Arsenic ignites as soon as it comes in contact with bromine burning with great brilliancy. G. S. Sérullas¹ introduced dry powdered arsenic in small portions at a time into a retort containing bromine; and distilled the product from an excess of arsenic. He thus obtained crystals of **arsenic tribromide**, AsBr₃. E. Jory passed the bromine vapour into a column of arsenic contained in a long, hard glass tube. J. Nicklès added powdered arsenic to a mixture of bromine with twice its weight of carbon disulphide, and agitated the mixture until decolorized. On evaporating the solvent, crystals of the tribromide remain. G. Oddo and U. Giachery obtained the tribromide by heating a mixture of stoichiometrical proportions of arsenic trioxide and sulphur in a current of bromine vapour; and A. C. Vournazos, by heating a mixture of arsenic trioxide, potassium bromide, and acetic acid at 100°.

G. S. Sérullas' analysis agrees with the formula AsBr₃, and E. Beckmann found this to be in accord with the effect of the tribromide on the b.p. of bromine; and W. Finkelstein with the f.p. of bromine. There is an abnormal depression in the f.p. of antimony trichloride by arsenic tribromide owing to chemical action—*vide infra*, arsenic triiodide.

At ordinary temp., arsenic tribromide forms a mass of colourless, prismatic crystals. W. Wallace and F. Penny obtained well-formed crystals by allowing the molten mass partly to solidify, and then pouring off the still liquid portion. P. Walden reported a few measurements of the crystal angles. The salt is stable at ordinary temp. in air, but if a little moisture be present, a little fuming occurs. P. Walden said that the smell is feebly aromatic, not arsenical; J. Nicklès said the smell is arsenical. C. H. D. Bödecker gave 3.66 for the sp. gr. at 15°/4°, and J. W. Retgers gave 3.540 at 25°/4° for the tribromide which had been fused. F. M. Jäger represented the sp. gr., *D*, of the liquid at *θ*, referred to water at 4°, by $D=3.3972-0.002822(\theta-25)+0.00000248(\theta-25)^2$. The cohesion, a^2 per sq. mm.,

the surface tension, σ dynes per cm., and the surface energy, μ ergs per sq. cm., were found to be :

	49.6°	74.5°	90°	121°	149.6°	165°	179.7°
Sp. gr.	3.328	3.261	3.234	3.143	3.076	3.041	3.008
A^2	3.04	2.96	2.82	2.66	2.53	2.48	2.45
σ	49.6	46.6	44.8	41.0	38.2	37.0	36.1
μ	1029.5	980.5	947.8	884.1	835.6	815.6	801.6

R. Lorenz and W. Herz studied some relations of the surface tensions of the family of halides. E. Rabinowitsch gave 111 for the mol. vol. I. I. Saskowsky found the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements to be 1.21. G. S. Sérullas gave 20°-25° for the m.p.; and P. Walden, S. Tolloczko and M. Meyer, N. A. Puschin and S. Löwy, and F. M. Jäger said that the tribromide melts sharply at 31°. G. S. Sérullas gave 220° for the b.p.; J. Kendall and co-workers, 175°; P. Walden, 221° at 760 mm., and 92° at 14 mm.; and F. M. Jäger, 109° at 20 mm. S. Tolloczko and M. Meyer gave 9.83 cal. for the heat of fusion; and W. Herz 8.93 cal. per gram. M. Berthelot gave for the heat of formation (As₃Br_{gas})=59.1 Cals., and (As₃Br_{liquid})=47.1 Cals. For the mol. depression of the f.p., S. Tolloczko gave 206; F. Garelli and V. Bassani, 194.2; and P. Walden, 189. W. Finkelstein observed that the lowering of the f.p. of bromine by arsenic tribromide corresponds with theory, and the soln. is a non-conductor of electricity. P. Walden found the eq. electrical conductivity of a mol of the tribromide in 101.4 and 925.3 litres of liquid sulphur dioxide to be respectively 0.249 and 2.347. The ionizing power of the tribromide is said to be rather less than that of the trichloride. The dielectric constant at 35° is 9.3, and at 20°, 3.4. W. Finkelstein found that the decomposition voltage of arsenic tribromide in benzene soln. is 0.50 volt. W. Herz gave 1.99×10^{12} for the vibration frequency.

Arsenic tribromide attracts moisture from the air, and, according to M. Berthelot, when mixed with oxygen it is decomposed by heat into free bromine and an oxybromide. According to G. S. Sérullas, the tribromide is rapidly decomposed by water into arsenic trioxide, bromine, and an oxybromide. W. Wallace and F. Penny found that one part of the tribromide dissolves in three parts of boiling water; and less is dissolved in the presence of hydrobromic acid; the boiling soln. in water on cooling deposits crystals of arsenic trioxide. C. Hugot found that liquid ammonia reacts with the tribromide. F. Oberhauser studied the reaction

FIG. 35.—Freezing-point Curve of the Binary System: AsBr₃-Br₂.

with cyanogen bromide. S. Tolloczko found that antimony trichloride and arsenic tribromide probably interact chemically—*vide supra*. M. P. Cady and R. Taft found that the tribromide is appreciably soluble in phosphoryl chloride. M. Ussanowitsch studied the electrical conductivity of mixtures of arsenic tribromide and ether. Molten arsenic tribromide was found by P. Walden to dissolve potassium bromide, tetramethylammonium iodide, anhydrous aluminium and ferric chlorides, but rubidium iodide and tetrachloroiodide, mercuric iodide, stannic bromide and iodide, anhydrous cadmium, manganese, and cobalt iodides, and cobalt bromide are almost insoluble therein. W. Biltz and K. Jeep obtained the f.p. curve, Fig. 35, for the binary system: AsBr₃-Br₂. The subject was discussed by E. Kordes. J. W. Retgers also examined the soln. of stannic iodide, and mercuric iodide in this menstruum. A. C. Vournazos obtained the complex **sodium arsenoctoazidotribromide**, Na₈[AsBr₃(N₃)₈]. According to H. L. Wheeler, **rubidium diarsenoenneabromide**, 3RbBr.2AsBr₃, is obtained by a method analogous to that used for the corresponding chloride. The amber-yellow trigonal crystals have the axial ratio $a:c=1:1.220$ and $\alpha=88^\circ 42'$. Similarly with **cæsium diarsenoenneabromide**, 3CsBr.2AsBr₃, which furnishes trigonal crystals with the axial ratio $a:c=1:1.219$, and $\alpha=88^\circ 43'$. The properties of these salts resemble those of the corresponding chlorides. According to J. Nicklès,

sodium thiosulphate first converts the tribromide into an oxybromide, and then into the trisulphide.

A. Besson, and W. Landau said that arsenic tribromide unites with ammonia and with many amines. The former obtained pale yellow **arsenic triamminotribromide**, $\text{AsBr}_3 \cdot 3\text{NH}_3$, by treating arsenic tribromide with ammonia. W. Landau obtained **arsenic hemiheptamminotribromide**, $\text{AsBr}_3 \cdot 3\frac{1}{2}\text{NH}_3$, by passing ammonia into a soln. of arsenic tribromide in benzene. The white precipitate can be recrystallized from hot absolute alcohol. The ammine loses ammonia and sublimes when heated. A. Besson said that at 300° the tribromide is decomposed into arsenic, nitrogen, and ammonium bromide. W. Landau found that cold water slowly dissolves the amine; while hot water decomposes it. A. Besson found that the tribromide reacts with phosphine: $\text{PH}_3 + \text{AsBr}_3 = 3\text{HBr} + \text{AsP}$. P. Walden said that the molten tribromide readily dissolves phosphoryl bromide, antimony trichloride, arsenic triiodide, and antimony triiodide. The soln. of arsenic and antimony triiodides and antimony tribromide were examined by J. W. Retgers. P. Walden found that molten arsenic tribromide dissolves ammonium thiocyanate very sparingly. J. W. Retgers observed that arsenic tribromide is soluble in methylene iodide, and in carbon disulphide. G. Gustavson observed that 29 per cent. of arsenic tribromide is converted into the trichloride when heated with carbon tetrachloride at 150° – 200° for about 60 days. For the interchange with organic halides, *vide infra*, arsenic triiodide.

S. Hilpert and F. Herrmann heated finely-divided precipitated silver with molten arsenic bromide in a sealed tube and obtained **silver tribromoarsenite**, Ag_3AsBr_3 ; and when copper is used in place of silver, **copper bromoarsenite**, $7\text{Cu} \cdot 2\text{AsBr}_3$, is formed. This may be the compound Cu_2AsBr_3 , in solid soln. with copper. The same products are obtained by the action of arsenic vapour on silver or cuprous bromide at 500° . J. Kendall and co-workers observed that arsenic tribromide and **aluminium tribromide** form no compound; the f.p. curve is shown in Fig. 36.

G. S. Sérullas, and M. Berthelot mentioned the formation of an arsenic oxybromide—*vide supra*. According to W. Wallace and F. Penny, molten arsenic tribromide easily dissolves arsenic trioxide, and when the tribromide in excess is distilled off, the residue separates into two layers—the upper layer is **arsenic oxybromide**, or **arsenyl bromide**, AsOBr , and the lower layer a mixture of that substance with arsenic trioxide. A. Michaelis made it by the action of phenylarsenic oxide on bromine; and W. Wallace and F. Penny, by evaporating a cold soln. of arsenic tribromide in water containing hydrobromic acid over sulphuric acid, when white crystals of the hemitrihydrate, $\text{AsOBr} \cdot 1\frac{1}{2}\text{H}_2\text{O}$, are formed. The oxybromide decomposes by heat into arsenic trioxide and tribromide. W. Wallace and F. Penny reported a complex **arsenic diarsenyl enneaoxydibromide**, $2\text{AsOBr} \cdot 3\text{As}_2\text{O}_3 \cdot 12\text{H}_2\text{O}$, or $(\text{AsO})_2\text{As}_6\text{O}_9\text{Br}_2 \cdot 12\text{H}_2\text{O}$, to be formed when a hot sat. soln. of arsenic tribromide in dil. hydrobromic acid is cooled. This substance may be a mixture.

§ 28. The Iodides of Arsenic

Four arsenic iodides have been reported: monoiodide, diiodide, triiodide, and pentaiodide. F. M. Jäger and H. J. Doornbosch¹ obtained the thermal diagram, Fig. 37, for mixtures of arsenic and iodine. Two compounds are formed, however, AsI_3 , melting at 140.7° , and As_2I_4 , which at $135^\circ\text{--}136^\circ$ is transformed into a pair

FIG. 37.—The Thermal Diagram of the Binary System: As-I.

of immiscible liquids, one of which has a composition differing only slightly from As_2I_4 , whilst the other contains 30.5 atomic per cent. of arsenic. The diiodide appears as a liquid layer at $135^\circ\text{--}136^\circ$ with a eutectic between the two compounds at 120.5° . It was not possible to isolate the diiodide either by extraction with solvents, or by the formation of solid soln. with the corresponding phosphorus diiodide. *L* in the diagram denotes a liquid melt. The diiodide is a definite compound formed by the dissociation of AsI_3 in accordance with $2\text{AsI}_3 \rightleftharpoons \text{As}_2\text{I}_4 + \text{I}_2$. It may also be formed by the interaction of AsI_3 and metallic arsenic in consequence of the occurrence of the reversible change represented by $8\text{AsI}_3 + 4\text{As} \rightleftharpoons 6\text{As}_2\text{I}_4$. There is no sign of a monoiodide; and, as emphasized by E. Quercigh, there is no sign of a pentaiodide.

He found the eutectic between iodine and arsenic triiodide to be at 71.5° .

A. Göpel reported that **arsenic monoiodide**, AsI , is formed as a chocolate-brown substance when a soln. of iodine in alcohol is saturated with arsine; and H. Schiff found that the decomposition of arsenic trianilinotriiodide, by boiling alcohol results in the formation of the same compound: $\text{AsI}_3 \cdot 3\text{C}_6\text{H}_5\text{NH}_2 = 2\text{C}_6\text{H}_5\text{NH}_2 + \text{C}_6\text{H}_4\text{I} \cdot \text{NH}_3\text{I} + \text{AsI}$. F. Meurer said that the monoiodide is formed when an excess of arsenic acts on an alcoholic soln. of iodine—*vide infra*, arsenic triiodide.

E. Bamberger and J. Philipp obtained **arsenic diiodide**, AsI_2 , or As_2I_4 , analogous with phosphorus and bismuth diiodides. The conditions of stability are indicated in connection with Fig. 37. J. T. Hewitt and T. F. Winmill found that while the analysis agreed with the formula AsI_2 , the effect on the b.p. of carbon disulphide agrees with the formula As_2I_4 . By heating arsenic with twice its weight of iodine in sealed tubes to 230° , a dark cherry-red crystalline mass is obtained, from which the diiodide is separated by crystallization from carbon disulphide, in an atm. of carbon dioxide. The diiodide forms thin prismatic crystals of a cherry-red colour, but, owing to their becoming opaque on exposure to the air, the measurement of their angles is rendered difficult; one of the angles, however, seems to correspond with one of the angles of the analogous phosphorus compound. T. Karantassis made the compound by introducing one part of finely-powdered arsenic and 2 parts of iodine into a retort-shaped tube; and after repeated evacuation and filling with pure, dry hydrogen, sealing the tube and heating the mixture to the b.p. for 2 hrs. On careful distillation, pure arsenic diiodide is obtained. The undistilled product

melts at 117°–120°, the distilled compound at 130°, the change in m.p. proving the solubility of arsenic in the crude product. E. Frank gave 120° for the m.p. T. Karantassis said that the diiodide boils at 375°–380° in an atm. of hydrogen or carbon dioxide. E. Bamberger and J. Philipp said that the diiodide is readily oxidized, and in air, the crystals become brick-red. J. T. Hewitt and T. F. Winnill said that the compound should be recrystallized in an atm. of dry carbon dioxide since it is very sensitive to moisture and oxygen; they also found that cold conc. sulphuric acid is apparently without action, but some iodine is eliminated when the acid is raised near its b.p. Cold fuming nitric acid has apparently little immediate action, but, on heating, oxides of nitrogen and iodine vap. are given off, whilst eventually arsenic and iodic acids are produced. Pyridine decomposes the substance immediately, arsenic is liberated, and arsenic triiodide passes into soln. The substance dissolves in boiling acetic anhydride; the material which separates on cooling is mostly yellow, but evidently not homogeneous. It is very probable that the greater portion of the product is a derivative of arsenic triiodide. The compound is soluble in carbon disulphide, ether, alcohol, and chloroform. The soln. rapidly darkens in air owing to the formation of arsenic triiodide; and when evaporated in air, the diiodide is completely decomposed. When treated with water it turns black with the separation of rather less arsenic than corresponds with: $3AsI_2 = 2AsI_3 + As$. This reaction distinguishes it from the triiodide. Alkaline liquids accelerate the decomposition. The alcoholic soln. is similarly decomposed by water. T. Karantassis could not prepare a complex of the diiodide with sulphur.

A. Plisson showed that **arsenic triiodide**, AsI_3 , can be obtained by the direct union of the elements. When the mixture is warmed, union occurs with the evolution of heat. This method was used by A. Bette, G. S. Sérullas and M. Hottot, A. Göpel, and A. T. Thomson. The triiodide is also formed when arsenic acts on iodine in the presence of water as was found by A. Plisson, W. Duncan, and R. C. Cowley and J. P. Catford; or on a soln. of iodine in ether or carbon disulphide as recommended by J. Nicklès, and J. W. Retgers. E. Bamberger and J. Philipp found J. Nicklès' method of heating arsenic and iodine in eq. proportions in carbon disulphide, to be the most convenient process. The product can be recrystallized from carbon disulphide or xylol. C. Brame obtained the triiodide by the action of iodine vap. on heated arsenic trioxide; E. Richter, by heating a mixture of iodine and arsenic trioxide; and A. Göpel, by sublimation from a mixture of arsenic trioxide, potassium iodide, and potassium hydrosulphate. J. F. Babcock treated arsenic trioxide with hydrogen iodide; and E. Bamberger and J. Philipp found that the triiodide is precipitated when a conc. soln. of potassium iodide is added to a hot soln. of arsenic trioxide in hydrochloric acid. The yellowish-red, crystalline powder is washed with hydrochloric acid to remove potassium chloride. G. Oddo and U. Giachery obtained the triiodide by heating a mixture of stoichiometrical proportions of arsenic trioxide and sulphur in the vap. of iodine; and A. C. Vournazos, by heating at 100° a mixture of arsenic trioxide, potassium iodide, and acetic acid. P. Hautefeuille also found that hydriodic acid reacts with arsenic chloride with the development of heat: $AsCl_3 + 3HI = 3HCl + AsI_3$; the triiodide can be crystallized from the trichloride in which it is soluble. C. Husson found that arsine reacts with dry iodine forming the triiodide, and O. G. Jacobsen based a method of removing arsine from hydrogen sulphide on this reaction. F. Meurer obtained the triiodide by the action of arsine on an alcoholic soln. of iodine—an excess of arsine produces the monoiodide. According to E. R. Schneider, arsenic triiodide is formed when a mol. of arsenic disulphide and six gram-atoms of iodine are heated together—with equimolar parts a sulphide is formed. The triiodide is also formed by the protracted heating of a mixture of iodine and the trisulphide. The product is dissolved in carbon disulphide, and on evaporation, the triiodide separates first, the sulphur last. E. R. Schneider made the triiodide by the action of arsenic disulphide or trisulphide on a soln. of iodine in carbon disulphide:

$\text{As}_2\text{S}_2 + 3\text{I}_2 = 2\text{AsI}_3 + 2\text{S}$. A. F. Duflos obtained the triiodide by sublimation from a mixture of mercuric iodide and arsenic trisulphide.

Analyses by A. Plisson, A. Bette, F. Meurer, and E. Bamberger and J. Philipp agree with the formula, AsI_3 ; and A. Wurtz found the vap. density to be 16.1 in agreement with 15.8 calculated for the simple formula. P. Walden also found the mol. wt., calculated from the lowering of the f.p. of arsenic tribromide, to be normal. S. Tolloczko found that the abnormal depression of the f.p. of arsenic triiodide in antimony trichloride can be explained by the increase in the number of mols of the solute owing to a reaction: $\text{AsI}_3 + \text{SbCl}_3 = \text{AsCl}_3 + 3\text{SbCl}_2\text{I}$. E. Beckmann obtained a mol. wt. about half the normal value. According to P. Friedländer, arsenic triiodide evaporates from its soln. in ether or carbon disulphide in red, hexagonal plates with the axial ratio $a : c = 1 : 2.998$. A. Bette said that the mass which has been fused is brick-red with a violet crystalline fracture; the plates obtained by sublimation are also brick-red. According to E. R. Schneider, if the fused mass contains a little trisulphide it may freeze to an amorphous mass. The vapour is yellow. B. E. Sloan said that a partial dissociation occurs when the triiodide is heated to 165° in a sealed tube. A. Plisson said that during sublimation a small proportion is decomposed into iodine and arsenic. C. H. D. Bödecker gave 4.39 for the sp. gr. at $15^\circ/4^\circ$; and H. G. F. Schröder, 4.374. S. Motylewsky found the drop-weight to be 45 units when that of water at 0° is 100. T. Carnelley gave 146° , S. Horiba and R. Inouye 144° , and B. E. Sloan 149° , for the m.p.; F. M. Jäger and H. J. Doornbosch gave 140.7° for the f.p.; E. Quercigh, 135.5° ; and A. M. Wasiléeff, 146° . T. Carnelley and W. C. Williams gave 394° – 414° for the b.p. S. Horiba and R. Inouye gave 19.2 Cals. for the mol. heat of vaporization; the vap. press. the vap. press., p mm., of the liquid is :

	11.35°	34.73°	85.60°	130.98°	145.79°	160.39°	182.41°
p . . .	0.000	0.015	0.203	0.706	1.158	2.777	7.891

or $\log p = -4.2T^{-1} + 10.1$. The results for the vap. press., p mm., of the solid are somewhat irregular, due, it is supposed, to the presence of an allotropic form. If the reddish-orange variety is cooled by a mixture of solid carbon dioxide and alcohol, it forms a yellow modification stable only at a low temp. The first sublimate from the reddish-orange variety in vacuo is yellow, and this changes slowly into the reddish-orange variety at room temp. The vap. press. of the yellow variety is greater than that of the reddish-orange form. M. Berthelot gave for the heat of formation $(\text{As}, 3\text{I}) = 28.8$ Cals.; and $(\text{As}, 3\text{I}_{\text{solid}}) = 12.6$ Cals. J. H. Mathews found that neither the solid nor the liquid conducts an electric current, but a sat. soln. in allyl isothiocyanate, at 60° , has a conductivity of 1.4×10^{-4} mho.

A. Plisson said that arsenic triiodide has no smell; A. T. Thomson, that it has a metallic taste; and A. Bette, that it gradually decomposes in air, forming iodine and arsenic trioxide. E. R. Schneider also found that the soln. in carbon disulphide gradually absorbs oxygen, and so acquires a dark colour owing to the liberation of iodine. M. Berthelot found that when the triiodide is heated in oxygen, it burns with a pale blue flame, forming arsenic trioxide and iodine. A. Plisson found that the triiodide dissolves freely in cold water, forming a yellow soln. which does not become brown when exposed to air. E. Bamberger and J. Philipp said that the triiodide is fairly stable in aq. soln. from which it may be recovered unchanged; and E. Richter, that a one per cent. soln. of the triiodide in water, or a water containing 5–10 per cent. of alcohol, is stable. A. Plisson found that the aq. soln. tastes acidic; but it does not turn starch-paper blue except on the addition of hydrochloric acid. If the aq. soln. be evaporated in an open vessel, crystals of the oxyiodide are formed; but if evaporated after the addition of hydriodic acid, W. Wallace and F. Penny obtained only arsenic triiodide. A. Plisson reported that the aq. soln. furnishes iodine when treated with sulphuric or nitric acid; arsenic trisulphide, when treated with hydrogen sulphide; a brown precipitate, with bismuth

nitrate; a yellow one, with lead nitrate; a green one, with copper ammoniosulphate; and none, with calcium sulphate. W. Wallace and F. Penny found that a boiling, sat., aq. soln. deposits arsenic triiodide unchanged; but the spontaneous evaporation of the cold aq. soln. yields colourless plates of what was regarded as **arsenic diarsenyl enneaoxydiiodide**, $2\text{AsOI}\cdot 3\text{As}_2\text{O}_3\cdot 12\text{H}_2\text{O}$, or $\text{As}_6(\text{AsO})_2\text{O}_9\text{I}_2\cdot 12\text{H}_2\text{O}$. It was also obtained by slowly cooling a hot sat. aq. soln. of one part of the triiodide in 3.32 parts of hot water, and drying the colourless plates between bibulous paper. The water of crystallization is lost by desiccation over sulphuric acid, but, according to A. Plisson, not over calcium chloride in vacuo. When heated, arsenic triiodide sublimes, and the trioxide remains. The compound is only slightly soluble in cold water, and less so in alcohol. By repeatedly crystallizing the compound from a hot aq. soln., it becomes poorer in iodine; alcohol slowly removes all the iodine. The substance may or may not be a chemical individual.

S. Zinno reported that a hot, aq. soln. of arsenic trioxide, sat. with iodine, deposits on cooling **arsenic trioxytetraiodide**, $\text{As}_3\text{O}_3\text{I}_4$. M. Wegner, however, said that the crystals thus obtained are, however, nothing but arsenious oxide containing a trace of hydriodic acid. When iodine is dissolved in a hot soln. of arsenic trioxide, the latter is oxidized, and arsenic acid and hydriodic acid are formed, which act on each other again when the soln. is conc., free iodine and arsenic trioxide being regenerated.

V. Auger mixed carbon disulphide soln. of arsenic triiodide and sulphur, and obtained orange plates or prisms of **arsenic tetracosisulphiodide**, $\text{AsI}_3\cdot 3\text{S}_8$, m.p. 104° . L. Ouvrard found that when the triiodide is heated to 200° in a current of hydrogen sulphide, thioiodides are formed. According to E. Bamberger and J. Philipp, if ammonia be passed into a soln. of the triiodide in ether or benzene, a bulky white **arsenic hemienneamminotriiodide**, $\text{AsI}_3\cdot 4\frac{1}{2}\text{NH}_3$, is precipitated. A. Besson found that the triiodide absorbs ammonia and is gradually transformed into **arsenic tetramminotriiodide**, $\text{AsI}_3\cdot 4\text{NH}_3$. The two amines are possibly the same. C. Hugot suggested that the alleged amines are mixtures of ammonium iodide and arsenic triamide (*q.v.*). According to A. Besson, the tetrammine begins to lose ammonia at 50° , and at 300° , decomposes like the bromide. Water dissolves it with decomposition; hydrochloric acid removes the ammonia, and arsenic triiodide is precipitated. If left for a long time in contact with ammonia at 0° , **arsenic dodecamminotriiodide**, $\text{AsI}_3\cdot 12\text{NH}_3$, is formed. F. M. Jäger and H. J. Doornbosch showed that arsenic and phosphorus triiodides form an isodimorphous series of crystals with a transition point at 73.5° , as indicated in Fig. 35; the sat. solid soln. at that temp. contains respectively 18 and 75 per cent. of phosphorus triiodide, PI_3 . *L* in the diagram denotes a liquid. A. C. Vournazov obtained a complex **sodium arsenooctozidotriiodide**, $\text{Na}_8[\text{AsI}_3(\text{N}_3)_8]$.

A. Besson found that arsenic triiodide reacts with phosphine: $\text{AsI}_3 + \text{PH}_3 = 3\text{HI} + \text{AsP}$; and L. Ouvrard, that it reacts with molten arsenic trisulphide, forming thioiodides. For the interaction of arsenic triiodide and antimony trichloride, *vide supra*. J. Tarible found that boron tribromide is dissolved by arsenic triiodide. According to J. W. Retgers, arsenic triiodide is soluble in carbon disulphide, alcohol, ether, chloroform, benzene, toluene, xylene, and at 12° , 100 parts of methylene iodide dissolve 17.4 parts of arsenic triiodide, forming a dark red soln. with a sp. gr. 3.449; more is dissolved at a higher temp. E. Bamberger and J. Philipp said that with alcohol at 150° , ethyl iodide is formed; and H. Schiff observed that it forms with aniline the complex $\text{AsI}_3\cdot 3\text{C}_6\text{H}_5\text{NH}_2$. G. J. Burrows and E. E. Turner studied the action of arsenic triiodide on the tertiary amines. R. Brix, and B. Köhnlein studied the interchange of halogen between the arsenic trihalides and organic halides, and found that arsenic unites by preference with iodine rather than with bromine or chlorine, and with bromine rather than with chlorine.

J. Nicklès studied the action of arsenic triiodide on the alkali halides, but the complexes formed were not very stable; and H. L. Wheeler reported **rubidium enneaiodide**, $3\text{RbI}\cdot 2\text{AsI}_3$, to be formed as in the corresponding case of the chloride. The pseudohexagonal crystals have the axial ratio $a:c=1:2.486$; and **caesium**

diarsenoenneaiodide, $3\text{CsI} \cdot 2\text{AsI}_3$, is said to be formed in an analogous way. The hexagonal bipyramids have the axial ratio $a : c = 1 : 2.488$. A. Mosnier prepared **lead arsenoenneadiiodide**, $3\text{PbI}_2 \cdot \text{AsI}_3 \cdot 12\text{H}_2\text{O}$, by adding a sat. soln. of lead iodide to a boiling sat. soln. of arsenic triiodide in fuming hydriodic acid. The heat of formation of the hydrate is 3.6 Cals., and the heat of soln. in 40 parts of water at 15° , -8.2 Cals. The salt is decomposed by water, alcohol, and ether. It becomes anhydrous at about 45° ; and the heat of formation of the anhydrous salt is 27.1 Cals.; and the heat of soln. in 40 parts of water at 15° , 12.5 Cals. P. Lemoult made **arsenic triiodomercuriate**, $\text{As}(\text{HgI})_3$, or $\text{HgI}_2 \cdot \text{AsHg}_2\text{I}$, by passing arsine diluted with hydrogen or carbon dioxide into a soln. of potassium iodomercuriate. The pale brown crystalline precipitate is more stable than the corresponding phosphorus compound. According to A. M. Wasiléeff, there is a eutectic at 106.2° with mixtures of **stannic iodide** and arsenic triiodide containing $\text{SnI}_4 : \text{AsI}_3 = 1 : 0.6936$.

B. E. Sloan reported **arsenic pentaiodide**, AsI_5 , to be formed by heating the stoichiometrical proportions of the elements in an atm. of carbon dioxide in a sealed tube at 150° . If a rather larger proportion of iodine be used, at 190° , the excess is volatilized. The garnet-brown crystals are probably monoclinic prisms with a sp. gr. 3.93, and a m.p. of 70° . The compound is more or less soluble in water, carbon disulphide, alcohol, ether, and chloroform. The compound is decomposed by soln. in carbon disulphide because on crystallization arsenic triiodide and iodine were obtained. The absorption spectrum of the soln. agrees with this assumption. The compound loses a little iodine when heated in nitrogen in a sealed tube at 100° . There is no evidence of a pentaiodide on the fusion curve, Fig. 38, and, as pointed out by E. Quercigh, the supposed pentaiodide is really

FIG. 38.—Fusion Curves of the Binary Mixtures: $\text{AsI}_3\text{-PI}_3$.

the eutectic which he found to have a f.p. at 73.5° . J. Tarible found that boron tribromide is dissolved by the alleged pentaiodide. R. Hanslian studied its mol. wt. from the f.p. of its soln. in iodine.

§ 29. Halogen Compounds of the Arsenites and Arsenates

A number of compounds of arsenic trioxide with the alkali and other halides has been reported. In the ternary systems: As_2O_3 -MX- H_2O , or As_2O_3 -MX₂- H_2O , where M stands for the metal and X for the halide, the conditions of equilibrium are represented by Fig. 39, when no compound is formed. In this case, *a* represents the solubility of arsenic trioxide in water; *ab*, the solubility of the trioxide in soln. containing different proportions of the halide; the area *abA* represents supersaturated soln. when the solid phase is arsenic trioxide; *bd* represents the solubility of the halide in the presence of arsenic trioxide; *f* represents soln. sat. with the halide, or the hydrated halide; *d*, the composition of the hydrated halide—if the halide does not form a hydrate *d* and *D* coincide. If the halide forms one complex salt with arsenic trioxide, its composition is represented by *B*, Fig. 40; *cb* then

FIG. 39.—Equilibrium in the Ternary System: As_2O_3 -MX- H_2O . (No complex salt.)

FIG. 40.—Equilibrium in the Ternary System: As_2O_3 -MX- H_2O . (Complex salt.)

denotes the soln. sat. with the complex salt, and *cbB*, soln. supersaturated with respect to the complex salt. The curves *ab* and *bd* have the same meaning as they have in Fig. 39.

F. Rüdorff¹ prepared **ammonium chloroarsenite**, $NH_4Cl.As_2O_3$, by slowly cooling a soln. containing 147 grms. of arsenic trioxide, 17 grms. of ammonia, and 40 grms. of ammonium chloride. F. A. H. Schreinemakers and W. C. de Baat also obtained this salt in their study of the ternary system As_2O_3 - NH_4Cl - H_2O at 30°. The equilibrium diagram is of the type, Fig. 38, when *d* and *D* coincide. They also found that the system As_2O_3 - $LiCl$ - H_2O at 30° is represented by Fig. 39, when *d* represents $LiCl.H_2O$; and there is no sign of the formation of a complex salt; this was also the case with the system As_2O_3 - $NaCl$ - H_2O at 30°. F. Rüdorff obtained **potassium chloroarsenite**, $KCl.As_2O_3$, by passing carbon dioxide into a soln. of 100 grms. of potassium arsenite in 200 grms. of water, and then mixing the sat. soln. with 30 grms. of potassium chloride dissolved in 150 grms. of water. The hexagonal plates decompose at 240°, and also when mixed with water. F. A. H. Schreinemakers and W. C. de Baat obtained this salt, and found the equilibrium curves of the

system $\text{As}_2\text{O}_3\text{-KCl-H}_2\text{O}$ at 30° were of the type shown in Fig. 39, when d and D coincide. F. Rüdorff also reported *potassium chlorobisarsenite*, $\text{KCl}(\text{As}_2\text{O}_3)_2$, but F. A. H. Schreinemakers and W. C. de Baat could not obtain this salt; H. L. Wheeler reported **rubidium chloroarsenite**, $\text{RbCl} \cdot \text{As}_2\text{O}_3$, to be formed from a soln. of the two components in 10 to 15 per cent. hydrochloric acid; and he obtained **caesium chloroarsenite**, $\text{CsCl} \cdot \text{As}_2\text{O}_3$, in a similar manner. F. A. H. Schreinemakers and W. C. de Baat did not observe the formation of any complex salt in their study of the systems $\text{As}_2\text{O}_3\text{-CaCl}_2\text{-H}_2\text{O}$ at 20° , when d , Fig. 39, represents $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$; and $\text{As}_2\text{O}_3\text{-SrCl}_2\text{-H}_2\text{O}$ at 30° , when d , Fig. 39, represents $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$; **barium bischloroarsenite**, $\text{Ba}(\text{Cl} \cdot \text{As}_2\text{O}_3)_2$. The curves were of the type, Fig. 39, when d represents, the hydrate, $\text{BaCl}_2 \cdot 2\text{H}_2\text{O}$. P. Gruhl mixed hot, sat. soln. of the component salts, but found the constituents crystallized out separately on cooling.

F. Rüdorff reported **ammonium bromobisarsenite**, $\text{NH}_4\text{Br} \cdot 2\text{As}_2\text{O}_3$, to be formed when aq. ammonia at 60° is saturated with arsenic trioxide and then mixed with ammonium bromide. The six-sided prismatic crystals decompose at 200° . F. A. H. Schreinemakers and W. C. de Baat obtained the same salt in their study of the ternary system $\text{As}_2\text{O}_3\text{-NH}_4\text{Br-H}_2\text{O}$ at 30° , when d and D coincide; they also obtained **lithium bromobisarsenite**, $\text{LiBr} \cdot 2\text{As}_2\text{O}_3$, in their study of the ternary system $\text{As}_2\text{O}_3\text{-LiBr-H}_2\text{O}$ at 30° , Fig. 40, when d represents $\text{LiBr} \cdot n\text{H}_2\text{O}$; as well as **sodium bromobisarsenite**, $\text{NaBr} \cdot 2\text{As}_2\text{O}_3$, in their study of the ternary system $\text{As}_2\text{O}_3\text{-NaBr-H}_2\text{O}$ at 30° , when d , Fig. 40, represents $\text{NaBr} \cdot 2\text{H}_2\text{O}$. This salt was also prepared in six-sided plates by F. Rüdorff from a mixed soln. of sodium bromide (120 parts), arsenic trioxide (20 parts), and water (350 c.c.). It is decomposed by water. He also made **potassium bromobisarsenite**, $\text{KBr}(\text{As}_2\text{O}_3)_2$, from a mixed boiling soln. of potassium arsenite, carbonate and bromide, and arsenic trioxide; and H. Schiff and F. Sestini from a mixed soln. of potassium arsenite and bromide, but not from a mixed soln. of potassium bromide and arsenic trioxide. The six-sided prisms are stable in air; and decompose at 300° . F. A. H. Schreinemakers and W. C. de Baat obtained this salt in their study of the ternary system $\text{As}_2\text{O}_3\text{-KBr-H}_2\text{O}$ at 30° , when d and D , Fig. 40, coincide. H. L. Wheeler reported **rubidium bromoarsenite**, $\text{RbBr} \cdot \text{As}_2\text{O}_3$, to be formed from a soln. of the components in dil. hydrobromic acid; similarly with **caesium bromoarsenite**, $\text{CsBr} \cdot \text{As}_2\text{O}_3$. F. A. H. Schreinemakers and C. W. de Baat did not observe the formation of any complex salt in their study of the ternary system $\text{As}_2\text{O}_3\text{-CaBr}_2\text{-H}_2\text{O}$ at 20° , when d , Fig. 40, represents $\text{CaBr}_2 \cdot 6\text{H}_2\text{O}$; similarly, also with the ternary system $\text{As}_2\text{O}_3\text{-SrBr}_2\text{-H}_2\text{O}$ at 30° , when d , Fig. 38, represents $\text{SrBr}_2 \cdot 6\text{H}_2\text{O}$. P. Gruhl obtained a white crystalline mass—possibly **strontium bisbromoarsenite**, $\text{Sr}(\text{Br} \cdot \text{As}_2\text{O}_3)_2$ —which decomposed very readily; he also obtained the analogous **barium bisbromoarsenite**, $\text{Ba}(\text{Br} \cdot \text{As}_2\text{O}_3)_2$, which was also very unstable. The same salt was obtained by F. A. H. Schreinemakers and W. C. de Baat in their study of the ternary system $\text{As}_2\text{O}_3\text{-BaBr}_2\text{-H}_2\text{O}$ at 30° , when d , Fig. 39, represents $\text{BaBr}_2 \cdot 2\text{H}_2\text{O}$.

F. Rüdorff prepared **ammonium iodobisarsenite**, $\text{NH}_4\text{I}(\text{As}_2\text{O}_3)_2$, from a dil. soln. of ammonium dihydroarsenite, arsenic trioxide, and ammonium iodide. The six-sided prisms are not decomposed at 180° . P. Gruhl obtained tabular crystals of **lithium iodobisarsenite**, $\text{LiI}(\text{As}_2\text{O}_3)_2 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, by crystallization from a hot soln. of arsenic trioxide and an excess of lithium iodide. F. Rüdorff obtained six-sided plates of **sodium iodobisarsenite**, $\text{NaI}(\text{As}_2\text{O}_3)_2$, from a mixed soln. of sodium arsenite and iodide, and from a hot soln. of 60 parts sodium iodide, 25 parts arsenic trioxide, and 500 parts of water. The salt is decomposed by water. H. L. Wheeler obtained yellow plates of **potassium iodoarsenite**, $\text{KI} \cdot \text{As}_2\text{O}_3$, from a hot soln. of arsenic trioxide and potassium iodide in dil. hydriodic acid. F. A. H. Schreinemakers and W. C. de Baat did not observe the formation of this salt in their study of the ternary system $\text{As}_2\text{O}_3\text{-KI-H}_2\text{O}$ at 30° , when d and D , Fig. 40, coincide, and the complex salt is **potassium iodobisarsenite**, $\text{KI}(\text{As}_2\text{O}_3)_2$. This salt was obtained by H. Schiff and F. Sestini, and F. Rüdorff as a precipitate by mixing conc. soln. of potassium arsenite and iodide when the arsenite has been partially decomposed by carbon

dioxide. The same salt was also obtained by saturating a boiling soln. of potassium iodide with arsenic trioxide. H. Schiff and F. Sestini obtained this salt from a soln. of iodine in one of potassium arsenite. J. P. Emmet, E. Harms, and P. Gruhl obtained impure salts—J. P. Emmet said $2\text{KI} \cdot 3\text{As}_2\text{O}_3$ —by partly neutralizing potassium arsenite with acetic acid before mixing it with arsenic trioxide. The hexagonal, prismatic crystals are stable in air; and decompose at 350° . 100 parts of water at ordinary temp. dissolve 2.5 parts of salt; and with boiling water, twice as much salt. The salt is also soluble in soln. of potassium hydroxide, or carbonate; and is decomposed by acids with the separation of iodine. E. Harms reported **potassium dihydroxydiiodotrisarsenite**, $2\text{KOH} \cdot 2\text{KI} \cdot 3\text{As}_2\text{O}_3$, to be precipitated on passing carbon dioxide into a hot, sat., aq. soln. of the iodobisarsenite; and **potassium hexahydroxydiiodotrisarsenite**, $6\text{KOH} \cdot 2\text{KI} \cdot 3\text{As}_2\text{O}_3$, by dissolving the precipitate from potassium arsenite and iodide in hot alcohol, and passing into the soln. a current of carbon dioxide. H. L. Wheeler prepared six-sided plates of **rubidium iodoarsenite**, $\text{RbI} \cdot \text{As}_2\text{O}_3$, by cooling a hot soln. of rubidium iodide and arsenic trioxide in dil. hydriodic acid; and **caesium iodoarsenite**, $\text{CsI} \cdot \text{As}_2\text{O}_3$, was obtained in an analogous manner.

P. Gruhl reported a white crystalline powder of **calcium diiodotrisarsenite**, $\text{CaI}_2 \cdot 3\text{As}_2\text{O}_3 \cdot 12\text{H}_2\text{O}$, to be formed from a soln. of arsenic trioxide in one of calcium iodide; similarly with **strontium diiodotrisarsenite**, $\text{SrI}_2 \cdot 3\text{As}_2\text{O}_3 \cdot 12\text{H}_2\text{O}$; with **barium diiodotrisarsenite**, $\text{BaI}_2 \cdot 3\text{As}_2\text{O}_3 \cdot 8\text{H}_2\text{O}$; with **beryllium diiodotrisarsenite**, $\text{BeI}_2 \cdot 3\text{As}_2\text{O}_3 \cdot 8\text{H}_2\text{O}$; and with **magnesium diiodotrisarsenite**, $\text{MgI}_2 \cdot 3\text{As}_2\text{O}_3 \cdot 12\text{H}_2\text{O}$; and with colourless **zinc diiodotrisarsenite**, $\text{ZnI}_2 \cdot 3\text{As}_2\text{O}_3 \cdot 10\text{H}_2\text{O}$. F. Ephraim and F. Moser added about 6 mols of ammonia at room temp., forming **zinc hexamminodiiodotrisarsenite**, and at -20° , formed **zinc heptamminodiiodotrisarsenite**. This passes to the hexammine at 70° ; **zinc tetramminodiiodotrisarsenite** is formed at 97° , and at 200° , **zinc diamminodiiodotrisarsenite**. P. Gruhl also prepared colourless **aluminium triiodohexarsenite**, $\text{AlI}_3 \cdot 6\text{As}_2\text{O}_3 \cdot 16\text{H}_2\text{O}$; colourless **manganese diiodotetrasarsenite**, $\text{MnI}_2 \cdot 4\text{As}_2\text{O}_3 \cdot 12\text{H}_2\text{O}$; colourless **ferrous diiodotetrasarsenite**, $\text{FeI}_2 \cdot 4\text{As}_2\text{O}_3 \cdot 12\text{H}_2\text{O}$; pale red **cobalt diiodotetrasarsenite**, $\text{CoI}_2 \cdot 4\text{As}_2\text{O}_3 \cdot 12\text{H}_2\text{O}$; and pale green **nickel diiodotetrasarsenite**, $\text{NiI}_2 \cdot 4\text{As}_2\text{O}_3 \cdot 10\text{H}_2\text{O}$. F. Ephraim and F. Moser found that this salt could not be heated above 160° without decomposition, and at low temp. they prepared nickel aminodiiodotetrasarsenite, carrying more than 10 mols of NH_3 . Excepting the magnesium salt, these compounds are sparingly soluble in water. Soln. of chromic and stannous hydroxides in hydriodic acid take up arsenic trioxide, but the product is completely decomposed on evaporation. On the assumption that the compound is formed by the union of the mols. of arsenic trioxide with the iodine atoms, and the metal forms the cation, the constitution was represented:

G. Aminoff² described a mineral from Langban, Sweden, which he called **finne-manite**—after K. J. Finneman. The analysis corresponds with **lead chlorotriorthoarsenite**, $\text{Pb}_5\text{Cl}(\text{AsO}_3)_3$. The colour is grey to black—in thin flakes, olive-green. The hexagonal crystals have the axial ratio $a : c = 1 : 0.6880$, or in alternate position $1 : 1.1917$. The cleavage is distinct and pyramidal. The optical character is negative. The indices of refraction $\omega = 2.295$, and $\epsilon = 2.285$ for the *D*-ray. The sp. gr. is 7.08 to 7.265; and the hardness 2.3. A. E. Nordenskjöld described a mineral from Langban, Sweden, which he called **ecdemite**, or rather *ekdemite*—from $\epsilon\kappa\delta\eta\mu\omicron\varsigma$, unusual. It occurs in yellow or green, coarsely foliated or granular masses; in tabular crystals; or as crystalline incrustations. A. E. Nordenskjöld represented his analysis by $2\text{PbCl}_2 \cdot 2\text{PbO} \cdot \text{Pb}_3(\text{AsO}_3)_2$; P. Groth wrote G. Flink's formula $(\text{PbCl})_4\text{Pb}_2\text{O}(\text{AsO}_3)_2$, that is, $(\text{PbCl})_2\text{AsO}_3 \cdot \text{Pb} \cdot \text{O} \cdot \text{Pb} \cdot \text{AsO}_3(\text{PbCl})_2$, or **lead**

oxytetrachlorodiarsenite. A. Hamberg used the more complex formula, $4\text{PbCl}_2 \cdot \text{Pb}_2\text{As}_4\text{O}_{15}$. G. Flink obtained a mineral from Pajsberg, Sweden, which he called *heliophyllite*—from $\eta\lambda\iota\omicron\varsigma$, sun; and $\phi\acute{\upsilon}\lambda\lambda\omicron\nu$, leaf—in allusion to the colour and structure. G. Flink gave for heliophyllite $\text{Pb}_4\text{As}_2\text{O}_7 \cdot 2\text{PbCl}_2$, and the deviation from this in the average analyses is within the limits of likely errors. G. Flink supposed the crystals of heliophyllite to be rhombic bipyramids with the axial ratios $a : b : c = 0.96662 : 1 : 2.2045$, corresponding with ochrolite, the analogous antimonate. A. E. Nordenskjöld supposed ecdemite to be rhombic; and A. Hamberg tetragonal. The sections of ecdemite have a complex optical structure at first thought to be due to two different minerals. Heliophyllite also has a complex structure. A. Hamberg said that the basal cleavage sections of heliophyllite are in part uniaxial and in part biaxial; while in the case of foliated masses, the lamellæ cross at right angles as if they were twinned about a prism of 90° . There are also acute, pyramidal, tetragonal crystals with sections parallel to c showing an isotropic matrix, and systems of birefringent lamellæ twinned as just indicated. The structure, however, is not yet satisfactorily established. The hardness of ecdemite is 2.5 to 3.0; that of heliophyllite, about 2.0. A. E. Nordenskjöld gave 7.14 for the sp. gr. of ecdemite; and G. Flink, 6.885 for that of heliophyllite. Ecdemite is easily soluble in nitric acid, and in hot hydrochloric acid.

G. Lechartier³ prepared **calcium chloroarsenate**, $\text{Ca}_2\text{AsO}_4\text{Cl}$, or $\text{Cl}-\text{Ca}-\text{O}-\text{AsO}_2=\text{O}_2=\text{Ca}$ —analogous to wagnerite, and hence called *calcium chloroarsenato-wagnerite*—by melting a mixture of calcium chloride and orthoarsenate as in the case of the corresponding chloroarsenatoapatite. C. Lefèvre also made it by melting calcium oxide with a mixture of potassium metarsenate and over 20 per cent. of potassium chloride. The corresponding **magnesium chloroarsenate**, $\text{Mg}_2\text{AsO}_4\text{Cl}$, or *magnesium chloroarsenato-wagnerite*, was obtained as well as mixed crystals, $\text{Mg}_2\text{AsO}_4(\text{Cl},\text{F})$. H. Sjögren described a mineral from Langban, Sweden, and called it **tilasite**—after D. Tilas. The analyses by H. Sjögren, G. F. H. Smith and G. T. Prior, and G. Aminoff correspond with **calcium magnesium fluorthoarsenate**, $\text{CaAsO}_4(\text{MgF})$, or $(\text{Mg},\text{Ca})\text{F}(\text{AsO}_4) \cdot \text{F} \cdot \text{Mg}-\text{AsO}=\text{O}_2=\text{Ca}$. Part of the fluorine may be replaced by hydroxyl and in the extreme case, the tilasite passes into adelite. Hence, tilasite can be called *fluoadelite*. G. F. H. Smith and G. T. Prior found a pale green tilasite from Kajlidongri, India, occurring in monoclinic crystals with the axial ratios $a : b : c = 0.7503 : 1 : 0.8391$, and $\beta = 59^\circ 0' 30''$, and belonging to the clinohedral class, with a plane of symmetry, but no axis of symmetry. G. Aminoff gave $0.7436 : 1 : 0.8454$, and $\beta = 121^\circ 00'$. It is grey with a tinge of violet. H. Sjögren gave for the optic axial angles, for red, yellow, and green light, $2H_a = 98.4^\circ$, 99.5° , and 100.2° ; and $2H_0 = 110^\circ 28'$, $111^\circ 40'$, and $112^\circ 20'$. G. F. H. Smith and G. T. Prior found the optic axial angle $2V = 82^\circ 44'$; and the indices of refraction, with Na-light, are $\alpha = 1.640$, $\beta = 1.660$, and $\gamma = 1.675$. G. Lechartier prepared **manganese chloroarsenate**, $\text{Mn}_2\text{AsO}_4\text{Cl}$, or *manganese chloroarsenato-wagnerite*, as in the case of the calcium salt; and E. Lensen obtained **stannous chloroarsenate**, $\text{Sn}_2(\text{AsO}_4)\text{Cl} \cdot \text{H}_2\text{O}$, as a crystalline precipitate by adding an excess of stannous chloride to an acetic acid soln. of potassium arsenate.

A. Ditte made **calcium bromoarsenate**, $\text{Ca}_2\text{AsO}_4\text{Br}$, or *calcium bromoarsenato-wagnerite*, as in the case of the corresponding chloro-compound. Similarly with **magnesium bromoarsenate**, $\text{Mg}_2\text{AsO}_4\text{Br}$, or *magnesium bromoarsenato-wagnerite*, and **manganese bromoarsenate**, $\text{Mn}_2\text{AsO}_4\text{Br}$, or *manganese bromoarsenato-wagnerite*.

F. Briegleb⁴ reported a fluoarsenate to be formed by fusing a mixture of calcium fluoride, arsenic trioxide, and sodium nitrate and carbonate, and extracting with water the powdered product. He thus obtained octahedral crystals belonging to the cubic system. H. Baker obtained similar crystals from a mixed soln. of sodium orthoarsenate, and fluoride in soda-lye. According to H. Baker, F. Briegleb wrongly assigned the formula $\text{Na}_3\text{AsO}_4 \cdot \text{NaF} \cdot 12\text{H}_2\text{O}$ to the salt; he claimed that it should be $2\text{Na}_3\text{AsO}_4 \cdot \text{NaF} \cdot 19\text{H}_2\text{O}$, **sodium fluodiorthoarsenate**. F. Briegleb said the sp. gr. is 2.85 at 25° ; and H. Baker found the refractive indices with Li-, Na-,

and Tl-light respectively 1.4657, 1.4693, and 1.4726. The salt is isomorphous with the corresponding complex phosphate and vanadate. F. Briegleb found that 100 parts of water at 25° dissolve 10.47 parts of the salt, and at 75°, 50 parts of salt giving soln. with the respective sp. gr. 1.034, and 1.194.

A. Ditte⁵ prepared **calcium fluotriorthoarsenate**, $\text{Ca}_5(\text{AsO}_4)_3\text{F}$, or *calcium fluoarsenatoapatite*, by melting together the halide of the alkaline earth with ammonium arsenate in stoichiometrical proportions, or by melting the arsenate of the alkaline earth with the alkali fluoride and an excess of sodium chloride. The soluble matters were washed out with cold water. The hexagonal prisms and pyramids were freely soluble in dil. nitric and hydrochloric acids, and give off hydrogen fluoride when treated with sulphuric acids. H. Sjögren described a mineral from Pajsberg, and Jakobsberg, Sweden, and he called it **svavite**, or *svabite*. It occurs in colourless hexagonal prisms with the axial ratio $a : c = 1 : 0.7143$, and in fibrous crystalline aggregates. The formula calculated from the analysis is $\text{Ca}_5\text{FAs}_3\text{O}_{12}$, or calcium fluotriorthoarsenate, $\text{CaF} \cdot \text{Ca}_4(\text{AsO}_4)_3$; G. Flink gave $(\text{Cl}, \text{F}, \text{OH})\text{Ca}_5(\text{AsO}_4)_3$; H. Sjögren said that the calcium may be in part replaced by lead, magnesium, iron (ous), and MnO ; and the fluorine, by chlorine and hydroxyl. The mineral is said to be isomorphous with apatite; and to have the axial ratio $a : c = 1 : 0.71094$. Its hardness is 5; and its sp. gr. 3.52. G. Flink gave 3.695. The birefringence is feeble and negative. The mineral is easily soluble in acids. A. Ditte made **strontium fluotriorthoarsenate**, $\text{Sr}_5(\text{AsO}_4)_3\text{F}$, in *strontium fluoarsenatoapatite*; **barium fluotriorthoarsenate**, $\text{Ba}_5(\text{AsO}_4)_3\text{F}$, or *barium fluoarsenatoapatite*; **magnesium fluotriorthoarsenate**, $\text{Mg}_5(\text{AsO}_4)_3\text{F}$, or *magnesium fluoarsenatoapatite*, by a process analogous to that employed for the calcium salt.

Orange-red crystals of a mineral occur in the Barranca tin mine, Durango, Mexico. The mineral was named **durangite** by G. J. Brush.⁶ Analyses corresponded with the formula $(\text{Na}, \text{Li})(\text{Al}, \text{Fe})\text{AsO}_4\text{F}$, or, as C. F. Rammelsberg wrote it, $\text{R}'''\text{AsO}_4 \cdot \text{NaF}$, or, according to P. Groth, **sodium aluminium fluoarsenate**, $\text{F} - \text{Al} = \text{AsO}_4 - \text{Na}$. W. T. Schaller regarded durangite, $\text{NaAsO}_4(\text{AlF})$ as an amblygonite, and related to soda-amblygonite as indicated by the formula $\text{NaPO}_4(\text{AlF})$, where some of the fluorine may be replaced by hydroxyl. According to G. J. Brush, and A. des Cloizeaux, the monoclinic crystals have the axial ratios $a : b : c = 0.77158 : 1 : 0.82499$ and $\beta = 64^\circ 17'$; the (110)-cleavage is distinct. A. des Cloizeaux gave for the optic axial angle for red and yellow light, $2H_a = 80^\circ 53'$ and $80^\circ 49'$, respectively; the optical character is negative: the hardness, 5; and the sp. gr., 3.94 to 4.07. It is decomposed by sulphuric acid with the evolution of hydrofluoric acid.

According to M. Amadori, when mixtures of lead fluoride and orthoarsenate are melted in the correct proportions, **lead fluotriorthoarsenate**, $3\text{Pb}_3(\text{AsO}_4)_2 \cdot \text{PbF}_2$, or $(\text{PbF})\text{Pb}_4(\text{AsO}_4)_3$, is formed with a m.p. 1042° . The conditions of stability are indicated in Fig. 41. On account of the general resemblance of this compound to mimetite, it is called **fluomimetite**. C. C. McDonnell and C. M. Smith obtained it by boiling lead arsenate for 5 hrs. with a soln. of 35 grms. of sodium fluoride in a litre of water. M. Amadori found that mixtures of fluopyromorphite with 0, 10, 25, 50, 75, 90, and 100 per cent. of fluomimetite melted respectively at 1098° , 1092° , 1086° , 1092° , 1058° , 1050° , and 1042° . The mixtures have been called **lead fluotriorthophosphatoarsenates**, $(\text{PbF})\text{Pb}_4(\text{As}_3\text{P})\text{O}_{12}$.

E. F. Holden⁷ reported a bright blue mineral from Bisbee, Arizona, with a fibrous structure. He called it *ceruleofibrite*; he at first regarded it as copper hydroxychloroarsenate, but later showed that it is a chlorosulphate—a variety of the

FIG. 41.—Freezing-point curves in the System: $\text{PbF}_2 - \text{Pb}_3(\text{AsO}_4)_2$.

mineral connellite described by C. Palache and H. E. Merwin. G. Lechartier melted a mixture of calcium arsenate and chloride, and obtained crystals of **calcium chlorotriorthoarsenate**, $\text{Ca}_5(\text{AsO}_4)_3\text{Cl}$, isomorphous with apatite, and hence called *calcium chloroarsenatoapatite*. J. H. Debray also made the salt by heating the constituents with water in a sealed tube; E. Weinschenk, by heating a mixture of calcium chloride, ammonium dihydroarsenate, and chloride in a sealed tube at 150° – 180° ; and C. Lefèvre, by melting sodium dihydroarsenate with calcium chloride and over 60 per cent. of sodium chloride. G. Lechartier found that if a mixture of calcium chloride and fluoride be employed, mixed crystals are formed, $\text{Ca}_5(\text{AsO}_4)_3(\text{Cl},\text{F})$. G. Lechartier, and C. Lefèvre prepared in an analogous way, **strontium chlorotriorthoarsenate**, $\text{Sr}_5(\text{AsO}_4)_3\text{Cl}$, or *strontium chloroarsenatoapatite*; and A. Ditte, G. Lechartier, E. Weinschenk, and C. Lefèvre, **barium chlorotriorthoarsenate**, $\text{Ba}_5(\text{AsO}_4)_3\text{Cl}$, or *barium chloroarsenatoapatite*; and A. de Schulten, **cadmium chlorotriorthoarsenate**, $\text{Cd}_5(\text{AsO}_4)_3\text{Cl}$, or *cadmium chloroarsenatoapatite*.

J. G. Wallerius,⁸ in 1748, described a green lead ore—*minera plumbi viridis*—which he described as *plumbum arsenico mineralisatum*; and partial analyses of *plomb vert arsenical* were made by J. L. Proust, and A. F. de Fourcroy. The mineral was also described by D. G. J. Lenz. F. S. Beudant called it *mimetèse*—from $\mu\mu\eta\tau\eta\varsigma$, an imitator—in allusion to its resemblance to pyromorphite. The term *mimetesite* is wrongly formed, and A. Breithaupt, W. Haidinger, and E. F. Glocker therefore called it **mimetite**. C. U. Shepard first called it *mimetene* and later *mimetite*. Specimens have been reported from numerous localities: Cornwall, Devonshire, and Cumberland, in England; Leadhills and Wanlockhead, Scotland; Saone, and Puy de Dôme, France; Nerchinsk, Siberia; Zinnwald and Badenwerhr, Germany; Långban, Sweden; Marqueza, Chili; Phenixville, Pennsylvania, Cerro Gordo mines, California; etc. The colour may be white, pale yellow, passing into orange-yellow and brown. The mineral usually occurs in crystals or rounded crystal aggregates; in capillary or filamentous crystals; and in concretionary masses, and mammillary crusts. Analyses were reported by F. Wöhler, J. L. Smith, A. Damour, E. Jannettaz and L. Michel, P. A. Dufrenoy, G. A. König, O. Pufahl, K. Biehl, C. C. McDonnell and C. M. Smith, C. Bergemann, A. Serra, L. E. Rivot, A. F. de Fourcroy, F. A. Massie, F. A. Genth, C. F. Rammelsberg, P. von Jeremejeff, D. Lovisato, H. Struve, C. M. Kersten, G. Lindström, W. Lindgren, etc. The results correspond with $3\text{Pb}_3(\text{AsO}_4)_2 \cdot \text{PbCl}_2$, or **lead chlorotriorthoarsenate**, $(\text{PbCl})\text{Pb}_4(\text{AsO}_4)_3$. A. Werner represented it $[\text{Pb}\{(\text{PbAsO}_3\text{O})_2\}_3]\text{Cl}_2$.

G. Lechartier prepared crystals of this compound by fusing lead arsenate with an excess of lead chloride, and afterwards washing out the excess of chloride;

FIG. 42.—Freezing-point Curves in the System: PbCl_2 – $\text{Pb}_3(\text{AsO}_4)_2$.

the conditions of existence are illustrated in M. Amadori's diagram, Fig. 40, showing the freezing-point curve of binary mixtures of these two components. L. Michel made this mineral by heating to 1050° stoichiometrical proportions of the two components in a porcelain crucible buried in magnesia contained in a fireclay crucible. E. Weinschenk heated a mixture of lead chloride and ammonium hydroarsenate; and C. Lefèvre, a mixture of lead chloride and sodium metarsenate together with 10 per cent. of sodium chloride. C. C. McDonnell and C. M. Smith obtained this compound from a sat. soln. of lead chloride in one of ammonium, sodium, or potassium arsenate with 0.04 mol of As_2O_5 per litre; by boiling lead hydroarsenate for 5 min. with a 2–10 per cent. soln. of sodium chloride; and by adding 30 grms. of arsenic acid to 2 litres of a boiling sat. soln. of sodium chloride, then adding lead acetate until the precipitate no longer redissolves, and finally 600 c.c. of water. The precipitate is then washed with boiling water until the

washings are free from chlorine. Crystals were also formed from a soln. of lead arsenate in hydrochloric acid; and a gelatinous precipitate of the composition of mimetite separated when a soln. of lead hydroarsenate in a boiling soln. of ammonium chloride was poured into a large vol. of cold water. Pseudomorphs after anglesite have been described by F. A. Genth, and G. vom Rath. The mineral is supposed to have been formed in nature as a secondary mineral by the action of soln. of arsenic acid or arsenates, and chlorides on lead minerals.

Mimetite is isomorphous with pyromorphite, vanadinite, and the fluophosphates. As emphasized by R. Brauns, there is a large family of isomorphous minerals of this type occurring as hexagonal pyramidal crystals with axial ratios $a : c$, nearly unity; *apatite*, $\text{Ca}_5\text{F}(\text{PO}_4)_3$, and $\text{Ca}_5\text{Cl}(\text{PO}_4)_3$, $a : c = 0.7346$; *polyspharite*, $(\text{Pb}, \text{Ca})_5\text{Cl}(\text{PO}_4)_3$, 0.73544; *pyromorphite*, 0.72926; *svabite*, $\text{Ca}_5(\text{F}, \text{Cl}, \text{OH})(\text{AsO}_4)_3$, 0.7143; *campylite*, $\text{Pb}_5\text{Cl}\{(\text{As}, \text{P})\text{O}_4\}_3$, 0.725; *mimetite*, $\text{Pb}_5\text{Cl}(\text{AsO}_4)_3$, 0.73147; *hedyphane*, $(\text{Ca}, \text{Pb})_5\text{Cl}(\text{AsO}_4)_3$, 0.7063; *endlichite*, $\text{Pb}_5\text{Cl}\{(\text{As}, \text{V})\text{O}_4\}_3$, 0.7495; and *vanadinite*, $\text{Pb}_5\text{Cl}(\text{VO}_4)_3$, 0.7122. The crystals of mimetite are hexagonal, with pyramidal hemihedrim. W. Haidinger gave for the axial ratio $a : c = 1 : 0.7224$; A. Serra, 1 : 0.7284; R. Brauns, 1 : 0.73147; J. Schabus, 1 : 0.71899; W. H. Miller, 1 : 0.74956; G. Aminoff and A. L. Parsons, 1 : 0.722; and for the artificial crystals, M. Amadori gave 1 : 0.72754. The crystals were also studied by J. F. L. Hausmann, W. H. Miller, P. von Jeremejeff, E. T. Wherry, O. Pufahl, E. S. Larsen, R. Brauns, K. Biehl, H. Ungemach, and V. Goldschmidt. M. Amadori found the axial ratios of artificial mixtures of pyromorphite and mimetite in agreement with the isomorphism of these salts. G. Carobbi and S. Restaino found that cerium, lanthanum, and didymium can replace the lead isomorphously. H. Baumhauer examined the corrosion figures. The $(10\bar{1}1)$ -cleavage is imperfect; twinning has not been observed. The artificial crystals were found by C. C. McDonnell and C. M. Smith to be optically uniaxial; but mimetite may be optically anomalous, being often biaxial, and E. Bertrand found that mimetite from Johanngeorgenstadt had an optic axial angle $2E = 64^\circ$; H. L. Bowman also gave $2E = 62^\circ$ for a Cornish sample. E. Bertrand said that the basal section shows a division into six triangular sectors with uniaxial planes parallel to the sides of the hexagon. Pyromorphite is normally uniaxial, and E. Jannettaz and L. Michel showed that there is an increase in the biaxial character in an isomorphous series of phosphates and arsenates as the proportion of arsenate increases in the arsenical varieties of pyromorphite to pure mimetite. P. von Jeremejeff attributed the optical anomaly *auf einer Molekularumlagerung* of the substance. This means that the cause is unknown. W. Eissner found that in passing from -160° to 650° , the crystal angles show abrupt changes. The case of $(0001) : (10\bar{1}1)$ is indicated in Fig. 43. These are explained by the assumption that the mineral is dimorphous. The curve AB represents the variation of the crystal angles of α -mimetite with temp.; and BC , the interval of transformation to β -mimetite; so that CD represents the effect of temp. on the crystal angle of β -mimetite. Pyromorphite shows analogous changes. G. Aminoff and A. L. Parsons found the X-radiogram agrees with a space-lattice with 0.92 mol. per unit cell; a c -axis of 7.28 Å.; an axial ratio $a : c = 1 : 0.727$; and a sp. gr. 7.25. The hardness of mimetite is about 3.5. C. F. Rammelsberg gave 7.218 for the sp. gr. of mimetite; J. L. Smith, 7.32; F. Katzer, 7.126; O. Pufahl, 6.98; and H. Struve, 6.653. L. Michel gave for the artificial crystals 7.12, and C. C. McDonnell and C. M. Smith, 7.14 at 15° . Calcareous varieties—hedyphane—have a smaller sp. gr. Thus, A. Damour gave 6.65; W. Lindgren, 5.85; G. Lindström, 5.82; and C. M. Kersten, and C. F. Rammelsberg, 5.49. M. Amadori found the m.p. of chloromimetite to be 1140° , Fig. 42: and the f.p. of mixtures of chloromimetite and 0, 30, 50, and

FIG. 43.—The Effect of Temperature on the Crystal Angles of Mimetite.

100 per cent. of chloropyromorphite to be respectively 1156° , 1150° , 1145° , and 1140° ; the mixtures have been called **lead chlorotriorthoarsenates**, $(\text{PbCl})\text{Pb}_4\{(\text{As},\text{P})\text{O}_4\}_3$; and for mixtures of fluomimetite with 0, 10, 30, 50, 80, and 100 per cent. of chloromimetite, the f.p. are 1042° , 1060° , 1087° , 1107° , 1128° , and 1140° . These mixtures have been called **lead fluochlorotriorthoarsenates**, $\text{Pb}(\text{Cl},\text{F})\text{Pb}_4(\text{AsO}_4)_3$. H. L. Bowman found the refractive indices for red, yellow, and blue light for a specimen of mimetite, from Wheal Alfred, Cornwall, $\omega=2.1236$, 2.1346 , and 2.2053 respectively; and $\epsilon=2.1392$, 2.1488 , and 2.2220 respectively; and for a specimen from Tintic, Utah, $\omega=2.1178$, 2.1286 , and 2.1750 respectively, and $\epsilon=2.136$, 2.1443 , and 2.1932 respectively. E. S. Larsen gave $\omega=2.14$, $\epsilon=2.13$; the negative birefringence for yellow light is $0.0142-0.019$; for red light, $0.0148-0.0214$; and for blue light, $0.0153-0.0182$. Earlier observers make the optical character positive. C. C. McDonnell and C. M. Smith found for the artificial mineral $\omega=2.16$, and $\epsilon=2.13$. W. G. Hankel studied the pyroelectricity of mimetite and found the basal surface becomes negative while the prismatic and pyramidal surfaces become positive. Mimetite is insoluble in water; but soluble in nitric acid, and in dil. alkali-lye. H. C. Bolton also found that it is soluble in cold conc. citric acid. J. G. Hibbs found that the mineral is readily decomposed by hydrogen chloride.

The mineral **hedyphane**, so named by A. Breithaupt⁹—from *ἡδύφανης*, of attractive aspect—is a calcareous variety of mimetite so far as can be judged from the analyses of C. M. Kersten, I. Domeyko, C. F. Rammelsberg, G. Lindström, W. F. Foshag and R. B. Gage and L. J. Igelström, $(\text{Ca},\text{Pb})_2\text{Cl}(\text{AsO}_4)_3$. The white or yellow mineral occurs at Langban, and Pajsberg, Sweden. A. des Cloizeaux thought that the crystals are monoclinic, but H. Sjögren found them to be hexagonal dipyramids with the axial ratio $a:c=1:0.7063$, and R. Brauns showed that they are isomorphous with mimetite. G. Aminoff examined the crystals. The hardness is $3.5-4.5$. A. Breithaupt gave 5.404 for the sp. gr.; F. Gonnard, 6.60 ; A. Damour, 6.65 ; and G. Lindström, 5.82 . W. F. Foshag and R. B. Gage found that the mineral is optically uniaxial and negative with the indices of refraction $\omega=2.026$, and $\epsilon=2.010$; and C. Palache and H. Berman gave $\epsilon=1.958$, and $\omega=1.948$ for Na-light. The optical character is positive. Another variety, partly described by L. J. Igelström, was called **pleonectite**—from *πλεονεκτείν*, to have more—in allusion to the occurrence of several related minerals in the mine at Oerebro, Sweden. It is considered without proof to be an antimonial mimetite. According to R. P. Greg and W. G. Lettsom, the mineral **campyllite**—from *καμπύλος*, curve—in allusion to the barrel-shaped crystals, occurs in Drygill, Cumberland. Analyses reported by A. Damour, H. Struve, W. Lindgren, C. F. Rammelsberg, and A. Lacroix show that it is an isomorphous mixture of pyromorphite and mimetite, $\text{Pb}_2\text{Cl}\{(\text{As},\text{P})\text{O}_4\}_3$. This subject was discussed by M. Amadori, E. Jannettaz and L. Michel, and F. Gonnard. L. Michel synthesized it as in the case of mimetite, but using variable proportions of lead phosphate and arsenate instead of arsenate alone. L. Michel said that some varieties are chromiferous; and G. Lindström, that some are bariferous. The sp. gr., according to A. Breithaupt, is $6.8-6.9$; C. F. Rammelsberg gave 7.218 . G. Aminoff found at Langban, Sweden, crystals of a mineral, which he called **finnemanite**. The analysis corresponds with lead chlorotrimetarsenite, $\text{Pb}_5\text{Cl}(\text{AsO}_4)_3$, or $3\text{Pb}_2(\text{AsO}_4)_3\cdot\text{PbCl}_2$. The hexagonal prisms have the axial ratio $a:c=1:0.6880$; the optical character is negative; the sp. gr., 7.08 to 7.265 ; the hardness, 2 to 3 ; and the indices of refraction, $\omega=2.2949$, and $\epsilon=2.3847$. According to G. Aminoff and A. L. Parsons, the X-radiogram agrees with 0.92 mol. per unit cell; a c -axis of 6.97 Å.; an axial ratio $a:c=1:0.683$; and a sp. gr. 7.26 .

A. Ditte¹⁰ obtained **calcium bromotriorthoarsenate**, $\text{Ca}_5(\text{AsO}_4)_3\text{Br}$, or *calcium bromoarsenatoapatite*, by the method which he employed for the chloro-compound. Similarly also with **strontium bromotriorthoarsenate**, $\text{Sr}_5(\text{AsO}_4)_3\text{Br}$, or *strontium bromoarsenatoapatite*; **barium bromotriorthoarsenate**, $\text{Ba}_5(\text{AsO}_4)_3\text{Br}$, or *barium bromoarsenatoapatite*; A. de Schulten made **cadmium bromotriorthoarsenate**, $\text{Cd}_5(\text{AsO}_4)_3\text{Br}$, or *cadmium bromoarsenatoapatite* and A. Ditte, **manganese bromotriorthoarsenate**, $\text{Mn}_5(\text{AsO}_4)_3\text{Br}$, or *manganese bromoarsenatoapatite*.

A. Ditte reported complexes with bromine to be formed by melting a mixture of 2 parts of lead bromide with 3 parts of lead arsenate in the presence of an excess of sodium iodide, and afterwards washing out the soluble salts, when pale yellow hexagonal prisms and plates of **lead bromotriorthoarsenate**, $(\text{PbBr})\text{Pb}_4(\text{AsO}_4)_3$, or $\text{PbBr}_2\cdot 3\text{Pb}(\text{AsO}_4)_3$, or, according to A. Werner, $[\text{Pb}\{(\text{PbAsO}_3\text{O})_2\text{Pb}\}_3]\text{Br}_2$, were

obtained. The salt was called *lead bromoarsenatoapatite*, or **bromomimetite**. C. C. McDonnell and C. M. Smith obtained it by boiling lead hydroarsenate for 5 hrs. with a 3.5 per cent. soln. of potassium bromide.

A. Ditte prepared **calcium iodotriorthoarsenate**, $\text{Ca}_5(\text{AsO}_4)_3\text{I}$, or *calcium iodoarsenatoapatite*, by a method analogous to that employed for the chloro-compound; similarly with **strontium iodotriorthoarsenate**, $\text{Sr}_5(\text{AsO}_4)_3\text{I}$, or *strontium iodoarsenatoapatite*; and **barium iodotriorthoarsenate**, $\text{Ba}_5(\text{AsO}_4)_3\text{I}$, or *barium iodoarsenatoapatite*. By working in a manner analogous to that employed for the bromo-compound, A. Ditte, and C. C. McDonnell and C. M. Smith obtained small yellow crystals of **lead iodotriorthoarsenate**, $(\text{PbI})\text{Pb}_4(\text{AsO}_4)_3$, or $\text{PbBr}_2 \cdot 3\text{Pb}(\text{AsO}_4)_3$; *i.e.* **iodomimetite**, or *lead iodoarsenatoapatite*.

C. Haack¹¹ reported **mercuric oxychloroarsenate**, $8\text{HgO} \cdot 5\text{HgCl}_2 \cdot 3\text{Hg}_3(\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$, to be formed by dropping a soln. of 3 mols of mercuric chloride into one containing 4 mols of sodium hydroarsenate. In 24 hrs., the yellow precipitate was washed with cold water and dried in air. By dropping a soln. of one mol of sodium hydroarsenate into a cold soln. of 3 mols of mercuric chloride, he obtained a hydrate, $8\text{HgO} \cdot 5\text{HgCl}_2 \cdot 3\text{Hg}_3(\text{AsO}_4)_2 \cdot 62\text{H}_2\text{O}$, when the lemon-yellow precipitate is washed and dried in air. C. C. McDonnell and C. M. Smith reported **lead dichlorotetraorthoarsenate**, $\text{PbCl}_2 \cdot 2\text{Pb}_3(\text{AsO}_4)_2 \cdot \text{H}_2\text{O}$, or $\text{Pb}_4(\text{PbCl})_2(\text{AsO}_4)_4 \cdot \text{H}_2\text{O}$, to be formed by adding to two litres of a boiling sat. soln. of sodium chloride, 30 grms. of arsenic acid, and lead arsenate until the precipitate formed no longer dissolves, and pouring the clear filtrate into 5 times its vol. of water at 28°–30°. The crystalline precipitate loses its water of crystallization when heated.

A. Lacroix and A. de Schulten¹² obtained a white or brownish-yellow, crystalline mineral from the lead slags at Laurion, Greece; they called it **georgiadesite**—after M. Georgiades. Its composition corresponded with **lead trichlororthoarsenate**, $3\text{PbCl}_2 \cdot \text{Pb}_3(\text{AsO}_4)_2$, or $(\text{PbCl})_3\text{AsO}_4$. The rhombic crystals have the axial ratios $a : b : c = 0.5770 : 1 : 0.2228$. The hardness is 3.5, and the sp. gr. 7.1.

A. Hirsch¹³ reported what he regarded as complex compounds of sodium chloride and copper arsenate. Thus, **sodium copper chlorotetraorthoarsenate**, $\text{NaCl} \cdot 2\text{Cu}_3(\text{AsO}_4)_2 \cdot 7\frac{1}{2}\text{H}_2\text{O}$, was formed by adding an aq. soln. of 2 mols of sodium hydroarsenate to one containing an excess of cupric chloride, say 30 mols, and washing the precipitate until the washings are free from chlorides. He also obtained it by allowing the filtrate from a mixture of equimolar parts of soln. of sodium hydroarsenate and cupric chloride to stand a few days. The original precipitate corresponds with **sodium copper dichlorohexaorthoarsenate**, $2\text{NaCl} \cdot 3\text{Cu}_3(\text{AsO}_4)_2 \cdot 13\frac{1}{2}\text{H}_2\text{O}$; by using a rather smaller proportion of cupric chloride, he obtained the hemihexacosihydrate. By using twice the molar proportion of cupric chloride, he obtained products with $\text{NaCl} : \text{Cu}_3(\text{AsO}_4)_2 : \text{H}_2\text{O}$ as 3 : 5 : 19, and as 3 : 5 : 23, but regarded them as mixtures. There is nothing to show that all are not mixtures.

J. W. Mallet¹⁴ reported a sulphur-yellow, orange, red, or brown, massive, cryptocrystalline mineral from Guanacere, Mexico, which he named **achrematite**—from *ἀχρηματός*, useless, in allusion to its being mistaken for a useful silver ore. The composition approximates to **lead oxymolybdatochloroarsenate**, $3\{3\text{Pb}_3(\text{AsO}_4)_2 \cdot \text{PbCl}_2\} \cdot 4\text{Pb}_2\text{MoO}_8$. Its sp. gr. is 5.965 in lump, and 6.178 in powder; the hardness is 3–4.

§ 30. The Sulphides of Arsenic—The Disulphide

Arsenic unites directly with sulphur when a mixture of the two elements is heated. The chemical individuality of the sulphides, As_2S_2 , As_2S_3 , and As_2S_5 , is well established. The existence of As_3S and As_4S_3 is not so well established. J. J. Berzelius¹ reported a number of other sulphides; thus, As_6S was said to be deposited as a brown powder when the di- or tri-sulphide is boiled with potash-lye, but A. Scott, O. B. Kühn, and L. F. Nilson showed that it is more likely to be a mixture of arsenic and arsenic sulphide. A. Schüller, as late as 1894, said the hexitasulphide is produced when molten As_4S_3 is exposed to the vap. of arsenic; but there is no sign of such a compound on the thermal diagram, Fig. 44. As_2S_{10} was reported by O. B. Kühn, and As_2S_{18} by J. J. Berzelius as a result of treating potassium pyrosulpharsenite with alcohol. Both were shown by L. F. Nilson to be mixtures of arsenic sulphide and sulphur. J. J. Berzelius reported yet higher sulphides, for he said that arsenic trioxide may be fused with any excess of sulphur whatever, forming a brownish-yellow sulphide, and the evolution of sulphur dioxide. On distilling a persulphide of this nature, sulphur passes over accompanied by a continually increasing proportion of arsenic. L. Gmelin could even say that in his time, 1850, "much of the sulphur of commerce is of this nature." There is no sign on the thermal diagram of the arsenic sulphides, Fig. 44, or of a compound with an at. ratio As : S higher than 2 : 5.

A. Scott reported arsenic tritasulphide, As_3S , to be formed in the following manner :

Two hundred grms. of crystallized sodium arsenate were dissolved in $3\frac{1}{2}$ litres of water, and then 150 c.c. of phosphorus trichloride added and allowed to stand till quite cold, the soln. filtered and sulphur dioxide passed in and allowed to stand for a day or two. The supernatant liquid is then poured off and the precipitate washed first with water, then with dil ammonia soln., then warmed with stronger soln. of ammonia, and into this hydrogen sulphide is passed and the digestion continued for an hour or two; the precipitate is then well washed with water by decantation, and finally with alcohol, and dried in a vacuum. The same sulphide is obtained from arsenites, but the yield is much smaller in proportion, owing to the precipitation of much arsenious oxide from the strongly acid soln. The corresponding antimony sulphide could not be prepared.

W. Farmer and J. B. Firth made arsenic tritasulphide by a reaction between a tervalent arsenic compound and sodium hyposulphite, while the trisulphide is produced by the interaction of the arsenic compounds with thiosulphate and other thio-decomposition products of the hyposulphite. A yellow precipitate of arsenic trisulphide is obtained when a soln. of sodium thiosulphate containing alkali arsenite is acidified with hydrochloric acid and warmed. Hence, an increased conc. of hydrochloric acid increases the rate of decomposition of the hyposulphite, and the quantity of subsulphide produced is diminished and that of the trisulphide

increased. In the case of quinquevalent arsenic compounds, reduction to the tervalent compound first takes place with the production of thio-decomposition products; the arsenic is subsequently precipitated, partly as disulphide by the hyposulphite and partly as trisulphide by the thiosulphate, etc. In no case was the arsenic completely precipitated from soln., but in neutral soln., with 10 grms. of hyposulphite for 1 gm. of arsenic trioxide, 99.24 per cent. was precipitated. The maximum precipitation of arsenic from quinquevalent compounds was 57.25 per cent., obtained in the same series under similar conditions. A. Scott observed that the tritasulphide is insoluble in aq. soln. of ammonia or colourless ammonium sulphide, but it is readily dissolved by a yellow soln. of ammonium sulphide. Hydrochloric acid precipitates arsenic trisulphide from the soln. in yellow ammonium sulphide. When heated, it forms the disulphide which sublimes, and arsenic which remains. Alkali-lye acts on it as in the case of the disulphide. A. Schüller reported that arsenic tritritrasulphide, As_4S_3 , is formed by melting a mixture of arsenic trisulphide and powdered arsenic, and purifying the powdered product either by carbon disulphide or sublimation in vacuo. The yellow or orange-yellow sulphide darkens when heated. J. A. Krenner showed that the crystals obtained by sublimation are rhombic with axial angles $a:b:c = 0.58787:1:0.88258$; and the optic axial angle $2H_a = 108^\circ 46'$; the optical character is positive; and the sp. gr. 2.6 at 19° . A. Schüller gave 3.60 for the sp. gr. at 19° . According to E. C. Szarvasy and C. Messinger, the vap. density of this sulphide is 8.204 at 792° , and 6.588 at 1000° . The calculated value for As_4S_3 is 13.69. This was taken to mean that the vap. of the compound is dissociated. W. P. A. Jonker, and W. Borodowsky found no evidence of the tritritrasulphide on the f.p. curve of mixtures of the two elements.

A. Scacchi obtained orange-yellow crystals of an arsenic sulphide from a fumarole in the Phlegrean fields, Italy. He called it *dimorfina*, which was altered by J. D. Dana to **dimorphite**. The analysis corresponds with the tritritrasulphide. The sp. gr. is 3.58. The rhombic crystals of the sulphide were said to occur in two forms with the respective axial ratios, α -dimorphite $a:b:c = 0.895:1:0.776$; and β -dimorphite $a:b:c = 0.907:1:0.603$. J. D. Dana showed that if the crystals of orpiment and those of α -dimorphite are so compared that the (001)-face of the former corresponds with the (010)-face of the latter, the axial ratios and crystal angles are so much in agreement that he could

FIG. 44.—Freezing-point Curves of the Binary System: As-S.

say that α -dimorphite and orpiment "are probably identical." The relations of β -dimorphite are not so clear. G. A. Kennigott showed that if the crystals are so placed that the (011)-face of β -dimorphite corresponds with the (110)-face of orpiment, the angles of the two crystals agree fairly closely with one another. J. A. Krenner considers β -dimorphite to be a definite species, and he said that if the crystals be oriented so that the (011)-face of a crystal of β -dimorphite coincides with the (110)-face of a crystal of the sublimed tritritrasulphide, the angles of the two crystals "are closely identical." S. Stevanovic also made some observations on this subject.

W. Borodowsky, and W. P. A. Jonker studied the equilibrium diagram of mixtures of arsenic and sulphur. The results obtained by the former are summarized in Fig. 44. The temp. at which

As	0	10.70	40.07	43.92	50.05	54.88	57.12	63.23	69.19	74.08	91.14
M_1	119°	112°	300°	279°	308°	307°	305°	255.5°	261.5°	294°	466°
M_2	119°	113°	300°	293°	308°	308.5°	308°	232°	268°	301°	476°
T	—	—	170°	140°	367°	—	260°	—	—	—	—

Mixtures between 20 and 60 molar per cent. of arsenic were viscid, and did not crystallize quickly enough to enable the curves to be completed. The m.p. of

sulphur drops from 119° to 118° with 0.21 molar per cent. of arsenic, and to 112° – 113° with 10.7 molar per cent. The m.p. of red trisulphide is 300° , and there is a transition temp. from α - As_2S_3 (yellow) to β - As_2S_3 (red) at 170° ; the m.p. of the disulphide is 308.5° , and the transition temp. from α - As_2S_2 (red) to β - As_2S_2 (black) is 267° . The corresponding eutectics are at 279° – 293° for 64.7 molar per cent. of arsenic and 225.5° – 232° for 80 molar per cent. of arsenic. The break at 301° may be due to the transformation of α - to β -arsenic, or to the formation of an unstable compound, *arsenic tritasulphide*, As_3S .

According to W. P. A. Jonker, arsenic sublimes at 616° , and a sat. soln. of realgar boils at 534° ; and natural or artificial orpiment at 707° . The form of the sublimation curve, Fig. 45, shows that arsenic disulphide is largely dissociated as vap., while the trisulphide distils unchanged. No evidence of the pentasulphide was observed on the b.p. curves.

The use of the words sandarach, arsenicon, and auripigmentum by the Greek and Roman writers has been discussed in connection with history of arsenic. The term *auripigmentum* was employed for the yellow sulphide—that is, arsenic trisulphide—and *sandarach*, for the red sulphide—that is, arsenic disulphide. A. Libavius² referred to the use of the term **realgar** for the red sulphide, by the Paracelsian school about the beginning of the sixteenth century, but the term appears to have been in use before this, for it was mentioned by Matthæus Sylvatius in 1336, and, according to C. Hintze, the term also occurs in S. de Renzi's *Collectio salernitana*. F. von Kobell said the term is of unknown origin; J. B. Dana said that it comes from the Arabic *rahj al ghar*, meaning dust of the mine. According to C. Hintze, this meets with the approval of the Arabic scholars, but he added that this derivation is *ein wenig zutreffenden ware*. G. Agricola called the red sulphide *reuschgeel*, and *rosgeel*; A. Libavius, *rosagallum*, and *Räuschgal*; J. G. Wallerius, *Rauschgelb*; A. G. Werner, and L. A. Emmerling, *rothes Rauschgelb*; and analogous terms were used by many subsequent writers for the red arsenic sulphide. The Italian word for realgar is *risigallo*, and the Spanish, *realgar*.

Realgar occurs in rose-red, orange-red, or orange-yellow prismatic crystals; in coarse or fine granules, in compact masses or as an incrustation. Strabo, in the first century of our era, in his *Geographia* (12. iii, 40), said that there were sandarach mines at Pompeiopolis, in Paphlagonia; and added:

The mountain is hollowed out by large trenches made by workmen in the process of mining. The work is always carried on at the public charge, and slaves were employed in the mine who had been sold on account of their crimes. Besides the great labour of the employment, the air is said to be destructive of life, and scarcely endurable in consequence of the strong odour issuing from the masses of mineral; hence the slaves are short-lived. The mining is frequently suspended from its becoming unprofitable, for great expense is incurred by the employment of more than two hundred workmen, whose number is continually diminishing by disease and fatal accidents.

Realgar has been reported to be found at Goramis, and Tacht-i-Soleiman (Persia); Julamerk (Kurdistan); Allchar (Macedonia); Matra (Corcia); Plateau Central (France); Asturias (Spain); Aetna, Vulcano Casa Testi, Tolfa, and the Solfatara of the Phlegrean Fields (Italy); Binnenthal (Switzerland); Schwarz Mitterberg, Hall (Salzberg); Fohnsdorf (Styria); Keutschach, Sachsenberg, St. Stephan, and Luschari (Carinthia); Reichenberg (Carniola); Kresewo (Bosnia); Kovaczna, Nagyag, and Zalathna (Siebenbürgen); Tajova, Nagybanya, Felsöbanya, Kapnik, and Neumoldova (Hungary); Schara-Dorna (Bukornia); Joachimsthal (Czechoslovakia); Beuthen (Silesia); Schneeberg, Freiberg, and Hänichen (Saxony); Wolfsberg and Andreasberg (Harz); Kahl (Bayern); Bieber (Hessen); Münslerthal, and Wiesloch (Baden); Markkirch (Alsace); Semipalatinsk (Siberia); Kianfui (China); Kiusiu (Japan); Nakety (New Caledonia); in Chili, Bolivia,

FIG. 45.—Boiling-point Curves of the Binary System: As-S.

and Peru; Guadeloupe (Antilles); Zimapan (Mexico); and California, Utah, etc. (United States).

Up to the end of the eighteenth century, J. J. Becher's idea that the realgar and orpiment contained white arsenic seems to have been generally accepted. In 1801, J. L. Proust³ proved that no oxygen is present in these compounds, and pointed out that the ratio of the constituent elements in these compounds is not accurately known. Indeed, the analyses available about this time were variable; some gave more sulphur in realgar than in orpiment, and *vice versa*. A. Laugier, and M. H. Klaproth made the relations quite clear; the red sulphide contains less sulphur than the yellow, and the results expressed in modern symbols correspond with **arsenic disulphide**, As_2S_2 , for the red sulphide or realgar; and **arsenic trisulphide**, As_2S_3 , for the yellow sulphide, orpiment, or auripigmentum. This also is in agreement with the analyses of J. J. Berzelius, L. F. Nilson, and R. Bunsen.

Arsenic disulphide is prepared as a red-glass by distilling a mixture of iron pyrites and mispickel, or mispickel and sulphur, and remelting the distillate with arsenic or sulphur so as to obtain the desired tin for use as a pigment. If sulphur and arsenic are merely fused together, the product does not possess the desired colour, neither does the product obtained by J. J. Berzelius,⁴ by fusing together arsenic trioxide and sulphur. To obtain a rich colour it seems necessary for the elements to combine in the state of vapour, although F. Faktor reported that he obtained a fiery-red product by melting arsenic trioxide or pentoxide with sodium thiosulphate. The preparation of the so-called *ruby-arsenic* or *ruby-sulphur*—trade names for realgar—has been described by C. R. Fresenius, A. Terreil, M. Buchner, E. Lampadius, J. F. L. Hausmann, and E. Kast and J. Bräuning. To obtain a rich colour it is not necessary to use sulphur and arsenic in the correct stoichiometrical proportions. The manufacturer finds the best proportions for any particular tint by the method of trial and failure. C. W. G. Fuchs, and F. Reich also mention the formation of realgar in the flues of furnaces roasting arsenical sulphide ores. F. Mayençon found realgar and several other sulphides amongst the sublimation products of a coal mine. W. H. Weed and L. V. Pirsson obtained realgar and orpiment from a deposit of the Norris Geysers, Yellowstone National Park; and T. Bergman,⁵ T. Monticelli and N. Covelli, and A. Scacchi observed it in the neighbourhood of volcanoes and solfatara. J. J. Berzelius, C. W. G. Fuchs, and A. Gélis obtained this sulphide by heating a mixture of the elements in the correct proportions. L. F. Nilson fused the mixture in an atm. of carbon dioxide. The conditions of equilibrium are shown in W. Borodowsky's diagram, Fig. 44. L. J. Thénard obtained realgar by melting the trisulphide with the correct proportion of arsenic. According to H. de Sénarmont, when pulverized realgar or orpiment is heated with a soln. of sodium hydrocarbonate in a sealed tube at 150° , the sulphide is dissolved and re-deposited as crystallized realgar; L. F. Nilson also found that a boiling conc. soln. of alkali carbonate dissolves arsenic trisulphide, and deposits realgar crystals on cooling; and W. Borodowsky heated a mixture of arsenic and sulphur in the required proportions with a 10 per cent. soln. of potassium carbonate in a sealed tube at 150° – 300° . The homogeneous soln. deposits black needles of realgar on cooling. For **colloidal arsenic disulphide** and the formation of realgar in nature, *vide infra*.

J. B. L. Romé de l'Isle said that the **crystals** appear to be rhombic like the octahedral modification of sulphur, but R. J. Haüy later regarded them as monoclinic, and F. Mohs likened them to the crystals of prismatic sulphur. According to A. des Cloizeaux, the monoclinic crystals have the axial ratios $a:b:c = 1.4403 : 1 : 0.9729$, and $\beta = 66^\circ 5'$; E. Liffa and K. Emszt gave $0.7201 : 1 : 0.4872$, and $\beta = 66^\circ 11'$; and R. Pilz and co-workers made a number of measurements agreeing with $0.7207 : 1 : 0.4859$, and $\beta = 66^\circ 15'$. The short prismatic crystals have the faces in the prismatic zone striated vertically. The (010)-**cleavage** is nearly perfect; and the (100)-, (001)-, (210)-, and (110)-cleavages less clear. A. des

Cloizeaux gave for the **optic axial angle** $2H=96^{\circ} 20'$, and $92^{\circ} 58'$ respectively for red- and yellow-light. The **optical character** is negative. The crystals were also examined by V. R. von Zepharovich, A. Lévy, L. Fletcher, P. Groth, F. Büchler and V. Goldschmidt, L. Tokody, K. Vřba, J. A. Krenner, F. Hessenberg, A. Scacchi, A. Lacroix, H. von Follon, V. Hackmann, E. Liffa and K. Emszt, M. Löw, R. Pilz and co-workers, V. Goldschmidt, I. Tokody, J. OrceI, etc. C. J. B. Karsten gave 3.5444 for the **specific gravity**; F. E. Neumann, 3.240; and F. Mohs, and R. Böttger, 3.556. W. Borodowsky gave 3.506 at $19^{\circ}/19^{\circ}$ for the sp. gr. of α -As₂S₂; 3.254 at $19^{\circ}/19^{\circ}$ for β -As₂S₂; and 3.161 at $19^{\circ}/19^{\circ}$ for amorphous or γ -form. E. Szarvasy and C. Messinger found the **vapour density** to be 19.16 at 450° ; 18.5 at 503° ; 15.9 at 513° ; 13.89 at 574° ; 12.52 at 588° ; 7.51 at *c.* 1000° ; and 6.95 at *c.* 2000° . The theoretical value for As₂S₂ is 7.403. According to E. J. Houston, when powdered realgar is heated, the **colour** darkens and changes to brown; the original colour is restored on cooling. L. F. Nilson, and H. Saito said that in the absence of air, fusion and **sublimation** occur at a temp. far below red-heat, without chemical change. The sublimate is reddish-yellow, and consists of minute prismatic crystals; large crystals were produced by A. Schüller by subliming the sulphide in vacuo at a temp. below the m.p. L. F. Nilson said that the vapour is the colour of chlorine gas. W. Borodowsky gave 308.5° for the **melting point**; W. P. A. Jonker, 320° ; and L. H. Borgström, 310° . W. Borodowsky observed that there is a **transition temp.** from the red α -As₂S₂ to the black β -As₂S₂ at 267° as illustrated in Fig. 42. The effect of arsenic and sulphur on the transition temp. is shown in the same diagram. The **boiling point** is 565° at 760° . W. P. A. Jonker gave 534° for the b.p. of the disulphide containing some dissolved arsenic. K. Jellinek and J. Zakowsky calculated the mol. **heat of formation** to be 40,300 cal. O. Weigel gave for the indices of refraction, at room temp., for light of wave-length λ :

λ	.	.	545 μ	575 μ	600 μ	630 μ	660 μ	700 μ	740 μ	760 μ
α	.	.	2.584	—	2.529	2.507	2.491	2.472	2.458	—
β	.	.	—	2.707	2.670	2.634	2.610	2.581	2.560	2.552
γ	.	.	—	2.728	2.688	2.654	2.627	2.600	2.578	—

The **absorption coefficients** are:

λ	.	.	546.5 μ	567 μ	599 μ	620 μ	641 μ	663 μ	686 μ	726 μ
α	.	.	0.005	0.138	—	0.383	0.410	0.457	0.505	0.551
β	.	.	—	—	—	0.377	0.400	0.451	0.503	0.552
γ	.	.	—	—	0.115	0.262	—	—	0.447	—

where α and β refer to plates 0.957 mm. thick, and γ to one 0.588 mm. thick. A. des Cloizeaux found the **birefringence** is strong. O. Weigel gave for the relative **photo-electrical conductivity**:

λ	.	.	440 μ	480 μ	520 μ	550 μ	560 μ	580 μ	600 μ	720 μ
L	.	.	0	15	840	1360	1260	575	200	0

T. W. Case found that realgar is a non-conductor in light and darkness. F. Beijerinck said that the crystals are **pleochroic**, being yellow in the direction of the base, and red in the direction of the axis. A. de Gramont examined the **spark spectrum**. According to G. H. O. Volger, and G. A. Kenngott, exposure to **light** converts realgar into arsenic trisulphide and trioxide; and A. Schüller added that arsenic tritetrakisulphide is formed. O. Weigel said that the disintegration of realgar in light is connected with the photochemical conductivity which is attributed to the separation of electrons which loosens the atomic linkages and favours oxidation. C. Doelter said that the mineral is opaque to the **X-rays** even when in thin layers. T. W. Case, and F. Beijerinck said that the **electrical conductivity** is very small, although with a high potential difference the hygroscopic surface may conduct the current. M. Lapschine and M. Tichanowitsch studied the electrodecomposition of realgar.

L. F. Nilson showed that arsenic disulphide is reduced to arsenic when heated

in a current of **hydrogen**. According to H. Pélabon, the interaction of realgar with hydrogen at temp. above 300° is reversible, $2\text{H}_2 + \text{As}_2\text{S}_2 \rightleftharpoons 2\text{H}_2\text{S} + \text{As}_2$. Experiments at 610° , in tubes containing 0.5 grm. of realgar and about 8 c.c. of hydrogen measured under atm. press., show that the reaction is balanced when R , the ratio of the partial press. of hydrogen sulphide to the total press. in the tube on cooling, has a value 93.07. If more than 0.3 grm. of realgar is used (that is, so that some remains unvolatilized at 610°), increasing the amount of arsenic gradually diminishes the value of R until a constant value 78.69 is reached. The action of hydrogen sulphide on arsenic at 610° has a limit characterized by $R=64.90$. He also studied the reducing action of hydrogen on mixtures of realgar and antimony. The reaction was further investigated by K. Jellinek and J. Zakowsky who calculated the vap. press. of the sulphur, p , at 440° to be $\log p = -5.24$, and at 610° , -2.86 . A. Schüller, and L. F. Nilson found that the disulphide is oxidized in **air**: $3\text{As}_2\text{S}_2 + 3\text{O} = 2\text{As}_2\text{S}_3 + \text{As}_2\text{O}_3$; and H. V. Regnault said that this sulphide burns with a blue flame when heated in air. H. Saito found that with a rising temp. realgar begins to decrease in weight at 215° ; and after that oxidation to arsenic trioxide and sulphur dioxide occurs. The reaction is finished at about 400° . According to P. de Clermont and J. Frommel, boiling **water** resolves arsenic sulphide into hydrogen sulphide and arsenic trioxide—*vide* the trisulphide—and H. V. Regnault showed that when steam acts on the red-hot sulphide, a sublimate of arsenic trisulphide and trioxide is produced. H. Rose observed that in **chlorine** realgar forms a yellow liquid if a small proportion of chlorine be present, and a brown liquid with a large proportion of gas; realgar inflames in a rapid current of chlorine producing arsenic trichloride and sulphur; sulphur chloride furnishes the same end-products. A. Schüller found that an aq. soln. of **bromine** oxidizes the realgar to arsenic acid; and, according to E. R. Schneider, when melted with **iodine** there is a reaction: $\text{As}_2\text{S}_2 + 3\text{I}_2 = 2\text{AsI}_3 + 2\text{S}$; a soln. of iodine in carbon disulphide is decolorized owing to the formation of these products. According to A. Geuther, when powdered realgar is heated with an aq. soln. of **sodium sulphide** in a sealed tube at 100° , sulpharsenate is formed; and L. F. Nilson said that a sulphoarsenate is also formed by the action of a boiling soln. of **sodium sulphoarsenate**: $2\text{As}_2\text{S} + 2\text{Na}_3\text{AsS}_4 = 6\text{NaAsS}_2$. H. V. Regnault found that with hot **sulphuric acid** sulphur dioxide and arsenic trioxide are formed. According to A. Gélis, dil. aq. **ammonia** does not attack realgar, but with a conc. soln., the surface becomes matte. G. Gore found that liquid ammonia dissolves realgar. H. V. Regnault observed that **nitric acid** oxidizes realgar to arsenic and sulphuric acids—*vide infra*, arsenic trisulphide—and it can be detonated when mixed with **potassium nitrate**; the so-called *Indian fire* is a mixture of nitre, sulphur, and realgar (24 : 7 : 2). H. Zieler observed some hydrogen sulphide is given off when realgar is treated with boiling 5 per cent. HNO_3 ; with boiling 10 per cent. HNO_3 , nitrous gases are evolved; with 20 per cent. HNO_3 , nitrous gases are given off only with the boiling acid; cold agitated 30 per cent. HNO_3 gives a smell of nitric oxide, and with 40 per cent. and over, the agitated acid yields nitric oxide. C. R. Fresenius showed that when mixed with **ammonium chloride and nitrate**, and heated, arsenic trichloride is formed. L. F. Nilson said that when mixed with **arsenic trioxide** and heated, arsenic sublimes: $3\text{As}_2\text{S}_2 + 4\text{As}_2\text{O}_3 = 6\text{SO}_2 + 14\text{As}$. A. Schüller said that realgar is slightly soluble in **carbon disulphide**, and **benzene**, especially at a high temp. O. B. Kühn said that **alkali-lye** decomposes realgar: $3\text{As}_2\text{S}_2 = 2\text{As} + 2\text{As}_2\text{S}_3$; and A. Geuther found that in a sealed tube at 100° an oxysulphide, $\text{Na}_2\text{As}_4\text{O}_5\text{S}_6$, is formed. L. F. Nilson said that no complex salts are formed analogous to those obtained by J. J. Berzelius with the trisulphide.

§ 31. Arsenic Trisulphide

As indicated in connection with the histories of arsenic, and realgar, the Greek and Roman writers used the names arrhenicum and auripigmentum—*arum*, gold; *pigmentum*, paint—for the yellow arsenic sulphide. G. Agricola¹ mutilated auripigmentum into *operment*, which in French and English became **orpiment**; in Italian, *orpimento*; and in Spanish, *oropimente*. The yellow sulphide was also called *arsenicum citrinum*, and *arsenicum fluvum*. It occurs in several shades of lemon-yellow in small crystals, or in foliated and fibrous masses. C. W. C. Fuchs² mentioned its formation as a product occurring in the flues of a furnace roasting arsenical ores. It has also been reported that arsenic trisulphide was found in the intestines of a person poisoned with arsenic trioxide.

Among the reported occurrences are the mine near Julamerk (Kurdistan); Allchar (Macedonia); Goramis (Turkey); Tolfa, and the Solfatara of the Phlegrean fields (Italy); Graubünden, St. Gothard, Tessin, and Binnenthal (Switzerland); Corsica, Luceram, and the Plateau Central (France); Hall (Tyrol); Schwarzleogang (Salzberg); Fohnsdorf (Steiermark); Keutschach (Carinthia); Kresewo (Bosnia); Olah Lepasbanya, Nagyag, Boieza, Porkura, and Kovaszna (Siebenbürgen); Tajova, Kapnik, Felsöbanya, and Neumoldova (Hungary); Wittichen (Baden); Andreasburg, and Wolfsberg (Harz); Hänichen (Saxony); Schara-Dorna (Bukowina); Elfdal, Sweden; New York, Utah, Wyoming, Nevada (United States); Tlazcosentitlan (Mexico); Guadeloupe (Antilles); and Acobambillo (Peru). The occurrence of orpiment in Sweden was discussed by D. Wallerius, and N. Zenzen and co-workers.

Analyses reported by J. J. Berzelius, A. Laugier, M. H. Kalproth, R. Bunsen, and L. F. Nilson are in agreement with the empirical formula As_2S_3 , **arsenic trisulphide**. E. Schmidt found that the precipitated trisulphide may contain both *arsenic hydrosulphide*, $As(SH)_3$, and the trioxide. Arsenic trisulphide is formed as a result of volcanic sublimation as noted by T. Bergman, T. Monticelli and N. Covelli, and A. Sacocchi. W. H. Weed and L. V. Pirsson obtained it from a hot spring in the Yellowstone National Park, and G. F. Becker, from the sinter at Steamboat Springs, Nevada. F. Mayençon reported orpiment among the products of a burning coal-mine. The commercial product known as orpiment, or *King's yellow*, employed as an artist's pigment, is manufactured by subliming together mixtures of arsenic trioxide and sulphur in proportions determined by the particular tint required. The process is analogous to that employed for realgar (*q.v.*). The method of manufacture was described by N. J. B. G. Guibourt, and L. A. Buchner. L. J. Thénard made the trisulphide by melting realgar with the required proportion of sulphur; and the conditions under which it is formed by fusing a mixture of the two elements are indicated in W. Borodowsky's diagram, Fig. 44. The trisulphide is produced by passing hydrogen sulphide into a hydrochloric acid soln. of arsenic trioxide; and, added L. F. Nilson, if the precipitation is not allowed to be complete,

the product has a high degree of purity—*vide supra*, the action of hydrogen sulphide on arsenic trioxide. J. H. Reedy found that the precipitation of arsenic trisulphide from acid soln. of the arsenates is greatly hastened by the presence of a soluble iodide, presumably by the cyclic actions: $\text{H}_3\text{AsO}_4 + 2\text{HI} \rightarrow \text{H}_3\text{AsO}_3 + \text{H}_2\text{O} + \text{I}_2$; and $\text{H}_2\text{S} + \text{I}_2 \rightleftharpoons 2\text{HI} + \text{S}$. W. Spring said that if the precipitate be dried in a current of dry air, its composition corresponds with the *hexahydrate*, $\text{As}_2\text{S}_3 \cdot 6\text{H}_2\text{O}$. Its colour is paler than that of the anhydrous sulphide, and its sp. gr. is 1.8806 at 25.6°. It is decomposed by a press. of 6000–7000 atm. into the anhydrous sulphide and water. Returning to anhydrous arsenic trisulphide, E. Weinschenk obtained it in crystals by heating a mixture of arsenic trioxide, ammonium thiocyanate, and hydrochloric acid in a sealed tube. If arsenic acid is used, sulphur is formed as well, owing to the reduction of the arsenic acid to arsenic trioxide. H. Vohl obtained it by treating a hydrochloric acid soln. of arsenic trioxide with sodium thiosulphate. A. Gages observed the formation of arsenic trisulphide by leaving arsenical pyrites to stand in dil. hydrochloric acid for some time. F. Sandberger observed its formation in nature from proustite, and K. F. Peters, from arsenic. The trisulphide can also be obtained by the decomposition of realgar (*q.v.*). For the colloidal trisulphide, and S. S. Bhatnagar and B. L. Rao's observations on the formation of orpiment in nature, *vide infra*. According to H. Winter, golden-yellow leaflets of arsenic trisulphide are formed in small amount when hydrogen sulphide is passed into an 0.2*N*-soln. of arsenic trioxide in water. The formation of this modification increases in amount with increase of conc. of arsenic trioxide up to 0.3*N*; as the conc. is still further increased, the amount diminishes. Traces only are formed with 0.05*N*-soln. of arsenic trioxide. H. Winter also found that the red modification of arsenic trisulphide was obtained by freezing the yellow colloidal soln., when the solid red form separated along with ice. It may also be conveniently obtained by evaporating the colloidal soln. on the water-bath. When yellow arsenic trisulphide, obtained by the addition of an electrolyte to the colloidal soln., was heated in an air oven at 100°, it was transformed into a red, vitreous mass; the yellow arsenic trioxide in hydrochloric acid does not, however, undergo a similar change at 100° unless it is completely freed from hydrochloric acid. The red form is gradually transformed into the yellow on exposure to the atm. for 5 to 6 weeks at the ordinary temp., or by being heated for some time at 150°–160°.

I. S. R. I. Eques a Born³ referred to the **crystals** as *crystallis polyedris*, and later called them *octaèdres complets ou tronqués*. Exact measurements were made by F. Mohs, who regarded them as belonging to the rhombic system, having the axial ratios $a : b : c = 0.60304 : 1 : 0.67427$. P. Groth at first regarded the crystals as rhombic and isomorphous with stibnite, but C. Hintze did not agree with this. Later, P. Groth, following A. Breithaupt, showed that the crystals are probably monoclinic and show *eine höchst auffallende Analogie mit Claudetit*. S. Stevanovic gave for the axial ratios of the crystals regarded as monoclinic prisms, $a : b : c = 0.5962 : 1 : 0.6650$, and $\beta = 90^\circ 41'$. Observations on the crystals were made by A. Lévy, O. Mügge, H. A. Miers, W. H. Miller, W. Phillips, and J. A. Krenner. The **cleavage** on the (010)-face is perfect; and that on the (100)-face shows in traces. According to O. Mügge, the (001)-face is a **gliding plane**. A. des Cloizeaux said that the **optic axial angle** is large; and the **optical character** negative. W. Spring found that the precipitated sulphide passes into a micro-crystalline powder when kept for many days at 150°. According to F. Mohs, the **specific gravity** of orpiment is 3.480; C. J. B. Karsten gave 3.459; and N. J. B. G. Guibourt, and R. Böttger, 3.44–3.45. J. F. L. Hausmann found the sp. gr. of a sample of the artificial citron-yellow pigment to be 2.762. The **hardness** of orpiment is 1.5–2.0; and the artificially prepared glass has a hardness of 3. There are two forms of orpiment. According to H. Winter, and W. Borodowsky, when ordinary or yellow $\alpha\text{-As}_2\text{S}_3$ is kept in the vap. of carbon disulphide below 170° it suffers no change, but above that **transition temperature**, red $\beta\text{-As}_2\text{S}_3$ is formed. The effect of an excess of arsenic or sulphur on the transition temp. is illustrated

in Fig. 44. H. Winter gave 150°–160° for the transition temp. The subject was studied by R. Lorenz and W. Herz. W. Borodowsky gave 300° for the **melting point** of arsenic trisulphide; R. Cusack, 325°; L. H. Borgström, 320°; and W. P. A. Jonker, 310°; he also found that an artificial preparation does not crystallize on cooling. H. Saito found that fusion and sublimation readily occur in a non-oxidizing gas. E. Mitscherlich said that the vap. is not decomposed if air be excluded and that the trisulphide has the **boiling point** 700°; W. P. A. Jonker gave 707°. F. Krafft found that the trisulphide, orpiment, distils unchanged at 240° in the vacuum of the cathode light; and C. Zenghelis observed signs of volatilization at ordinary temp. J. J. Berzelius said that when distilled, the first fractions are richest in sulphur, and the last fractions richest in arsenic. A. Schüller found that orpiment volatilizes in vacuo less readily than realgar, and the sublimation begins after the compound has melted. L. Merz said that in the vacuum of the cathode light, sublimation begins just over 220°. E. Szarvasy and C. Messinger found that the **vapour density** indicates that the trisulphide is dissociated at 1000°. E. Weinschenk said that the crystals are strongly **pleochroic**, *a* being greenish-yellow, and *c*, reddish-yellow. When heated to 150°, the crystals have the pleochroism of realgar—possibly, said C. Hintze, in virtue of the reversible reaction $3\text{As}_2\text{S}_3 \rightleftharpoons 2\text{As}_2\text{S}_2 + \text{As}_2\text{S}_5$ —but the original state is restored on cooling provided the temp. has not exceeded 150°. C. Doelter found the crystals opaque to the **X-rays**. W. Herz gave 3.75×10^{12} for the **vibration frequency** of AsS (?). W. W. Coblentz examined the **photoelectric effect**, and found that at +20° to –50° the spectrophotoclectric sensitivity curve of proustite has a slight maximum at about 0.61μ , and a marked sensitivity with a maximum in the extreme violet. As the temp. is lowered (to –100°) the maximum in the ultra-violet is more or less obliterated by a new maximum (the 0.61μ band), which occurs at about 0.58μ . The position of this new maximum remains quite constant as the temp. is decreased to –170°. No photoelectric sensitivity was observed for radiation stimuli of wavelengths extending from 1μ to 2μ in the ultra-red. T. W. Case observed that light has no effect on the electrical conductivity of orpiment. R. Robl observed no **fluorescence** with the trisulphide in ultra-violet light. T. W. Case, and F. Beijerinck said that at ordinary temp. the **electrical conductivity** is inappreciable, but as the temp. rises above 60°, the conductivity becomes apparent. E. Jannettaz studied the electrical conductivity of the crystals. C. Tubandt and M. Haedicke found that up to the transition temp. arsenic trisulphide is an insulator.

D. Vitali⁴ found that arsenic trisulphide is not poisonous; the commercial product, however, contains more or less arsenious trioxide, which is very poisonous. The administration of considerable quantities of the trisulphide to a dog is attended by an improvement in the health of the animal; the explanation of this lies in the fact that only a small proportion of the sulphide passes into the urine as arsenic acid. The effect is hence the same as that of administering very small doses of the latter substance; this, as is known, is beneficial. According to J. J. Berzelius, when **hydrogen** is passed over a red-hot mixture of alkali carbonate and arsenic sulphide, arsenic sublimes. H. Pélabon has studied the reduction of arsenic trisulphide by hydrogen—*vide supra*—when antimony is present, and also silver sulphide. G. H. O. Volger said that in **air**, the trisulphide is oxidized to arsenic trioxide; and E. Pollacci found that the oxidation of moist arsenic trisulphide to sulphur and arsenic trioxide, and the subsequent oxidation of the sulphur to sulphuric acid proceeds slowly in air; J. J. Berzelius showed that the trioxide is formed when the trisulphide is roasted in air. H. Saito found that with a rising temp., orpiment begins to decrease in weight at about 200°, forming arsenic trioxide and sulphur dioxide. The reaction is finished at about 750°. According to E. H. Riesenfeld and W. Haase, a colloidal soln. of arsenic trisulphide is decomposed by **ozone**, forming arsenic acid. M. Decourdemanche observed that when arsenic trisulphide is boiled with **water**, it evolves a very small quantity of hydrogen sulphide, and a trace of arsenic trioxide passes into soln.; indeed, this action goes on for several

days at ordinary temp., and it is accelerated by sulphuric or hydrochloric acid. F. L. Hünefeld added that the native sulphide is also attacked by water, but only superficially. O. Weigel found that a litre of water at 18° dissolves 2.1×10^{-6} mol of precipitated arsenic trisulphide—*vide infra*, colloidal trisulphide. J. Roth found that water slowly converts arsenic trisulphide into the trioxide and hydrogen sulphide. P. de Clermont and J. Frommel believe that the sulphide is hydrated before it is attacked by the boiling water, for (i) the freshly precipitated sulphide gives off hydrogen sulphide more rapidly than the same sulphide previously dried at 125°; and (ii) if the dried sulphide be kept in contact with hot water in a closed vessel and then be boiled with water, it gives off hydrogen sulphide as rapidly as the freshly precipitated sulphide. K. Chodounsky suggested that the more rapid attack by water of the freshly precipitated trisulphide may be due to a soluble form of the trisulphide which reacts with water at ordinary temp. producing a hydroxysulphide. Contrary to S. E. Linder and H. Picton, and J. Billitzer, D. Vorländer and R. Häberle observed no hydrolysis of arsenic trisulphide suspended in water. E. Schmidt found that precipitated arsenic trisulphide is appreciably decomposed by water, and even by alcohol, forming hydrogen sulphide. He said that the trisulphide is appreciably attacked by water. P. de Clermont and J. Frommel found that when arsenic trisulphide is boiled with water in vacuo, it commences to decompose at 22°. The presence of arsenic trioxide impedes the dissociation of arsenic trisulphide by water, owing to the formation of an oxysulphide which dissociates more slowly. Crystallized arsenic trioxide does not retard the reaction so much as arsenic trioxide obtained by the dissociation of the sulphide. C. S. Ward observed that when carbon dioxide is passed through water in which arsenic trisulphide has been precipitated by hydrogen sulphide, hydrolysis sets in as soon as the temp. rises above 35°. At 100°, 24 per cent. of the trisulphide was decomposed in $2\frac{1}{2}$ hrs. More trisulphide was decomposed by water alone than by water in the presence of carbon dioxide. This statement wants confirmation. H. V. Regnault said that steam reacts with arsenic sulphide, forming arsenic oxysulphide of variable composition. A. Classen and O. Bauer found that arsenic trisulphide in an ammoniacal soln. is oxidized by **hydrogen dioxide** to arsenic and sulphuric acids.

H. Rose found that arsenic trisulphide deliquesces when placed in **chlorine**, much heat is evolved, and what appeared to be a complex $2\text{AsCl}_3 \cdot 3\text{SCl}_2$ was formed; L. F. Nilson said that the product is really a mixture of arsenic and sulphur chlorides. R. Bunsen oxidized a soln. of arsenic trisulphide to arsenate by the action of chlorine. E. Reichardt showed that an aq. soln. of **bromine** oxidizes arsenic trisulphide quantitatively to arsenic acid; and on evaporating the soln., arsenic tribromide appears. L. L. de Koninck observed that the trisulphide is similarly oxidized by a soln. of bromine in hydrochloric acid, or in aq. potassium bromide. According to E. A. Schneider, a soln. of **iodine** in carbon disulphide is without action on natural orpiment, but is decolorized by the precipitated sulphide, forming arsenic triiodide and sulphur. The attempt to prepare the complex $\text{As}_2\text{S}_3 \cdot 2\text{AsI}_3$ was not successful. A mixture of the trisulphide and iodine fuses at a low temp. to a homogeneous, brown mass which dissolves in carbon disulphide and the soln. yields only arsenic triiodide and sulphur. He further showed that while arsenic trisulphide and iodine at moderate temp. form arsenic triiodide and sulphur, at higher temp., these products react to form the original trisulphide and iodine. This shows that the reaction $\text{As}_2\text{S}_3 + 3\text{I}_2 \rightleftharpoons 2\text{AsI}_3 + 3\text{S}$ is a reversible one. He was able to prepare a complex with sulphur iodide and arsenic iodide, $\text{As}_4\text{SI}_{12}$, as a reddish-brown powder melting at 72°; while with a mixture of iodine, and arsenic trisulphide and trioxide, he obtained the complex: $\text{As}_{13}\text{O}_9\text{I}_9\text{S}_6$. In both cases where the chemical individuality of the products was not established, J. Kelley and E. F. Smith found that arsenic trisulphide is completely volatilized in a current of dry **hydrogen chloride**; the reaction commences in the cold, and a liquid is formed which volatilizes when heated. Similar results were obtained

with **hydrogen bromide**. L. Gmelin said that when the trisulphide is boiled with conc. **hydrochloric acid**, it is decomposed with difficulty, and the hydrogen sulphide and arsenic trichloride which are evolved from the containing retort, recombine in the receiver. E. Schmidt noted that the trisulphide is attacked by dil. acid. P. de Clermont and J. Frommel also found that when arsenic trisulphide is boiled with water containing a trace of hydrochloric acid, some arsenic trichloride is volatilized—*vide supra*, the chlorination of the sulphide for the preparation of arsenic trichloride; and the analytical reactions of arsenic. The reaction with hydrochloric acid, or with sodium chloride and sulphuric acid, was studied by A. Fyfe, H. Becker, W. Wallace and F. Penny, H. Beckurts, J. A. Kaiser, H. Rose, and A. Lintner, and it was shown that the decomposition of the trisulphide is incomplete. The acceleration of the reaction in the presence of ferric chloride (T. Rieckher), cuprous chloride (C. F. Rammelsberg, etc.), has been previously discussed. According to W. R. Lang and C. M. Carson, arsenic trisulphide may be treated with hydrochloric acid of sp. gr. 1.16 without danger of soln. provided the liquid be sat. with hydrogen sulphide. R. F. Weinland and P. Gruhl found arsenic trisulphide to be insoluble in a soln. of potassium iodide, and soln. of the sulphoarsenites and potassium iodide fail to give halide compounds with arsenic trisulphide like those with arsenic trioxide. C. R. Fresenius and C. H. L. von Babo oxidized the trisulphide by heating it with a mixture of hydrochloric acid and **potassium chlorate**, and R. Bunsen showed that some arsenic may be lost as trichloride during the process of volatilization.

S. E. Linder and H. Picton found that the precipitate formed by passing **hydrogen sulphide** into a hydrochloric or acetic acid soln. of arsenic trioxide contains rather more sulphur than corresponds with the trisulphide. They inferred that the product corresponds with *arsenic hydrosulphide*, $8As_2S_3 \cdot H_2S$, because (i) the sulphur content is not reduced by treatment with carbon disulphide, and (ii) a current of hydrogen removes hydrogen sulphide from the product at 115° . W. Biltz and E. Keunecke found that dry liquid hydrogen sulphide does not dissolve arsenic trisulphide. According to R. E. O. Puller, the trisulphide dissolves when digested with sulphur and **ammonium sulphide**, and is completely precipitated from the soln. as ammonium magnesium arsenate by magnesia-mixture. C. Eckert found that when the mixture of sulphur and arsenic trisulphide, precipitated by hydrogen sulphide from an arsenate, is digested with aq. ammonia, the trisulphide first dissolves, then the sulphur, and arsenic pentasulphide and ammonium thiosulphate are formed. H. Rose also showed that oxidation occurs in this reaction. R. Bunsen found that arsenic trisulphide dissolves when digested with an aq. soln. of **sulphur dioxide**, or of potassium hydrosulphite, forming arsenic trioxide and sulphur which dissolve in the liquid, and when boiled, sulphur dioxide escapes: $2As_2S_3 + 9K_2SO_3 + 3SO_2 = 2As_2O_3 + 9K_2S_2O_3$. J. Milbauer and J. Tucek found that between 300° and 800° , arsenic trisulphide reacts with sulphur dioxide, forming sulphur and a sulphate. It is also soluble in a hot soln. of **potassium hydrosulphite**. H. Rose showed that conc. **sulphuric acid** dissolves the trisulphide faster than it does realgar, forming arsenic trioxide and sulphur dioxide. A. Baudrimont, and H. Feigl found that **sulphur monochloride** acts vigorously on the trisulphide, forming a molten mixture of arsenic trichloride and sulphur; and J. Kelley and E. F. Smith found that complete decomposition occurs at about 140° . H. B. North and co-workers found that **thionyl chloride** at 150° in a sealed tube attacks arsenic trisulphide and also orpiment. E. A. Schneider found that when the **sulphur iodides** are fused with the trisulphide, arsenic trichloride and sulphur are produced.

According to J. J. Berzelius, finely divided arsenic trisulphide slowly absorbs **ammonia** without changing its colour; and A. Bineau said that the product is saturated in about 3 weeks when its composition corresponds with **arsenic ammonio-trisulphide**, $As_2(NH_3)_3S_3$. The ammine, said J. J. Berzelius, rapidly loses ammonia on exposure to air, and when treated with water it forms ammonium arsenite and sulpharsenite. Arsenic trisulphide is easily dissolved by an aq. soln. of ammonia,

and K. Heumann found that copper acts on the soln., forming a yellowish-brown precipitate containing copper, arsenic, and sulphur. G. Gore, and E. C. Franklin and C. A. Kraus found that the trisulphide is slightly soluble in liquid ammonia. The trisulphide is easily decomposed by **nitric acid** and by **aqua regia**. J. L. Proust found that a few drops of fuming nitric acid placed on melted orpiment produce a deflagration; and R. Bunsen showed that with nitric acid of sp. gr. 1.42, the sulphur which separates during the oxidation fuses into globules which may entangle a little trisulphide and protect it from oxidation. This effect does not occur with fuming acid of sp. gr. 1.53. P. Askenasy and co-workers found that arsenic sulphides are oxidized by nitric acid and oxygen under press. to arsenic and sulphuric acids. When orpiment is treated with boiling 10 per cent. HNO_3 , there is a faint smell of nitric oxide; with boiling 20 per cent. acid, a little nitric oxide is given off; cold 30 to 40 per cent. nitric acid, agitated, gives a faint smell of nitric oxide; and with 50 per cent. acid, a little nitric oxide is given off. With oxygen at 20 atm. press., and at 120° , realgar is completely oxidized with twice its weight of 10 per cent. acid during 30 min. action, while orpiment requires 40 per cent. acid and 15 min. action. In the cases of arsenical pyrites, about 16 per cent. of the arsenic is not attacked, and some oxygen is used in oxidizing the iron. The amount of nitric acid required is in every case less than the amount that would theoretically be needed if no oxygen were used, and the losses are very small. Treatment of aq. suspensions of the sulphides with oxygen alone oxidizes some of the sulphur to sulphuric acid, but no arsenic acid is formed. Sulphuric acid may be removed as calcium sulphate from the arsenic acid soln. by addition of calcium carbonate or hydroxide, and subsequent conc. of the filtrate. O. Materne found that a 2 per cent. soln. of **borax** slowly dissolves arsenic trisulphide in the cold, and rapidly when heated. The sulphide is not quantitatively precipitated by acids unless hydrogen sulphide is introduced. A. Schüller found that arsenic trisulphide is insoluble in **carbon disulphide**, and in **benzene**; and J. Spiller, that it is soluble in a soln. of **citric acid**, or **alkali citrates**. According to C. R. Fresenius and C. H. L. von Babo, when arsenic trisulphide is fused with **potassium cyanide**, the alkali thiocyanate is formed, and all the arsenic is sublimed. The reduction obtained by heating the sulphide with a mixture of potassium cyanide and sodium carbonate was studied by J. Haidlen and C. R. Fresenius, W. Fresenius, and H. Rose. The reduction of the sulphide by heating it with **carbon** and lime, or charcoal and potassium carbonate, was examined by J. von Liebig; with **calcium oxalate**, by H. Rose; and with **potassium oxalate** and calcium carbonate, by A. Duflos. J. Ossikowsky found that during the decomposition of organic bodies easily oxidizable bodies are oxidized, and that arsenic trisulphide under such circumstances is converted into arsenic trioxide, and to a small extent into arsenic pentoxide. The precipitated sulphide undergoes oxidation more readily than auripigmentum. In cases of poisoning by arsenic trisulphide, the oxidation products appear more or less quickly, according to the nature of the decomposing body; the presence of water and heat also exerts much influence.

According to H. Rose, when the vap. of arsenic trisulphide is passed over red-hot **iron**, iron arsenide is formed; and in the case of **silver**, silver arsenide. A. Taufflieb also noted the reducing action of silver on arsenic trisulphide. When arsenic trisulphide is suspended in water, and mixed with five times its weight of powdered **magnesium**, it furnishes at first a yellow soln., from which hydrochloric acid precipitates arsenic trisulphide; if the reaction is prolonged, the whole of the arsenic may be removed from the soln. The addition of methyl alcohol tends to keep the arsenic trisulphide in soln. According to J. F. Simon, when the vap. of arsenic trisulphide is passed over red-hot **calcium oxide**, arsenic and calcium sulphide are formed as well as a little calcium sulphite, arsenite, and arsenate; red-hot **magnesium oxide** had "little or no action." P. de Clermont and J. Frommel found that magnesia reacts with the trisulphide suspended in water: $2\text{As}_2\text{S}_3 + 6\text{MgO} = \text{Mg}_3(\text{AsS}_3)_2 + \text{Mg}_3(\text{AsO}_3)_2$; and when the liquid is boiled,

$\text{Mg}_3(\text{AsS}_3)_2 + 6\text{H}_2\text{O} = 6\text{H}_2\text{S} + \text{Mg}_3(\text{AsO}_3)_2$. J. J. Berzelius' observations on the solvent action of a soln. of an **alkali hydroxide** on the arsenic sulphides have been indicated above—alkali arsenite and sulpharsenite are formed as well as partially decomposed arsenic sulphides mixed with sulphur which he seems to have regarded as definite compounds. According to R. F. Weinland and P. Lehmann, sodium hydroxide and arsenic trisulphide yield arsenic, thioarsenate, and mono- and di-thioxyarsenates. When alcoholic sodium hydroxide is employed, mono- and di-thioxyarsenates and arsenates are formed. H. Rose said that when fused with **sodium carbonate**, arsenic, and the alkali arsenate and sulpharsenate, are formed. The reactions may be symbolized: $5\text{As}_2\text{S}_3 = 4\text{As} + 3\text{As}_2\text{S}_5$; and $3\text{As}_2\text{S}_5 + 15\text{Na}_2\text{CO}_3 = 15\text{Na}_2\text{S} + 3\text{As}_2\text{O}_5 + 15\text{CO}_2$, and the sodium sulphide and arsenic pentoxide form alkali salts: $8\text{As}_2\text{S}_5 + 24\text{Na}_2\text{CO}_3 = 10\text{Na}_3\text{AsS}_4 + 6\text{Na}_3\text{AsO}_4 + 24\text{CO}_2$; and, as shown by E. Soubeiran, the arsenate may be partly reduced by hydrogen, forming arsenite, and finally arsenic: $2\text{Na}_3\text{AsO}_4 + 5\text{H}_2 = 2\text{As} + 6\text{NaOH} + 2\text{H}_4\text{O}$. Arsenic trisulphide dissolves rapidly and completely in a soln. of **alkali carbonate or hydrocarbonate**; and, added E. Biltz, the alkali hydrocarbonate dissolves the sulphide in virtue of the carbonate it contains because carbon dioxide precipitates arsenic trisulphide from its soln. in alkali carbonate. According to L. F. Nilson, a boiling soln. of the trisulphide in sodium carbonate gives off carbon dioxide and hydrogen sulphide, there is a separation of arsenic disulphide, and a sulpharsenate passes into soln.; when cooled, the soln. deposits $\text{NaAs}_3\text{S}_5 \cdot 4\text{H}_2\text{O}$. If the soln. be evaporated, garnet-red plates or prisms of $\text{Na}_3\text{As}_{18}\text{O}_7\text{S}_{24} \cdot 30\text{H}_2\text{O}$ are deposited—K. Preis gives a different composition—*vide infra*. J. S. F. Pagenstecher observed that when the trisulphide is placed in an aq. soln. of **mercuric chloride**, there is formed a white powder, mercuric sulphochloride, and a soln. of hydrochloric acid and arsenic trioxide; F. Kessler symbolized the reaction: $\text{As}_2\text{S}_3 + 3\text{HgCl}_2 = 3\text{HgS} + 2\text{AsCl}_3$. According to E. Schürmann, arsenic trisulphide decomposes soln. of mercuric chloride and of **copper sulphate** completely; and also **lead nitrate**, **zinc sulphate**, and **nickel sulphate** completely if heated under press. in a sealed tube; a soln. of **ferrous sulphate** is only partially decomposed by the sulphide. S. S. Bhatnagar and co-workers found that the reactions of **gold and silver salts** with arsenic trisulphide sol. are photosensitive.

Colloidal arsenic trisulphide.—H. O. Schulze⁵ showed that colloidal arsenic trisulphide is probably the primary product of the action of hydrogen sulphide on soln. of arsenious salts; while the crystalline trisulphide is produced by a secondary reaction of acids or salts on the colloid. Amorphous arsenic trisulphide, if really non-crystalline, is the **hydrogel** of **arsenic trisulphide**. According to J. J. Berzelius, finely divided arsenic sulphide obtained by precipitation from an aq. soln. of arsenic trioxide by hydrogen sulphide, after it has been washed with cold water, dissolves to a slight extent in hot water, forming a yellow soln. It does not dissolve in an aq. soln. of hydrogen sulphide, and, according to C. G. C. Bischof, a dil. aq. soln. of arsenic trioxide does not give a precipitate with hydrogen sulphide—aq. soln. or gas—but forms a yellow soln.—while a conc. soln. of arsenic trioxide gives a yellow precipitate under these conditions. J. J. Berzelius added that “the yellow soln. is for the present to be regarded as a suspension of transparent particles because arsenic trisulphide gradually separates from the soln. as a precipitate.” In modern language, the arsenic trisulphide is in a colloidal state, *i.e.* a **hydrosol**; when flocculated or coagulated, the product is a **hydrogel**. N. R. Dhar and S. Ghosh found arsenic trisulphide and the complex sulphides are peptized by alkali-lye, yellow ammonium sulphide, and sodium arsenite. H. O. Schulze concluded that water actually dissolves the arsenic trisulphide. He passed hydrogen sulphide into a soln. of 10 grms. of arsenic trioxide in a litre of water and found that the liquid became yellow and turbid, forming very thin golden-yellow flakes on the surface, which, on agitation, sank to the bottom in a flocculent state. The remaining soln. was slightly turbid and of a reddish-yellow tint. This turbidity, however, could not be removed by filtration, and on examination under the microscope no trace

of solid matter could be detected. The liquid remained clear and yellow. When the soln. was rendered turbid by the addition of an acid or salt, insufficient to produce complete precipitation, solid particles in a yellow menstruum were seen under the microscope. The soln., moreover, was not turbid when viewed by transmitted light in thin layers between parallel plates of glass, but it appeared turbid only in reflected light—an effect attributed to fluorescence. Carbon dioxide was passed through the soln. to remove the excess of hydrogen sulphide, and the arsenic and sulphur were found to be in the ratio of $As_2 : S_3$. The arsenic trisulphide so obtained is a colloid, and the hydrogen sulphide cannot be readily removed from it by dialysis. On evaporation to dryness, an amount of arsenic trisulphide remains proportional to the amount of arsenic trioxide taken, this solid sulphide being no longer soluble in water. There is a limit to the conc. of the soln. of arsenic trisulphide prepared by passing hydrogen sulphide through an aq. soln. of arsenic trioxide on account of the sparing solubility of the latter, but by passing hydrogen sulphide and then dissolving fresh arsenic trioxide, and so on, H. O. Schulze obtained a 37.46 per cent. soln. of As_2S_3 (1 part of As_2S_3 in 1.67 parts of water). This soln. was like an intensely yellow milk, but perfectly transparent under the microscope. The more conc. soln. deposited a small quantity of solid matter on standing for a long time; dil. soln. are more permanent, thus a soln. of 1 in 500 was quite unchanged after standing three months. Dil. soln. of arsenic trisulphide prepared from more conc. soln. by dilution are more turbid than dil. soln. of the same conc. prepared directly; and they have a yellow rather than a reddish-yellow tint. V. Gazzi found that the colloidal soln. always contained some arsenic trioxide.

S. S. Bhatnagar and B. L. Rao inferred that the hydrosulphide ion, SH' , and not the sulphide ion, S' , is the active agent in the precipitation of metallic sulphides by hydrogen sulphide. The colloidal soln. of sulphides obtained in this way can be regarded as soln. of hydrosulphides. When a colloidal soln. of arsenic sulphide sol is heated or when hydrogen is passed through it so that all the free and combined hydrogen sulphide is removed, the formula of the colloidal sulphide is not As_2S_3 but much more nearly As_2S_2 , or AsS . It is shown that the action of heat on a red colloidal soln. converts it into a yellow sol with the precipitation of sulphur, according to the equation: $As_2S_2 \cdot xH_2S + xO = As_2S_3 + xH_2O + (x-1)S$. When the content of combined hydrogen sulphide is small, no sulphur is precipitated. The action of heat and light consists mainly in the transformation of one variety into the other and may be represented by the equation: $As_2S_2 + H_2S + O = As_2S_2S + H_2O$. By analysis and measurement of the absorption spectrum and the density, it is inferred that the red variety is identical with realgar and the yellow precipitate with orpiment, both in colour and other properties. According to S. G. Chaudhury and P. Kundu, the atomic ratio of arsenic to sulphur in an arsenious sulphide sol in which arsenious acid is in excess is 1 : 1.46, whilst in another sol prepared by the action of an excess of hydrogen sulphide on arsenious acid, but in which both free arsenious acid and hydrogen sulphide are absent, the ratio is 1 : 2. The constitution of the former sol, therefore, corresponds with arsenic trisulphide, and the latter either with As_2S_3 , As_2S_5 , or $As_2S_3 \cdot H_2S$, the latter being the more probable.

H. Picton prepared the colloidal soln. by allowing an aq. soln. of arsenic trioxide to flow into a sat. soln. of hydrogen sulphide through which a current of gas was passing. The uncombined hydrogen sulphide was then removed by a current of hydrogen. F. W. Küster and G. Dahmer showed that although no precipitation occurs in the preparation of these colloidal soln., the arsenic is quantitatively converted into the trisulphide. L. Gmelin also showed that the soln. may be kept for weeks with very little deposition. H. Picton said that conc. soln. containing 11 to 12 grms. of trisulphide per litre may be kept for 4 months with only a mere trace of a precipitate; while dil. soln. under the same conditions are almost entirely unchanged. No change was observed with a 2 per cent. soln. when kept 3 years. F. W. Küster and G. Dahmer found a 2.3 per cent. soln. to be very stable.

D. Vorländer and R. Häberle found that with very dil. soln. arsenic trioxide and

hydrogen sulphide do not appear to react because the product is devoid of **colour**; and they attributed the phenomenon to the hydrogen sulphide. N. P. Peskoff showed that the lack of colour is due (i) to the extremely small magnitude of the particles, and more especially (ii) to the complete individuality of these particles. A. Semler showed that the colour of arsenic sulphide sols varies from the orange-red of the coarser suspensions to the pure citron-yellow of the finely divided sols which show only a slight milkiness by transmitted light. Flocculation by an acid or a neutral salt gives a citron-yellow precipitate, but by drying at 100° the product precipitated by barium or calcium chloride becomes red. When heated, this red product behaves similarly to realgar, but its behaviour with water shows that its colour is probably due to the presence of barium thioarsenite. In agreement with H. O. Schulze, H. Picton said that although the soln. are clear by transmitted light, they appear turbid by reflected light; and on sending a beam of lime-light through the soln., the track of the beam is marked by a soft yellow glow, the light from which is completely polarized. This proves the existence of solid particles. F. Haber found that **X-radiograms** of the colloidal soln. show evidence of incipient crystallization. E. F. Burton and J. E. Currie studied the distribution of particles in a column of liquid and found no difference at the different levels. A. Dumansky measured the rate of settling. In cases where the particles are large enough to be variable under the microscope they exhibit the **Brownian movement**—provided their size does not exceed 5μ in diameter. In other cases, the existence of the particles may be revealed by the ultramicroscope. S. E. Linder and H. Picton suspected that the **size of the particles** of trisulphide is smaller the more dil. the soln. of arsenic trioxide used in their preparation, and G. Börjeson found that when the conc. was $10^{-2}N\text{-As}_2\text{O}_3$, the radius of the trisulphide particles was $39\mu\mu$; with $5 \times 10^{-4}N\text{-As}_2\text{O}_3$, $16\mu\mu$; and with $10^{-4}N\text{-As}_2\text{O}_3$, $11\mu\mu$. H. R. Kruyt and H. J. C. Tendeloo, and R. Zsigmondy and C. Carius also discussed this subject. A. Boutaric and M. Vuillaume observed that if the hydrogen sulphide is allowed to diffuse into the aq. soln. of arsenic trioxide the grain-size is less than when the gas is bubbled through the liquid. The grain size is also increased by a prolonged passage of the gas, and by a protracted boiling. H. Bechhold found that the ultra-filter will allow arsenic trisulphide to pass, but not Prussian blue, and it would hold back arsenic trisulphide when mixed with Prussian blue, presumably owing to mutual adsorption. From a study of the optical properties—the schlieren-effect—H. Freundlich inferred that the **shape of the particles** of arsenic trisulphide is almost spherical. S. E. Linder and H. Picton found that the relation between the **specific gravity** and the conc. of the colloidal soln. is represented by a straight line. Thus, with soln. containing

Per cent. As_4S_3	4.4	2.2	1.1	0.275	0.06875	0.01719
Sp. gr.	1.033810	1.016880	1.008435	1.002110	1.000535	1.000137

R. Wintgen, S. S. Bhatnagar and B. L. Rao, and A. Boutaric and R. Simonet also measured the sp. gr. of these soln. A. Dumansky gave 2.938 for the sp. gr. of the colloidal sulphide. R. Wintgen found the **specific volume** is a linear function of the conc. S. E. Linder and H. Picton observed that no change of vol. occurs when the arsenic trisulphide is coagulated and precipitated. No change in the **surface tension** was observed between water and the colloidal soln. S. E. Linder and H. Picton measured the **diffusion** of the arsenic trisulphide hydrosol into water, and this is in agreement with general observations which show that colloids and crystalloids are diffusible; and that the difference between colloids and crystalloids is one of degree and not of kind. The rate of diffusion of the colloids is much slower than that of crystalloids. H. Bechhold and J. Ziegler found that the diffusion of both electrolytes and non-electrolytes is diminished by gels, and this the more the greater the conc. of the gel. When a little soluble tartrate was present, the rate of diffusion was accelerated. There are three plausible explanations, (i) the dispersion or degree of fineness of the colloid is **augmented** by the trace of soluble salt; (ii) that

the adsorbed salt in its tendency to rapid diffusion drags the colloidal particles with them; or (iii) that movements in the liquid set up by the diffusion of the salts set up currents which carry along the colloidal particles by convection. H. Picton favoured the second hypothesis. J. Thovet calculated the molar weight of arsenic trisulphide in colloidal soln. from the diffusion constant, and found it to be over 6000. C. H. Pfaff observed that the arsenic trisulphide separates in yellow flakes during the **freezing** of the yellow soln.; but, added S. E. Linder and H. Picton, if alcohol be added to prevent freezing no coagulation occurs when the temp. is lowered by a freezing mixture of ice and salt. Measurements of the **lowering of the freezing point** of water by colloidal arsenic trisulphide gave no perceptible result; nor were they able to detect any permanent effect on the **osmotic pressure**. These results, added H. Picton, "might simply be due to very high mol. wt." A. Boutaric and R. Simonet, and D. N. Chakravarti and N. R. Dhar measured the **viscosity** of the hydrosol of the trisulphide. H. R. Kruyt and J. van der Spek found that the **heat of coagulation** of the colloidal trisulphide by alum or potassium chloride is small amounting to 0.01 to 0.05 cal. per gram of the trisulphide.

H. Freundlich and A. Nathansohn found that sols of arsenic trisulphide are **photochemically active**; they sensitize the oxidation of colour substances, such as eosin and malachite-green, in light. The formation of colloidal sulphur by illuminating arsenic trisulphide sols depends on this photochemical sensitization, for the hydrogen sulphide which is set free by the hydrolysis of the arsenic trisulphide is oxidized to sulphur through the sensitizing action of the trisulphide micellæ. N. P. Peskoff found that anthracene added to colloidal arsenic sulphide causes precipitation in light in 5–8 hrs., but no such change occurs in darkness in 17 days. R. V. Murphy and J. H. Mathews showed that the electrical conductivity of the soln. increases on exposure to light, and the rate of change increases with decreasing conc. of the colloid. The increased photochemical activity is attributed to the greater dispersion of the more dil. soln. The chemical action involved is a photochemical oxidation of hydrogen sulphide to colloidal sulphur and a thionic acid, accompanied by a reaction between hydrogen sulphide and the thionic acid, which serve as stabilizing electrolytes for the micellæ of arsenic trisulphide and sulphur, respectively. Removal of the stabilizing electrolytes produces a de-stabilization of the two colloids which are consequently precipitated. The increase in electrical conductivity is explained as due to the building up of a concentration of the thionic acid sufficient to serve as the stabilizing electrolyte for the colloidal sulphur, the reaction between hydrogen sulphide and the thionic acid then proceeding at such a rate that the equilibrium is maintained between the several components of the system, further change in the electrical conductivity thus being prevented. S. S. Bhatnagar and B. L. Rao, and A. Boutaric and M. Vuillaume measured the **absorption spectrum** of the colloidal soln. There is an absorption due to diffusion, and one caused by a reflection of the incident rays from the surfaces of the colloidal particles. R. Wintgen, and I. Lifschitz and G. Beck measured the **refractive index**, and found the product of the sp. vol. into the refractive index is a linear function of the conc. K. Schaum and P. Friedrich observed that exposure to ultra-violet light and to light of long wave-length made no difference to the migration velocity of electrophoresis of arsenic trisulphide sols. B. Lange studied the polarization of light by the colloid; and S. S. Bhatnagar and co-workers, the action of light.

S. E. Linder and H. Picton, and H. Freundlich noticed that the hydrosol of arsenic trisulphide is transported towards the anode by cataphoresis—*vide* 3. 23, 8. The subject was discussed by K. von der Grinten, J. J. Bikermann, and by A. Ivanitzkaja and M. Proskurnin. A. Dumansky gave 136×10^{-6} mho for the **electrical conductivity** of colloidal arsenic trisulphide. Observations were made by W. Pauli and A. Semler on the electrical conductivity of the soln. and on the electrometric titration with baryta-water. According to A. Charriou, when arsenic trisulphide is precipitated by means of hydrogen sulphide in presence of a barium salt, the precipitate contains adsorbed barium. When the precipitate is washed with

a soln. of sodium or potassium chlorides, no displacement of barium occurs, whilst with soln. of aluminium, ferric and chromic chlorides interchange of barium and trivalent metal takes place. A. J. Rabinovitsch measured the **H⁻ion concentration** of sols of arsenic trisulphide, before and after coagulation with barium chloride, and in the filtrate from each coagulum the total H⁻ion conc. was found to be unaltered; but after correcting for dilution by the barium chloride soln., the filtrate was more acid than the original sol. The increase of acidity rises with the conc. of the sols. Arsenic trisulphide sols are considered to be fairly strong complex acids, ionizing as follows: $(As_2S_3).nSH_2 \rightleftharpoons (As_2S_3).nSH + H^- \rightleftharpoons (As_2S_3).nS + 2H^-$; the second ionization constant is less than the first. In the coagulum it was found that the hydrogen had been completely replaced by an eq. amount of barium; there was no chlorine present. P. H. Boutigny found that the arsenic trisulphide in colloidal soln. is precipitated by boiling; L. Gmelin added that the precipitation is incomplete; W. Biltz observed the colour is darkened by boiling; and H. Winter showed that the trisulphide may be converted into the red modification—*vide supra*. A. Dumansky found that flocculation slowly occurs when the soln. is rapidly centrifuged; and P. B. Ganguly and N. R. Dhar, by exposure to sunlight. According to F. W. Küster and G. Dahmer, the hydrosol of arsenic trisulphide is only slowly precipitated by barium sulphate; vigorous shaking is required, and precipitated barium sulphate causes the effect better than the powdered mineral. Furthermore, a large quantity of the solid is necessary. The precipitation is also brought about by charcoal, copper oxide, glass powder, and best of all by powdered Iceland spar. C. H. Hall observed no precipitation of arsenic trisulphide suspended in transformer oil of resistance 1.5×10^{16} ohms per c.c., and subjected to alternating and direct currents of voltages 10^4 to 2×10^5 for 3 hrs.

In 1832, P. H. Boutigny found that the addition of a small quantity of an acid precipitates arsenic trisulphide in yellow flakes from its colloidal soln. The greatest effect was produced by sulphuric, hydrochloric, or nitric acid; then followed oxalic acid, then acetic acid, and even carbonic acid produced some effect. He also found that on adding certain salts—ammonium chloride, sodium nitrate or sulphate, or magnesium sulphate—the trisulphide was similarly precipitated. N. R. Dhar and A. C. Chatterji studied the adsorption of soln. and ions by arsenic trisulphide. H. O. Schulze found that the addition of a cold soln. of boric, tartaric, benzoic, or salicylic acid, arsenic trioxide, cane sugar, chloral hydrate, absolute alcohol, or glycerol occasioned no precipitation. The following caused the **coagulation** or flocculation of the arsenic trisulphide hydrosol when added in the given state of dilution:

HCl.aq., 1:555; HNO₃.aq., 1:276; H₂SO₄.aq., 1:255; H₂SO₃.aq., 1:138; H₂C₂O₄.aq., 1:65; H₃PO₄.aq., 1:26; HC₂H₃O₂.aq., 1:0.18; K₂SO₄.aq., 1:76; Na₂SO₄.aq., 1:129; (NH₄)₂SO₄.aq., 1:188; CaSO₄.aq., 1:2780; MgSO₄.aq., 1:2630; ZnSO₄.aq., 1:3330; MnSO₄.aq., 1:2860; NiSO₄.aq., 1:3440; FeSO₄.aq., 1:2380; Al₂(SO₄)₃.aq., 1:52600; Ti₂SO₄.aq., 1:799; KCl.aq., 1:137; KBr.aq., 1:103; KI.aq., 1:55; LiI.aq., 1:127; NaCl.aq., 1:212; NH₄Cl.aq., 1:207; BaCl₂+aq., 1:2860; CaCl₂.aq., 1:4370; MgCl₂.aq., 1:10000; FeCl₃.aq., 1:50000; AlCl₃.aq., 1:83000; CrCl₃.aq., 1:20000; KNO₃.aq., 1:84; NaNO₃.aq., 1:117; NH₄NO₃.aq., 1:138; Ba(NO₃)₂.aq., 1:2080; KClO₃.aq., 1:88; CaH₂(CO₃)₂.aq., 1:3120; K₂C₂H₄O₄.aq., 1:85; K₂C₂O₄.aq., 1:81; NaC₂H₃O₂.aq., 1:78; Urea.aq., 1:25; (NH₄)₂Fe(SO₄)₂.aq., 1:1160; K₂Al₂(SO₄)₄.aq., 1:50000; K₃Fe₃(SO₄)₄.aq., 1:55500; K₂Cr₂(SO₄)₄.aq., 1:25000; K₄Fe(CN)₆.aq., 1:67; K₃Fe(CN)₆.aq., 1:81. E. Herrmann studied the flocculation with organic anions.

All this is in agreement with the rule of H. O. Schulze that the active ion in coagulation has a charge of opposite sign to that of the colloid. This was discussed in connection with the gold hydrosol—**3**, 23, 8. There is a limiting conc. for the complete precipitation, and also a limiting conc. below which no precipitation occurs even after a long interval of time. Thus, H. Freundlich found that with a hydrosol containing 9.57 millimols of arsenic trisulphide per litre, and when 1.219 and 2.438 millimols of potassium chloride per litre were added, at the

end of nearly a year, the soln. contained respectively 9.60 and 9.45 millimols of the trisulphide, and with a soln. containing 3.9 millimols of potassium chloride, almost complete precipitation had taken place. Again, the way the reagent is added has a marked influence. The more slowly the reagent is added, the greater the length of time and the greater the excess of reagent required for complete precipitation. In figurative language, the hydrosol seems to become acclimatized to the precipitant. This subject was studied by S. Ghosh and co-workers, W. Krestinskaja and W. Jakovleva, and V. V. Lepeshkin. As H. B. Weiser showed, the amount of electrolyte which when added all at once produces coagulation, will not do so if added drop by drop over a long period, owing to the adsorption of the precipitating ion by the neutralized colloidal particles. Likewise also the presence of one electrolyte may diminish the activity of a second one. Thus, if lithium chloride be added to the hydrosol of arsenic trisulphide, and then magnesium chloride, more magnesium chloride must be added if lithium chloride were absent. W. Biltz also observed that negatively charged colloids like arsenic trisulphide are precipitated by positively charged colloids like ferric oxide, added in the proper proportion. Thus, 24 mgrms. of arsenic trisulphide hydrosol are precipitated by the following hydrosols:

Hydrosol . . .	Fe ₂ O ₃	ThO ₂	CeO ₂	ZrO ₂	Al ₂ O ₃	CeO ₂
Milligrams . . .	12	6	4	2	2	0.5

J. Billiter observed that the soln. is negative or positive according as one or other component is in excess, and this holds whether precipitation has occurred or not. The results with hydrosols of ferric hydroxide and arsenic trisulphide, are shown in Table IX. The subject was studied by H. Freundlich and G. V. Stottman, and J. J. Bikermann. A. W. Thomas and L. Johnson studied the mutual precipitation

TABLE IX.—CATAPHORESIS OF ARSENIC TRISULPHIDE.

10 c.c. of the mixture contains in mgrms.		Result.	Charge on particles.	Cataphoresis.
Fe ₂ O ₃	As ₂ S ₃			
0.61	20.3	Opalescence	—	To anode
6.08	16.6	Precipitation immediate	—	To anode
9.12	14.5	Precipitation complete	0	Neutral
15.2	10.4	Precipitation immediate	+	To cathode
24.3	4.14	Opalescence slight	+	To cathode
27.4	2.07	No change	+	To cathode

of ferric hydroxide and arsenic trisulphide sols which is attributed to the chemical action $S'' + 2Fe''' = S + 2Fe''$. A. Boutaric and G. Perreau found that the presence of lithium chloride protects arsenic trisulphide sol from flocculation by potassium, magnesium, barium, and ammonium chlorides, while the flocculation is accelerated by cadmium and aluminium chlorides. B. Papaconstantinou studied the protective action of soaps; and J. Traube and E. Rackwitz, and S. Sugden and M. Williams, studied the action of protective colloids; and H. B. Weiser, the antagonistic action of ions.

S. E. Linder and H. Picton showed that when arsenic trisulphide hydrosol is coagulated by a metal salt, a sensible amount of metal is withdrawn from the soln. by the sulphide, while the acid radicle remains in soln. in undiminished amount. This was confirmed by W. R. Whitney and J. R. Ober, who inferred that the coagulant is hydrolyzed by the colloid, the base combining with the colloid while the acid remains in soln. On the other hand, S. E. Linder and H. Picton say that when a metallic salt is added to arsenious sulphide, an interchange takes place between the metal of the salt and the hydrogen of the hydrosulphide. The extent to which this

interchange takes place is governed almost entirely by mass action, as the hydro-sulphide itself is insoluble equally with the metallic derivatives in presence of excess of electrolyte, whether acid or salt. The reactions for potassium and barium chlorides are represented as follows: $mAs_2S_3 \cdot H_2S + 2KCl \rightleftharpoons mAs_2S_3 \cdot K_2S + 2HCl$; and $mAs_2S_3 \cdot H_2S + BaCl_2 \rightleftharpoons mAs_2S_3 \cdot BaS + 2HCl$. J. Duclaux assumed that when barium chloride is used as coagulant, it is probable that there is double decomposition between the barium chloride and the sulphide, perhaps by replacement of an AsO-group existing in the sulphide by barium.

As indicated above, S. S. Bhatnagar and B. L. Rao, and S. E. Linder and H. Picton, regarded colloidal sulphides as hydrosulphides. A. J. Rabinovitch represented the colloid by $(As_2S_3)_n \cdot H_2S$. By precipitating arsenic trisulphide hydrosol with barium chloride, W. Pauli and A. Semler found four eq. of barium are present in the precipitate for each eq. of hydrogen ion found in the sol. The colloid is regarded as having the constituent $(xAs_2S_3 \cdot H_2As_2S_4 \cdot HAs_2S_4)H$, only one of the hydrogen atoms being ionized in soln., but all four being replaced on precipitation. The flocculation of the hydrosol was examined by A. Dumansky, who observed that the precipitate contains a considerable proportion of silver and copper when the nitrates of these metals are used as coagulents; lead acetate coagulates without forming lead sulphide; alkali hydroxides and cyanides have no coagulating power; iodine and potassium permanganate react chemically with the sulphide without coagulation. K. Matsuno, and H. Freundlich and H. P. Zeh examined the coagulating effect of cobalt-ammines. J. Mukhopadhyaya found that hydrogen sulphide renders colloidal soln. more stable towards electrolytes; and he was unable to find any marked adsorption of the electrolytes by the colloidal trisulphide. H. R. Kruyt and C. F. van Duin observed that the coagulation of the hydrosol by electrolytes is influenced in the presence of ethyl, propyl, isobutyl, and isoamyl alcohols, and phenol, such that the limiting conc. of the electrolyte is diminished in the case of uni- and ter-valent inorganic cations, and increased for bi- and quadri-valent cations. The flocculation of arsenic trisulphide hydrosol was examined by H. R. Kruyt and J. van der Spek, H. R. Kruyt and P. C. van der Willigen, H. Freundlich and V. Birstein, S. Sugden and M. Williams, A. Boutaric and C. Simonet, A. J. Rabinovitch, N. P. Peskoff and V. I. Sokoloff, O. K. Rice, G. Rossi and B. Cecchetti, G. Rossi and co-workers, K. C. Sen, A. Ivanitzkaja and L. Orlova, F. Powis, E. F. Burton and co-workers, A. Boutaric and M. Vuillaume, J. N. Mukherjee and S. G. Chaudhury, J. N. Mukherjee and co-workers, H. D. Murray, W. R. Whitney and J. R. Ober, Wo. Ostwald, J. Mukhopadhyaya, N. Bach, N. Schiloff, C. K. Jablczynsky and H. Lorentz-Zienkovska, A. Janek and B. Jirgensons, S. Ghosh and co-workers, etc. N. R. Dhar and A. C. Chatterji observed the rhythmic coagulation of arsenic trisulphide. H. Freundlich and P. H. Zeh found that there is a close relationship between the precipitating value of an electrolyte and its effect on cataphoresis. With univalent to quadrivalent cations derived from complex cobalt salts, K. Matsuno noticed that eq. amounts have a similar coagulating effect on colloidal arsenic trisulphide, and cations of different valency are equally adsorbed from equimolar soln. H. B. Weiser has shown that H. O. Schulze's rule that the coagulating power of an electrolyte is greater the higher the valency of the precipitating ion is only a qualitative rule; and in so far as this rule holds, the adsorbability of an ion is greater the higher the valency; and that the observation of N. R. Dhar and co-workers that ions with the lowest precipitating power are adsorbed most, and conversely, is not true. He also showed that with strong electrolytes containing weakly adsorbed precipitating ions and the same stabilizing ion, there is a direct relationship between the relative adsorbability of the precipitating ions and the coagulating power of the electrolytes in the sense that the electrolyte containing the most readily adsorbed precipitating ion, coagulates a sol in lowest conc. The amount of various precipitating ions carried down on precipitating a sol are determined by (a) adsorption by the electrically

charged particles during neutralization and (b) adsorption by the electrically neutral particles in case the adsorption of the stabilizing ions of the several electrolytes is constant or is negligibly small; but the amounts of (b) will vary with the nature and conc. of the electrolyte. M. Prasad and co-workers studied the adsorption of sugars. C. K. Jablczynsky and co-workers measured the rate of coagulation; H. Freundlich and F. Oppenheimer, the rate of crystallization; V. V. Lepeshkin the temp. coeff. of the rate of coagulation; A. J. Rabinovitsch and W. A. Dorfman, the electrometric changes during the coagulation; and S. S. Bhatnagar and co-workers, the effect of the size of the particles of the colloidal trisulphide.

C. K. Jablczynsky measured the **rate of coagulation** of arsenic trisulphide sols. H. Freundlich and S. K. Basu measured the effect of stirring on the coagulation of the hydrosol. J. N. Mukherjee found that a rise in temp. has different effects on the rate of coagulation, depending on the nature of the electrolyte, the quality of the sol, and the conc. of the electrolyte. These effects are not due to any irreversible change in the sol. The salts of the alkali metals show a stabilization at higher temp.; the salts of the alkaline earth metals always show a diminution in stability, the same being also the case with sulphuric and hydrochloric acids. The same results are obtained, even when the sol contains small quantities of alcohol or phenol in soln. H. Freundlich and V. Birstein studied the coagulation by salts of the amines; A. J. Rabinovitsch, by barium chloride. A. Boutaric and M. Vuillaume found that the rapidity of the flocculation caused by potassium chloride or barium chloride diminishes as the granules increase in size, but the inverse is the case when the flocculating agent is aluminium chloride. In the latter case, the speed of flocculation increases, and in the former cases diminishes, as the conc. of the sol increases; and A. Boutaric and Y. Manière found that light had little effect on the coagulation—the blue rays caused a slight acceleration with aluminium or potassium chloride as coagulant, and a slight retardation with barium chloride. Red light had no effect. P. B. Ganguly and N. R. Dhar also found that a sol of arsenic trisulphide is coagulated by exposure to tropical sunlight. H. P. Corliss observed that colloidal soln. of arsenic trisulphide containing alcohol and ether are more transparent, and less readily coagulated by salts than aq. soln. These soln. undergo a change on keeping, so that the amount of arsenic found in the filtrate after coagulation with acid increases. Under similar conditions the distribution of the arsenic between the two liquid phases varies continuously with the decomposition of the phases, and that, other things being equal, the fraction of the arsenic sulphide going into the upper layer decreases with an increase in the conc. of the sulphide. W. Reinders measured the distribution of colloidal arsenic trisulphide and other colloids between water and isobutyl alcohol, amyl alcohol, benzene, ether, carbon tetrachloride, and carbon disulphide. According to H. Freundlich and F. Moor, a mixture of silver and arsenious sulphide sols undergoes, in the dark, a change of colour from golden-brown through greenish-brown to lilac, and, with exposure to light, through green to a golden-yellow. Both changes are prevented in the presence of a gelatin gel. The reaction in the dark is regarded as a direct interchange between the particles of the two sols. The secondary change under the action of light is purely chemical and involves oxygen, with the probable formation of a silver sulphoarsenate. N. P. Peskoff found that while the presence of gelatin does not affect the velocity of reaction in true soln., it enormously reduces the velocity of dissolution of colloids by suitable reagents—*e.g.* the dissolution of colloidal arsenic trioxide by alkali-lye, and the reaction $3\text{HgCy}_2 + \text{As}_2\text{S}_3 = 2\text{AsCy}_3 + 3\text{HgS}$. S. S. Bhatnagar and D. L. Shrivastava found that adsorbed sucrose, glucose, or galactose loses its optical activity, thus suggesting a chemical explanation of the protective action of these agents. N. P. Peskoff and V. I. Sokoloff found that at low conc., gelatin renders arsenic trisulphide sol unstable; but larger quantities stabilize it. N. R. Dhar and S. Ghosh studied the ageing of the colloid.

J. J. Bickermann made **organosols of arsenic trisulphide** by passing a stream

of dry hydrogen sulphide through soln. of arsenic trichloride in anhydrous nitrobenzene, or acetoacetic ester, and removing hydrogen chloride, and the excess of hydrogen sulphide with a current of dry air. The highest conc. obtained was 29 millimols of the trisulphide per litre. The conductivity of the soln. was less than 10^{-7} mho per c.c. The soln. are stable for an indefinitely long time at room temp., but, on boiling, a red coagulum separates. The soln. are not coagulated by freezing and remelting, or by centrifuging at 2000 revs. per min. The soln. are red by reflected light, and yellow by transmitted light. The arsenic trisulphide is not removed from nitrobenzene by water, nor will organic liquids remove the trisulphide from the hydrosol. Coagulation by ferric chloride, cupric acetoacetate, or tetrapropylammonium iodide occurs when the electrokinetic potential has been reduced to 25×10^{-3} volts, and this value is nearly independent of the conc. of the soln., or of the nature of the dispersion medium. The valency rule is applicable. If the coagulation depended on the weakening of the electrostatic repulsion of the micelles, the dielectric constant of the medium would be expected to influence the magnitude of the precipitation value. This does not seem to be the case as the electrokinetic potential at the coagulation point does not vary more than 20 per cent., while the dielectric constant varies fivefold. W. L. Miller and R. H. McPherson found that arsenic trisulphide forms a colloidal soln. with ether, and that on shaking the hydrosol with ether, the trisulphide distributes itself between the two phases.

§ 32. The Complex Salts of Arsenic Trisulphide—The Sulpharsenites

Arsenic trisulphide plays the part of an acid anhydride in forming a series of complex salts with the basic sulphides, and the products may be regarded as derivatives of a series of hypothetical **sulpharsenious acids**, which A. Hilger and R. F. Weinland¹ tabulated in a slightly different form:

Orthosulpharsenious acid	H ₃ AsS ₃
Metasulpharsenious acid	HAsS ₂
Pyrosulpharsenious acid	H ₄ As ₂ S ₅
Metasulphotriarsenious acid (<i>i.e.</i> H ₉ As ₃ S ₉ less 4H ₂ S)	HAs ₂ S ₅
Orthosulphotetrasenious acid (<i>i.e.</i> H ₁₂ As ₄ S ₁₂ less 3H ₂ S)	H ₆ As ₄ S ₉
Metasulphotetrasenious acid (<i>i.e.</i> H ₁₂ As ₄ S ₁₂ less 5H ₂ S)	H ₄ As ₄ S ₇
Metasulphoctarsenious acid (<i>i.e.</i> H ₂₄ As ₈ S ₂₄ less 11H ₂ S)	H ₂ As ₈ S ₁₃
Metasulphenarsenious acid (<i>i.e.</i> H ₂₇ As ₉ S ₂₇ less 13H ₂ S)	HAs ₉ S ₁₄
Metasulphododecarseenious acid (<i>i.e.</i> H ₃₆ As ₁₂ S ₃₆ less 17H ₂ S)	H ₂ As ₁₂ S ₁₉

They added that the ortho-acid has the greatest number of hydrogen atoms and is $H_{3n}As_nS_{3n} = H_{n+2}As_nS_{2n+1} + (n-1)H_2S$; the pyro-acid is formed when a mol. of hydrogen sulphide is abstracted from two mols. of the acid: $H_{3n}As_nS_{3n} = H_{2n}As_nS_{2n/2} + \frac{1}{2}nH_2S$; and the meta-acid has the smallest number of hydrogen atoms when derived according to the equation $H_{3n}As_nS_{3n} = H_{\frac{1}{2}\{3+(-n)^n\}}As_nS_{\frac{1}{2}\{3+(-n)^n\}} - \frac{1}{2}\{3+(-n)^n\}H_2S$.

A fair number of salts of these acids occurs in nature. There are also compounds which can be regarded as products of these acids with hydrogen sulphide of crystallization instead of water of crystallization, *e.g.*, $H_3AsS_3 \cdot \frac{1}{2}H_2S$, and $H_3AsS_3 \cdot 2H_2S$. A few basic salts have also been reported. A general study of the natural sulpho-salts was made by G. Cesaro, W. F. Foshag, E. T. Wherry, F. Zambonini, and P. Niggli.

J. J. Berzelius obtained sulphoarsenites by heating the sulphoarsenites in the absence of air when some sulphur is driven off. They are obtained in an impure state by the fusing arsenic trisulphide with a mixture of carbon and sulphates. The unstable alkali ortho-salts are also precipitated when alcohol is added to a soln. of arsenic trisulphide in alkali sulphide in the proportions required for the pyro-salt: $K_4As_2S_5 = K_3AsS_3 + KAsS_2$. The sulpharsenites of the metals are produced by double decomposition with the alkali salts. L. F. Nilson made the sulpharsenites by saturating with arsenic trisulphide an aq. soln. of the alkali or alkaline earth hydrosulphides, and evaporating in vacuo or in air. The soln. of the alkali sulpharsenite may decompose during the evaporation: $5K_3AsS_3 = 3K_3AsS_4 + 2As + 3K_2S$; and with the ammonium salt a condensation product may be formed, $(NH_4)As_3S_5$. J. J. Berzelius obtained sulpharsenites by the action of aq. soln. of the hydroxides of the alkalies or alkaline earths on arsenic trisulphide: $2As_2S_3 + 4KOH = 3KAsS_2 + KAsO_2 + 2H_2O$ —the trisulphide is again precipitated on the addition of, say, hydrochloric acid. K. Preis obtained sulpharsenites by boiling arsenic trioxide with a soln. of sodium monosulphide; and L. F. Nilson, with a soln. of alkali carbonate. Some of the condensed sulpharsenites are produced when water acts on the metasulpharsenites. O. B. Kühn, and L. F. Nilson obtained them by the action of hydrogen sulphide on arsenites; and by boiling realgar with potassium hydroxide: $3As_2S_2 + 4KOH = 3KAsS_2 + KAsO_2 + 2As + 2H_2O$; by J. B. Senderens, by the action of sulphur on soln. of alkali-arsenites; and by O. von der Pfordten by the action of arsine on potassium trisulphide at 300°–350°: $2AsH_3 + 3K_2S_3 = 2K_3AsS_3 + 3H_2S$. H. Sommerlad produced sulpharsenites by heating arsenic trisulphide with the metal chlorides.

The sulpharsenites are usually yellow or red; they are sometimes blue, green, or colourless. Some of them crystallize well. They are usually stable when solid. J. J. Berzelius added that when calcined with the exclusion of air they usually lose

arsenic trisulphide, though the alkali salts remain unchanged. L. F. Nilson said that only the alkali and alkaline earth salts can be obtained in soln. The soln. have a yellow colour, and a bitter taste. Soln. of the metasulpharsenates are obtained by direct saturation of soln. of the hydrosulphides with the required amount of arsenic trisulphide, but when solid, they are not easily dissolved in water, and are decomposed by that menstruum. The aq. soln. of the metasulphoarsenites can be evaporated in air without decomposition. Soln. of the orthosulpharsenites are obtained as in the case of the metasulpharsenites and, with the exception of the alkali salts, they cannot be evaporated in vacuo without decomposition into sulpharsenates and arsenic. Boiling the aq. soln. of the metasulpharsenites results in their decomposition—L. F. Nilson obtained the metasulphotriarsenite from potassium metasulpharsenite; and J. J. Berzelius obtained arsenic trisulphide from soln. of the alkaline earth salts. When the soln. are exposed to air, thio-sulphates are formed. Acids liberate the complex acids, but there is an immediate decomposition into hydrogen sulphide and arsenic trisulphide which is precipitated; but, added L. F. Nilson, the condensed alkali and calcium salts may be decomposed incompletely by hydrochloric acid. E. Berglund found that a boiling soln. of a sulpharsenite is decomposed by copper oxide into arsenate and cuprous sulphide; and J. J. Berzelius, that cupric hydroxide forms copper sulpharsenites; and an excess of silver oxide desulphurizes the sulpharsenites. E. W. von Siemens and J. G. Halske observed that on electrolysis the alkali sulpharsenites deposit arsenic on the cathode and form alkali hydrosulphides.

J. J. Berzelius prepared **ammonium orthosulpharsenite**, $(\text{NH}_4)_3\text{AsS}_3$, by adding alcohol to a soln. of arsenic trisulphide and washing the product with water. The white, feathery crystals decompose in air, ammonium sulphide escapes, and arsenic trisulphide remains. L. F. Nilson obtained **ammonium metasulphotriarsenite**, $\text{NH}_4\text{As}_3\text{S}_5 \cdot 2\text{H}_2\text{O}$, by evaporating a soln. of ammonium hydrosulphide sat. with arsenic trisulphide; and adding one or two mols of ammonium hydrosulphide to a soln. of ammonium metarsenite, and evaporating in vacuo over potassium hydroxide and sulphuric acid. The red powder consists of spherical aggregates; it is not attacked by water; potash-lye dissolves it with the evolution of ammonia and the formation of arsenic trisulphide; it is soluble in aq. ammonia especially when heated; it is stable towards hydrochloric acid even when boiling.

J. J. Berzelius reported that **potassium orthosulpharsenite**, possibly K_3AsS_3 , can be prepared by a method analogous to that used for the ammonium salt; and likewise also with **sodium orthosulpharsenite**, Na_3AsS_3 . An excess of alkali hydrosulphide transforms the sulpharsenite into sulpharsenate with the deposition of arsenic: $5\text{K}_3\text{AsS}_3 = 3\text{K}_3\text{AsS}_4 + 2\text{As} + 3\text{K}_2\text{S}$. J. J. Berzelius, and L. F. Nilson prepared **potassium metasulpharsenite**, $\text{KAsS}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, by evaporating in vacuo a soln. of potassium hydrosulphide sat. with arsenic trisulphide. L. F. Nilson obtained **sodium metasulpharsenite**, $\text{NaAsS}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, in a similar way and also by boiling a similar soln., and then allowing it to stand over sulphuric acid. The *hemitrihydrate*, $\text{NaAsS}_2 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, separates as an amorphous brown powder. The potassium salt is stable in air; it is partly dissolved by water with some decomposition; and it is slowly attacked by boiling hydrochloric acid. The sodium salt forms with water a red, gelatinous mass, and, when heated, it forms a red soln., but if dried over sulphuric acid, the product is no longer wholly soluble in water. J. J. Berzelius reported **potassium pyrosulpharsenite**, presumably $\text{K}_4\text{As}_2\text{S}_5$, by heating pyrosulpharsenate. The yellow mass melts to a dark red liquid, and is decomposed by water; **sodium pyrosulpharsenite**, $\text{Na}_4\text{As}_2\text{S}_5$, was prepared in a similar way. L. F. Nilson showed that when arsenic trisulphide is treated with a boiling soln. of sodium carbonate, arsenic disulphide is precipitated; and when the clear soln. is allowed to cool, a bulky brown precipitate of **sodium metasulphotriarsenite**, $\text{NaAs}_3\text{S}_5 \cdot 4\text{H}_2\text{O}$, gradually subsides: $4\text{NaAsS}_2 + 3\text{H}_2\text{O} = \text{Na}_3\text{AsO}_3 + 3\text{H}_2\text{S} + \text{NaAs}_3\text{S}_5$.

According to L. F. Nilson, if instead of allowing the soln. of arsenic trisulphide

in a soln. of sodium carbonate to cool, it is kept for a long time at 70°–80°, a yellowish-brown crust of impure arsenic trisulphide is formed; and when the soln. is evaporated until it solidifies on cooling, a brown amorphous mass is obtained which on standing deposits four crystalline substances: (i) yellow, monoclinic prisms of sodium sulpharsenate; (ii) small white crystals of sodium hydrocarbonate; (iii) colourless crystals of sodium hydroarsenate; and (iv) garnet-red hexagonal crystals or short prisms of sodium pentoxyhexasulphotetrarsenite. In the case of potassium carbonate, the clear soln. remaining after the separation of arsenic disulphide was evaporated to dryness, and it furnished a yellowish-green amorphous mass, which, after standing for two months, gave a soln. containing a large amount of small globular red masses of **potassium metasulphotriarsenite**, $\text{KAs}_3\text{S}_5 \cdot \text{H}_2\text{O}$. These were washed with water, which decomposes the compound but very slightly. This substance is scarcely attacked by hydrochloric acid, but dissolves in caustic potash to a yellow liquid, which when boiled gives a blackish-brown deposit. The reddish-brown microscopic prisms of the potassium salt melt when heated, and the dark fluid burns leaving a white residue. Water has very little action; boiling hydrochloric acid decomposes it very slowly; potash-lye dissolves it in the cold, forming a yellow liquid which, when boiled, furnishes sulpharsenate and arsenic; it is easily soluble in a soln. of sodium carbonate with the evolution of carbon dioxide. L. F. Nilson found that when a soln. of potassium metasulpharsenite is evaporated not quite to dryness, treated with water, and filtered from the blood-red mass of possibly *potassium metasulphotetrarsenite*, $\text{K}_2\text{As}_4\text{S}_7$, the filtrate, when evaporated over sulphuric acid, furnishes **potassium orthosulphotetrarsenite**, $\text{K}_6\text{As}_4\text{S}_9 \cdot 8\text{H}_2\text{O}$. Dark brown **sodium metasulphotetrarsenite**, $\text{Na}_2\text{As}_4\text{S}_7 \cdot 6\text{H}_2\text{O}$, is produced on evaporating a soln. of arsenic trisulphide in one of sodium hydrosulphide. When treated with water, the sodium salt furnishes a blood-red coagulum, and an orange-red soln. It is soluble in a large proportion of water; when dried it is attacked by hydrochloric acid very slowly.

H. Sommerlad prepared **cuprous orthosulpharsenite**, Cu_3AsS_3 , or $3\text{Cu}_2\text{S} \cdot \text{As}_2\text{S}_3$, by heating the pyrosulpharsenite in a current of hydrogen sulphide so long as arsenic trisulphide sublimes. It looks like cuprous sulphide; it gives up no arsenic trisulphide to aq. ammonia, although it is attacked by alkali sulphides. The mineral **julianite** reported by M. Websky from the Friedrich-Julian mine, Rudelstadt, Silesia, approximates closely in composition to this salt. It occurs in small reddish-grey crystals of sp. gr. 5.12. Julianite is one member of a group of minerals included in the general term **fahlerz**.

J. G. Wallerius² referred to fahlerz as *argentum arsenico cupro et ferro mineralisatum*, and as *falerts*, and *grauerts*. A. Cronstedt called it *pyrites cupri griseus*, and *Fahlkupfererz*. I. S. R. I. Eques a Born described it as *argentum cinereum crystallis pyramidatis trigonis*. There were also the *Antimonfahlerz* and the *Graugültigerz* of M. H. Klaproth, A. Breithaupt, L. A. Emmerling, and A. G. Werner. These ores were grouped together as *cuvire gris* by R. J. Häuy, and J. B. L. Romé de l'Isle. A. Breithaupt called a variety *clinohedrite* and *fahlite*. W. Haidinger called it *tetrahedrite*; and F. S. Beudant, *panabas*—from “*πάβ*, tout; et *βάσις*, bases.” The more antimonial varieties are now called **tetrahedrite**. Argentiferous varieties were called *argentum rude album* by G. Agricola; *weissgülden*, and *minera argenti alba*, by J. G. Wallerius, and A. Cronstedt; *Weissgültigerz*, *Silberfahlerz*, etc., by J. F. L. Hausmann, A. Breithaupt, etc.; *aphithorite*, by L. F. Svanberg; *freibergite*, by G. A. Kenngott; *polytelite*, by F. von Kobell; and *leucargyrite*, by A. Weisbach. Mercurial varieties were called *Schwarzerz*, by A. G. Werner; *mercurial fahlerz*, *Quecksilberfahlerz*, by E. F. Glocker, and A. Breithaupt; *spaniolite*, by F. von Kobell; *schwartzite*, by G. A. Kenngott; and *hermesite*, by A. Breithaupt. Arsenical varieties were called *gray sulphuret of copper* by J. Sowerby; **tennantite**—after S. Tennant—by W. and R. Phillips; *sandbergite*, by A. Breithaupt; *erythroconite*, by M. Adam; and *fredricite*, by H. Sjögren. Bismuthiferous varieties were called *annivite* by D. Brauns; *riónite*, by T. Petersen; and *Kobaltwismuthfahlerz*, by F. Sandberger. Other varieties received various names. A plumbiferous variety was described as *malinowskite* by A. Raimondi. The *nepanvite*, regarded by H. Piddington as a carbonate of bismuth, copper, etc., was shown by F. R. Mallet to be tetrahedrite. The *falkenhaynite* of R. Scharizer, the *studerite* of L. R. von Fellenberg, the *frigidite* and *coppite* of A. d'Achiardi, the *Nickelfahlerz* of A. Arzruni, and the *Kobaltfahlerz* of F. Sandberger, are varieties of tetrahedrite. The *fieldite*

of G. A. Kenngott was described by F. Field, and C. Ettlting. The *clayite* by W. J. Taylor—after J. A. and J. R. Clay—is an alteration product. The *dufrenoyite* of A. Damour, and W. S. von Waltershausen, or the *binnite* of A. des Cloizeaux was at first thought to be cubic. The crystals were examined by C. Heusser, G. A. Kenngott, W. S. von Waltershausen, F. Hessenberg, W. J. Lewis, H. Baumhauer, C. O. Trechmann, and G. T. Prior and L. J. Spencer. Analyses reported by W. S. von Waltershausen, C. F. Rammelsberg, T. Petersen, and G. A. Kenngott, and R. W. E. MacIvor, were represented by various formulæ: $\text{Cu}_2\text{S.CuS.As}_2\text{S}_3$; $3\text{Cu}_2\text{S.2As}_2\text{S}_3$; $3\text{Cu}_2\text{S.As}_2\text{S}_3$; $4\text{CuS.Cu}_2\text{S.As}_2\text{S}_3$, and $3\text{Cu}_2\text{S.As}_2\text{S}_3$. G. T. Prior and L. J. Spencer showed that the best representative formula is $3\text{Cu}_2\text{S.As}_2\text{S}_3$, or Cu_3AsS_3 , and that the crystallographic, physical, and chemical properties of binnite have no essential difference from those of tennantite.

A very large number of analyses of fahlerz has been reported.³ H. Rose represented the results by $4\text{Cu}_2\text{S}(\text{Sb,As})_2\text{S}_3$, or generally, by $4\text{R}''\text{S.R}_2'''\text{S}_3$, where R'' denotes Cu_2 , Ag_2 , Fe , Zn , etc., and R''' , Sb , As or Bi . It is assumed that the bivalent atoms Fe , and Zn can isomorphously replace Cu_2 . C. F. Rammelsberg attributed any deviations from the analysis to the contamination of the mineral by foreign matters. Actually, very few analyses of fahlerz agree closely with the formula, while many approach the 3 : 1 formula, *viz.*, $3\text{Cu}_2\text{S}(\text{As,Sb})_2\text{S}_3$. G. A. Kenngott, in his memoir *Ueber die Fahlerzformel*, assumed that the mineral is a mixture of two others, $4\text{R}_2'\text{S.R}_2'''\text{S}_3 + n(3\text{R}''\text{S.R}_2'''\text{S}_3)$. G. Tschermak represented fahlerz as a combination of $3\text{Cu}_3(\text{As,Sb})\text{S}_3 + \text{CuZn}_2(\text{As,Sb})\text{S}_4$, while T. Petersen, and J. Palacios preferred 3 : 1 formula, *viz.*, $3\text{Cu}_2\text{S}(\text{As,Sb})_2\text{S}_3$, or $\text{Cu}_3(\text{As,Sb})\text{S}_3$. A. N. Winchell doubted the accuracy of the $4\text{Cu}_2\text{S.Sb}_2\text{S}_3$ formula. E. T. Wherry and W. F. Foshag gave $\text{Cu}_{10}(\text{Zn,Fe,Cu})_2\text{Sb}_4\text{S}_{13}$, in which part of the copper is bivalent. G. T. Prior and L. J. Spencer pointed out that the analyses which approach most nearly to the 4 : 1 formula have a high proportion of bivalent elements; and where the proportion of these elements is small, the 3 : 1 formula is the best representative value. Their analyses agree with the assumption that fahlerz is a mixture: $3\text{Cu}_2\text{S}(\text{Sb,As})_2\text{S}_3 + n(\text{R}_6''\text{Sb}_2\text{S}_6)$. This formula suggests that R'' atoms may proxy for univalent copper, and that the extra three atoms of sulphur fall into the interspaces of the lattice. The antimonial mineral *tetrahedrite*, Cu_3SbS_3 , is at one end of the series and the arsenic mineral *tennantite*, Cu_3AsS_3 , is at the other end of the series. Usually both antimony and arsenic are present so that the two species gradually merge into one another without a sharp dividing line. Bismuth also appears in some varieties, chiefly at the arsenic end of the series. The copper can be in part replaced by silver, zinc, mercury, lead, iron, and rarely cobalt and nickel. F. Sandberger reported tin in one variety, and L. N. Vauquelin, platinum in another.

J. Durocher⁴ obtained tetrahedral crystals which resembled fahlerz by passing the vapours of the metal chlorides, including arsenic and antimony trichlorides, and of hydrogen sulphide, through a red-hot porcelain tube. H. Sommerlad did not obtain satisfactory results by heating mixtures of cuprous chloride and arsenic trisulphide. B. Cotta observed the formation of fahlerz in the flues of some metallurgical furnaces. A. Daubrée noticed the formation of fahlerz as a crust on some Roman bronzes in the thermal springs of Bourbonne-les-Bains. The various occurrences of fahlerz in nature were described by C. Hintze.

Fahlerz occurs massive, and granular; it also appears in cubic crystals with the tetrahedral habit. The crystals were examined by P. Groth,⁵ A. Lacroix, J. Schweitzer, F. Sandberger, T. Petersen, C. Blömecke, L. Buchdrucker, F. Hessenberg, A. Sadebeck, O. Luedecke, M. Websky, K. Zimanyi, H. Baumhauer, W. J. Lewis, C. O. Trechmann, G. T. Prior and L. J. Spencer, W. Phillips, R. P. Greg and W. G. Lettsom, P. von Jeremejeff, G. Seligmann, A. Cathrein, F. Becke, G. vom Rath, L. Colombo, E. V. Shannon, A. Breithaupt, etc. There is no cleavage. The contact twins about the (111)-plane may have a composition face parallel or perpendicular to the twinning plane; there may be penetration twins. There may be twins with axes parallel and symmetrical with reference to a cubic plane. H. Baumhauer examined the corrosion figures. J. Palacios⁶ found that the X-radiogram corresponds with a space-lattice with a unit cell having

$a=10.39$ A., and is in agreement with the formula for tetrahedrite $3\text{Cu}_2\text{S.Sb}_2\text{S}_3$. Sp. gr., determined in most cases on the samples used for analysis, are 4.75 to 4.90 for antimonial fahlerz, 4.85 to 5.00 for argenteriferous fahlerz; 4.73 to 5.35 for mercurial fahlerz; 4.37 to 5.12 for arsenical fahlerz. H. Fizeau gave for the coeff. of linear expansion at 40° , 0.000009 with an increase of 0.072 per degree. A. Sella found the sp. ht. to be 0.0987. L. H. Borgström gave 630° for the m.p.; and J. Joly, 460° – 590° for the sublimation temp. A. de Gramont examined the spark spectrum of fahlerz. C. Friedel found that when warmed an electric current flows from the edges to the surfaces of the crystals. E. T. Wherry found the crystals to be good radio-detectors. The roasting of fahlerz was studied by C. F. Plattner, F. Janda, and M. de Florin. E. Schäfer found that the mineral is more readily decomposed when heated in a current of chlorine than in a current of carbon dioxide charged with bromine vap. J. Lemberg found that a soln. of bromine in alkali-lye attacks the mineral slowly. E. F. Smith found that there is a marked rise of temp. when the mineral is brought in contact with sulphur monochloride; the mineral is completely decomposed on heating to 140° . O. Gasparini said that the attack by nitric acid is much more energetic if made while the acid is being electrolyzed. C. A. Burghardt decomposed the mineral by fusion with ammonium nitrate. J. Lemberg found that the mineral is decomposed by a boiling soln. of potassium cyanide containing alkali-lye. C. Davies and A. D. Munro found that if arsenic trisulphide be associated with 0.200 grm. of copper as sulphide, and the mixture treated with 50 c.c. of yellow ammonium sulphide, $(\text{NH}_4)_2\text{S}_2$, the amount of copper dissolved rises steadily with increasing amounts of arsenic, and it may attain ten times its original value. Thus:

As present	0	83.3	113.6	253.2	349.7	613.5 mgrms.
Cu dissolved	7.8	29.5	34.5	52.0	61.0	80.4 „

with sodium polysulphide soln. (Na_2S_2):

As present	0	149.2	237.7	365.5	480.0	620.2 mgrms.
Cu dissolved	41.8	48.5	50.7	51.8	52.0	53.0 „

H. Sommerlad ⁷ heated to 200° – 300° a mixture of 6 mols of cuprous chloride and 3 mols of arsenic trisulphide, some arsenic trichloride and trisulphide sublimed, and there remained a coke-like mass of sp. gr. 4.289. The analysis corresponded with **cuprous pyrosulpharsenite**, $\text{Cu}_4\text{As}_2\text{S}_5$. The product was decomposed by acids, and by soln. of alkali hydroxide or sulphides, but not by aq. ammonia. By heating a mixture of equimolar parts of arsenic trisulphide and cuprous chloride, he obtained a steel-grey mass approximating **cuprous metasulpharsenite**, CuAsS_2 . J. J. Berzelius obtained what he considered to be a basic salt, $12\text{CuS.As}_2\text{S}_3$, as a reddish-brown mass by treating hydrated cupric oxide with a soln. of potassium metasulpharsenite until decolorized. There is nothing to indicate that a chemical compound is here involved. When hydrochloric acid is added to the resulting red soln. he said that **cupric orthosulpharsenite**, $\text{Cu}_3(\text{AsS}_3)_2$, is formed. He also said that when a soln. of a cupric salt is treated with sodium sulpharsenite, a brownish-black precipitate of **cupric pyrosulpharsenite**, $\text{Cu}_2\text{As}_2\text{S}_5$, is formed. It is decomposed by heat.

H. Sommerlad ⁸ reported two basic salts, $12\text{Ag}_2\text{S.As}_2\text{S}_3$ and $5\text{Ag}_2\text{S.As}_2\text{S}_3$, to be formed as black or grey crystalline masses by melting together the component sulphides in stoichiometrical proportions. The former had a sp. gr. 6.279, and the latter 5.517. There is no evidence of the chemical individuality of these products on the thermal diagram, Fig. 45, studied by F. M. Jäger and H. S. van Klooster. There are two maxima on the curve, one corresponding with **silver orthosulpharsenite**, or *proustite*, $3\text{Ag}_2\text{S.As}_2\text{S}_3$, m.p. 490° ; and one with **silver metasulpharsenite**, or *arsenomiarqyrite*, $\text{Ag}_2\text{S.As}_2\text{S}_3$, m.p. 417° . There are two eutectics at 469° and 399° respectively. The transition temp. is 179° —*vide* 3. 22, 18. Silver orthosulpharsenite was prepared as a bright red mass by F. Wöhler by fusing

together stoichiometrical proportions of the constituent sulphides ; H. Sommerlad, by fusing together the required proportions of silver chloride and arsenic trisulphide : $3\text{AgCl} + \text{As}_2\text{S}_3 = \text{AsCl}_3 + \text{Ag}_3\text{AsS}_3$; J. Margottet, by heating a mixture of powdered silver and arsenic with an excess of sulphur in an evacuated sealed tube, and distilling off the excess of sulphur ; H. de Sénarmont, by treating a soln. of a silver salt with sodium sulpharsenite in the presence of an excess of sodium hydrocarbonate ; and K. Preis, by treating sodium sulpharsenate first with potassium cyanide, and then with a quantity of silver nitrate insufficient for complete precipitation. If more potassium cyanide be added, and the mixture allowed to stand for a few days, the amorphous orange-red or brown precipitate becomes crystalline.

A red mineral was named *Rothguldenerz*, or *Rothguldenerz*, by the early writers—e.g. G. Agricola, C. Gessner, and J. F. Henckel. J. G. Wallerius recognized eight varieties of the *minera argenti rubra pellucida*. J. Hill called the mineral *red silver ore*. J. F. Henckel, and T. Bergman showed that arsenic, sulphur, and silver are present. The former thought that the pale red mineral contained arsenic and the dark red mineral, sulphur. M. H. Klaproth found antimony, sulphur, and silver in two varieties of the red ore ; L. J. Thénard found antimony, but not arsenic in a variety ; W. A. Lampadius, both antimony and arsenic ; and J. L. Proust showed that there are varieties (i) with antimony and no arsenic ; (ii) with arsenic and no antimony ; and (iii) with both antimony and arsenic. He also showed that no oxygen was present. F. S. Beudant called the arsenical mineral **proustite**—after J. L. Proust. Even in 1824, F. Mohs regarded the light and dark *Rothgiltigerz*, or *Rubinbelnde*, as he called them, to be varieties of one species. A. Breithaupt called the dark *ruby ore*, or dark *red silver ore*, *antimonial silver blende*, and the light ruby ore or light red silver ore, *arsenical silver blende*. F. S. Beudant called the antimonial ore *argyrythrose* ; C. J. Selb, *arosite* ; and E. F. Glocker, *pyrargyrite*—from $\pi\upsilon\rho$, fire ; and $\acute{\alpha}\rho\gamma\upsilon\rho\omicron\varsigma$, silver, in allusion to the colour. Analyses of proustite reported by H. A. Miers, H. Rose, F. Field, I. Domeyko, H. de Sénarmont, H. Sommerlad, A. Streng, F. Sandberger, and E. Rethwisch show that the composition approximates closely with that of **silver orthosulpharsenite**, Ag_3AsS_3 , some varieties contain up to 3.74 per cent. of antimony. The mineral *sanguinite* reported by H. A. Miers to occur on the argentite of Chanarcillo is thought to be a variety of proustite. The various occurrences of proustite in nature are described by C. Hintze.

Proustite occurs in scarlet or vermilion, trigonal, hemimorphic crystals having, according to H. A. Miers, the axial ratio $a : c = 1 : 0.80393$, and $\alpha = 103^\circ 32'$. It also occurs massive and compact. The crystals were described by A. Frenzel, P. Groth, A. L. Parsons, F. Sandberger, A. Lacroix, O. Luedecke, M. Fenoglio, etc. Twinning about the $(10\bar{1}4)$ -, (1011) -, and the (0001) -planes is common ; and rarely about the $(41\bar{3}0)$ -plane. The habit is often acute rhombohedral or scalenohedral. The (1011) -cleavage is distinct. The sp. gr. reported on many of the samples analyzed ranges from 5.555 to 5.64. The hardness is about 2. A. Sella gave 0.0807 for the sp. ht. F. M. Jäger and H. S. van Klooster gave 490° for the m.p.—Fig. 46. A. de Granont examined the spark spectrum ; and A. des Cloizeaux found the indices of refraction to be $\omega = 2.9789$ and $\epsilon = 2.7113$ for Li-light ; and $\omega = 3.0877$ and $\epsilon = 2.7924$ for Na-light. The double refraction is strong ; and the optical character negative. The pleochroism is weak, ω being blood-red, and ϵ , cochineal-red. W. W. Coblenz found that when proustite is exposed to thermal radiation with a wave-length extending from 0.3μ to 2μ , the

FIG. 46.—Freezing-point Curves of Mixtures of Arsenic Trisulphide and Silver Sulphide.

greatest photoelectric activity occurs between 0.5μ and 0.7μ , and there is then a rapid decrease, and no reaction was observed with wave-lengths exceeding 0.7μ . At 22° , the activity has a wide maximum in the ultra-violet with a weak ill-defined maximum near 0.6μ . Decreasing the temp. to -167° increases the sensitivity throughout the spectrum, and the maximum at 0.6μ shifts to 0.578μ when, for low temp., the greatest photoelectric activity is localized. H. E. McKinstry observed a surface effect when the mineral is exposed to the electric arc-light. The electrical conductivity of proustite increases with increase in applied voltage; and with a constant voltage, the conductivity increases with time. T. W. Case observed that the resistance is less than a megohm, and light has no measurable influence. C. Tubandt and M. Haedicke observed that the pure salt is an ionic conductor, and that the silver ions are alone mobile. M. von Laue, and E. Giebe and A. Scheibe studied the piezoelectric properties of the crystals, and P. H. Geiger found that proustite shows a photoelectric effect. C. A. Burghardt found that the mineral is decomposed by fusion with ammonium nitrate; it is decomposed by nitric acid; and it is blackened by hot alkali-lye. H. B. North and C. B. Conover said that it is attacked by thionyl chloride at 150° - 160° in a sealed tube.

J. J. Berzelius reported **silver pyrosulpharsenite**, $\text{Ag}_4\text{As}_2\text{S}_5$, to be formed when the metasulpharsenite is heated out of contact with air; and H. Sommerlad, by heating a mixture of silver chloride and arsenic trisulphide in the proportions: $12\text{AgCl} + 5\text{As}_2\text{S}_3 = 3\text{Ag}_4\text{As}_2\text{S}_5 + 4\text{AsCl}_3$. It is a homogeneous mass with a conchoidal fracture, and a sp. gr. 4.886. The compound is not changed when heated out of contact with air; but when heated in a current of hydrogen sulphide, it slowly forms proustite. J. J. Berzelius found **silver metasulpharsenite**, AgAsS_2 , to be formed by the action of a sat. soln. of arsenic trisulphide in one of sodium sulphide upon silver nitrate. H. Sommerlad prepared it by heating a mixture of silver chloride and arsenic trichloride in the proportions: $3\text{AgCl} + 2\text{As}_2\text{S}_3 = 3\text{AgAsS}_2 + \text{AsCl}_3$. The reaction begins at about 180° . The reddish-black crystalline mass has a sp. gr. 4.700. F. M. Jäger and H. S. van Klooster gave 417° for the m.p., Fig. 46. J. J. Berzelius said that when heated, arsenic trisulphide is given off and the pyro-salt is formed; H. Sommerlad said the ortho-salt.

According to J. J. Berzelius, the yellow precipitate formed by a soln. of sodium sulpharsenite and a gold salt consists of **gold sulpharsenite**, $2\text{AuS}_3 \cdot 3\text{As}_2\text{S}_3$. It soon becomes black. It fuses in a glass retort, and gives off orpiment at a dull red-heat, and finally a residue of gold remains.

J. Voigt and J. F. A. Götting,⁹ and J. J. Berzelius prepared impure **calcium orthosulpharsenite**, $\text{Ca}_3(\text{AsS}_3)_2 \cdot 15\text{H}_2\text{O}$, by digesting arsenic trisulphide with lime-water, and evaporating the filtrate. The product contained a brown mass of the pyrosulpharsenite, and crystals of the ortho-salt. J. J. Berzelius also obtained it by adding alcohol to a soln. of arsenic trisulphide in an excess of a soln. of calcium hydrosulphide. The colourless, feathery crystals are soluble in water. The corresponding **barium orthosulpharsenite**, $\text{Ba}_3(\text{AsS}_3)_2 \cdot 14\text{H}_2\text{O}$, was obtained by J. J. Berzelius in an analogous way; and L. F. Nilson mixed a sat. soln. of arsenic trisulphide in a soln. of barium hydrosulphide with twice its vol. of the barium hydrosulphide soln., and evaporated the product in vacuo for crystallization. The mother-liquor deposits crystals of the pyrosulpharsenite. The barium salt appears in pale yellow prisms, sparingly soluble in water. The crystals soon turn brown on exposure to air. If a soln. of a mol of arsenic trisulphide and 3 mols of calcium hydrosulphide be evaporated in vacuo, L. F. Nilson found that colourless, four-sided prisms of the basic salt, **calcium tetrasulphorthosulpharsenite**, $\text{Ca}_3(\text{AsS}_3)_3 \cdot 4\text{CaS} \cdot 25\text{H}_2\text{O}$, are formed. The crystals are stable in air, sparingly soluble in hot and cold water, and are decomposed by hydrochloric acid. According to J. J. Berzelius, a brown mass of **calcium pyrosulpharsenite**, possibly $\text{Ca}_2\text{As}_2\text{S}_5 \cdot n\text{H}_2\text{O}$, is formed as a by-product in preparing the orthosalt as indicated above. It is easily soluble in water. L. F. Nilson found that **strontium pyrosulpharsenite**,

$\text{Sr}_2\text{As}_2\text{S}_5 \cdot 15\text{H}_2\text{O}$, is obtained in large yellow crystals when a soln. of arsenic trisulphide and strontium hydrosulphide, in the molar proportions 1 : 1 or 2 : 3, is evaporated in vacuo. When a sat. soln. of arsenic trisulphide in one of barium hydrosulphide is mixed with an equal vol. of the soln. of the hydrosulphide, and evaporated in vacuo, hydrogen sulphide is evolved, and greyish-green **barium pyrosulpharsenite**, $\text{Ba}_2\text{As}_2\text{S}_5 \cdot 5\text{H}_2\text{O}$, is formed. If this substance be allowed to remain in the mother-liquor for some time, it turns indigo-blue, and retains this colour even after washing with water, in which it is sparingly soluble. The blue salt has the same formula as the greyish-green salt. The blue salt probably contains a little colloidal sulphur. A *pentadecahydrate*, $\text{Ba}_2\text{As}_2\text{S}_5 \cdot 15\text{H}_2\text{O}$, is obtained in monoclinic prisms as a by-product in the preparation of the ortho-salt as indicated above. L. F. Nilson found that **calcium metasulpharsenite**, $\text{Ca}(\text{AsS}_2)_2 \cdot 11\text{H}_2\text{O}$, is deposited as a crystalline cake or yellow prisms on evaporating in vacuo a sat. soln. of arsenic trisulphide in one of calcium hydrosulphide. If the salt be exposed to air it absorbs water, and becomes brown. It is decomposed by water; and by hydrochloric acid. An orange-yellow crystalline mass of **strontium metasulpharsenite**, $\text{Sr}(\text{AsS}_2)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, was prepared in an analogous manner; likewise also with **barium metasulpharsenite**, $\text{Ba}(\text{AsS}_2)_2 \cdot 2\text{H}_2\text{O}$. When calcium metasulpharsenite is treated with cold water, it partially dissolves, leaving a brown residue of **calcium metasulphoctarsenite**, $\text{CaAs}_9\text{S}_{13} \cdot 10\text{H}_2\text{O}$; with boiling water, **calcium metasulphoennearsenite**, $\text{Ca}(\text{As}_9\text{S}_{14})_2 \cdot 10\text{H}_2\text{O}$, is left. When barium metasulpharsenite is treated for many hours with hydrochloric acid, **barium metasulphododecarsenite**, $\text{BaAs}_{12}\text{O}_{19}$, is formed.

J. J. Berzelius reported **beryllium sulpharsenite** to be precipitated when a sat. soln. of arsenic trisulphide in one of sodium hydrosulphide is added to a soln. of a beryllium salt. L. F. Nilson made **magnesium orthosulpharsenite**, $\text{Mg}_3(\text{AsS}_2)_2 \cdot 9\text{H}_2\text{O}$, by treating a sat. soln. of arsenic trisulphide in one of magnesium hydrosulphide. It appears as a yellow crystalline precipitate sparingly soluble in hot and cold water, but is decomposed by hydrochloric acid. According to P. de Clermont and J. Frommel, when magnesia is added to water holding arsenic trisulphide in suspension, soluble magnesium orthosulpharsenite, and insoluble magnesium hydroarsenite are formed: $2\text{As}_2\text{S}_3 + 5\text{MgO} + \text{H}_2\text{O} = \text{Mg}_3(\text{AsS}_2)_2 + 2\text{MgHAsO}_3$. The soluble sulpharsenite is dissociated when boiled thus: $\text{Mg}_3(\text{AsS}_2)_2 + 7\text{H}_2\text{O} = \text{Mg}_2\text{HAsO}_3 + 6\text{H}_2\text{S} + \text{MgO}$. Magnesia is an excellent antidote in cases of poisoning by arsenious acid, as the arsenite is completely insoluble; but if a portion of the arsenious acid becomes converted into trisulphide in the stomach or intestines, the magnesia would render this soluble. L. F. Nilson made **magnesium pyrosulpharsenite**, $\text{Mg}_2\text{As}_2\text{S}_5 \cdot 8\text{H}_2\text{O}$, by evaporating in vacuo a soln. of equimolar parts of arsenic trisulphide and magnesium hydrosulphide. The salt is sparingly soluble in hot and cold water, but is decomposed by hydrochloric acid. J. J. Berzelius, and L. F. Nilson obtained a **magnesium metasulpharsenite**, $\text{Mg}(\text{AsS}_2)_2 \cdot 5\text{H}_2\text{O}$, by evaporating a sat. soln. of arsenic trisulphide in one of magnesium hydrosulphide. The evaporation is best conducted in vacuo since J. J. Berzelius observed that the sulpharsenate is formed when the aq. soln. is evaporated and also when the conc. soln. is cooled to -5° . J. J. Berzelius reported **zinc sulpharsenite** to be formed as a bulky, lemon-yellow precipitate, when a sat. soln. of arsenic trisulphide in one of sodium hydrosulphide is treated with a zinc salt. The compound is decomposed by heat. According to J. Morozewicz, a mineral called **miedziankite**, from the copper mine at Miedzianka, Central Poland, is a **copper zinc sulpharsenite**, $3\text{Cu}_3\text{AsS}_3 \cdot \text{ZnS}$. It is grey in colour and compact or porous. Its sp. gr. is 4.700, and its hardness 3-4. According to J. J. Berzelius, **cadmium sulpharsenite** is formed by a process analogous to that used for the zinc salt; and similarly also with **mercurous pyrosulpharsenite**, $\text{Hg}_4\text{As}_2\text{S}_5$, which was deposited as a black precipitate from a soln. of mercurous nitrate. When heated, it furnishes a blackish sublimate of **mercuric pyrosulpharsenite**, $\text{Hg}_2\text{As}_2\text{O}_5$. If a soln. of mercuric chloride be treated with a sat. soln. of arsenic trisulphide in one

of sodium sulphide, orange-yellow **mercuric metasulpharsenite**, $\text{Hg}(\text{AsS}_2)_2$, is formed.

According to J. Loczka,¹⁰ thallium is not precipitated by hydrogen in acid soln., but in presence of dissolved arsenic, antimony, or tin, red precipitates are formed which contain thallium. The larger the amount of acid present, the less the amount of thallium precipitated, and, with a large excess of acid, no thallium is thrown down. J. W. Gunning has described the precipitates formed when a mixture of arsenious and thalious salts are treated with hydrogen sulphide in acid or alkaline soln. The composition of the precipitates varied widely with the mode of preparation, but in several cases the composition was near that required for **thalious metasulphoarsenite**, TlAsS_2 . G. Canneri and

L. Fernandes found the equilibrium conditions those indicated in Fig. 47. The meta-salt melts at 300° . According to L. F. Hawley, when the precipitates obtained in either acid or alkaline soln., are examined under the microscope, they are found to be perfectly homogeneous for all compositions between pure arsenic trisulphide and about 62 mol. per cent. arsenic trisulphide. The colour varies gradually from the light yellow of arsenic trisulphide through orange to a bright red as the amount of thalious sulphide increases. At about 62 mol. per cent. arsenic trisulphide, a second phase appears, the black thalious sulphide, and from that point to pure thalious sulphide two phases are present. These observations show that thalious sulphide and arsenic trisulphide under the conditions named form a limited series of solid soln. extending from pure arsenic trisulphide to about 62 mol. per cent. of arsenic trisulphide, and that no compound is formed. From these precipitates acids will dissolve more or less thalious sulphide, depending on the conc. of the acid and the composition of the precipitate. Likewise soln. of alkaline sulphides will dissolve out varying amounts of arsenic trisulphide. The nearly constant composition of some of Gunning's precipitates obtained in acid soln. with excess of thallium present was probably due to the nearly constant conc. of the acid used. This agrees with the observations of L. Bruner and J. Zawadsky. G. Canneri and L. Fernandes obtained the results indicated in Fig. 45 for the f.p. curves of mixtures of thalious sulphide and arsenic trisulphide. **Thalious orthosulpharsenite**, $\text{Tl}_3\text{As}_2\text{S}_5$, is unstable and decomposes on fusion at 295° ; **thalious pyrosulpharsenite**, $\text{Tl}_4\text{As}_2\text{S}_5$, also decomposes on fusion at 278° . The other part of the curve explored is normal. **Thalious orthosulphotetrarsenite**, $\text{Tl}_6\text{As}_4\text{S}_9$, melts at 317° . J. A. Krenner found crystals of a cochineal-red or carmine-red mineral on the realgar of Allchar, Macedonia. He named the mineral **lorandite**. The analyses by J. A. Krenner, J. Loczka, and P. Jannasch correspond with thalious metasulpharsenite. The tabular, or short prismatic crystals are monoclinic, and, according to V. Goldschmidt, have the axial ratios $a : b : c = 1.3291 : 1 : 1.0780$, and $\beta = 52^\circ 27'$. The (100)-cleavage is perfect, while the (001)- and (101)-cleavages are good. A. S. Eakle, and L. Tokody consider lorandite to be isomorphous with miargyrite. The cleavage lamellæ are flexible like selenite. The refractive index is high. E. S. Larsen gave $+2.72$ for Li-light. The hardness is 2.0-2.5; and the sp. gr. 5.529. T. W. Case said that the poor conductivity of lorandite is not affected by light. The mineral is soluble in nitric acid.

FIG. 47.—Freezing-point Curves of Binary Mixtures: $\text{Tl}_2\text{S}-\text{As}_2\text{S}_3$.

These observations show that thalious sulphide and arsenic trisulphide under the conditions named form a limited series of solid soln. extending from pure arsenic trisulphide to about 62 mol. per cent. of arsenic trisulphide, and that no compound is formed. From these precipitates acids will dissolve more or less thalious sulphide, depending on the conc. of the acid and the composition of the precipitate. Likewise soln. of alkaline sulphides will dissolve out varying amounts of arsenic trisulphide. The nearly constant composition of some of Gunning's precipitates obtained in acid soln. with excess of thallium present was probably due to the nearly constant conc. of the acid used. This agrees with the observations of L. Bruner and J. Zawadsky. G. Canneri and L. Fernandes obtained the results indicated in Fig. 45 for the f.p. curves of mixtures of thalious sulphide and arsenic trisulphide.

Thalious orthosulpharsenite, $\text{Tl}_3\text{As}_2\text{S}_5$, is unstable and decomposes on fusion at 295° ; **thalious pyrosulpharsenite**, $\text{Tl}_4\text{As}_2\text{S}_5$, also decomposes on fusion at 278° . The other part of the curve explored is normal. **Thalious orthosulphotetrarsenite**, $\text{Tl}_6\text{As}_4\text{S}_9$, melts at 317° . J. A. Krenner found crystals of a cochineal-red or carmine-red mineral on the realgar of Allchar, Macedonia. He named the mineral **lorandite**. The analyses by J. A. Krenner, J. Loczka, and P. Jannasch correspond with thalious metasulpharsenite. The tabular, or short prismatic crystals are monoclinic, and, according to V. Goldschmidt, have the axial ratios $a : b : c = 1.3291 : 1 : 1.0780$, and $\beta = 52^\circ 27'$. The (100)-cleavage is perfect, while the (001)- and (101)-cleavages are good. A. S. Eakle, and L. Tokody consider lorandite to be isomorphous with miargyrite. The cleavage lamellæ are flexible like selenite. The refractive index is high. E. S. Larsen gave $+2.72$ for Li-light. The hardness is 2.0-2.5; and the sp. gr. 5.529. T. W. Case said that the poor conductivity of lorandite is not affected by light. The mineral is soluble in nitric acid.

J. J. Berzelius¹¹ prepared **cerous pyrosulpharsenite**, $\text{Ce}_4(\text{As}_2\text{S}_5)_3$, as an orange-yellow powder, by adding sodium pyrosulpharsenite to a soln. of a cerous salt. The product is sparingly soluble in water. He obtained **yttrium sulpharsenite** by the method employed for the beryllium salt. According to J. J. Berzelius, an orange-yellow precipitate of **zirconium sulpharsenite** is produced when a soln. of a zirconium

salt is treated with a sat. soln. of arsenic trisulphide in one of sodium hydro-sulphide. For **copper germanium sulpharsenite**, *vide* germanite, 7. 45, 1. J. J. Berzelius obtained reddish-brown **stannous sulpharsenite**, and yellow **stannic sulpharsenite**, by treating soln. of stannous and stannic chlorides respectively in a similar way. J. J. Berzelius obtained reddish-brown **lead sulpharsenite** in an analogous way. J. Fournet heated to whiteness a mixture of 10 parts of galena and 5 parts of orpiment, and obtained one part of ductile lead. H. Sommerlad found that lead sulpharsenites can be obtained by melting mixtures of lead sulphide or chloride and arsenic trisulphide. The occurrence of metallic grey mineral in *le dolomie de Binnen* was mentioned by C. Lardy in 1833, as *une substance métallique d'un gris de plomb*; and D. F. Wiser observed that this substance contained sulphur, lead, silver, copper, antimony, and arsenic. This term "binnite" was at first given indiscriminately to the grey minerals; they were later distinguished as *pea-shaped binnite*—*Kugelbinnit*, and *rod-shaped binnite*—*Stangenbinnit*. A. Damour analyzed the Stangenbinnit, but described the crystals of *Kugelbinnit*. He called the combination *dufrénoysite*. W. S. von Waltershausen pointed out A. Damour's mistake, but curiously he himself made a similar blunder. The confusion was accentuated by J. C. Heusser, and A. des Cloizeaux and J. C. G. de Marignac. The subject was cleared up by the work of G. vom Rath,¹² H. Baumhauer, and R. H. Solly. As a result, crystals of nearly a dozen lead sulpharsenites have been since reported from the dolomite region of Binnenthal, Switzerland. They have the ratio PbS : As₂S₃ ranging from 4 : 1 to 1 : 1. The constitution was discussed by G. Cesaro.

Two basic salts with the mol. ratio 4 : 1 and 7 : 2 are represented by the minerals *jordanite* and *legenbachite*. G. vom Rath discovered **jordanite**—named after J. Jordan—in cavities of the dolomite of Imfeld, Binnenthal, Switzerland. Analyses reported by L. Sipöcz, A. Sachs, C. Guillemin, R. H. Solly, E. Ludwig, and H. Sommerlad correspond with 4PbS.As₂S₃, or **lead disulphopyrosulpharsenite**, (Pb.S.Pb)₂As₂S₅. S. S. Smirnoff gave 4PbS.(As,Sb)₂S₃. L. Sipöcz regarded this mineral as a salt of pyrosulpharsenic acid, H₄As₂S₅, in which each pair of hydrogen atoms is replaced by the dyad radicle—Pb.S.Pb. C. F. Rammelsberg represented it

and V. Wartha regarded it as a salt of pyrosulpharsenic acid, H₄As₂S₇, with each pair of hydrogen atoms replaced by the dyad group—Pb.Pb—

H. Sommerlad prepared a substance of the same composition by fusing stoichiometrical proportions of lead sulphide and arsenic trisulphide in a current of hydrogen sulphide, and by strongly heating lead metasulpharsenite in a current of hydrogen sulphide until no more arsenic trisulphide is evolved. The lead-grey, six-sided crystals often have the (001)-face predominating, or they may be tabular with the pyramidal planes narrow and striated. G. vom Rath supposed the crystals to be rhombic, and to have the axial ratios $a : b : c = 0.53747 : 1 : 2.0305$; but H. Baumhauer showed that they are more probably monoclinic prisms with the axial ratios $a : b : c = 0.4945 : 1 : 0.2655$, and $\beta = 90^\circ 33\frac{1}{2}'$. The oft-repeated lamellar twinning about the (10 $\bar{1}$)-plane may furnish pseudo-hexagonal forms like those of aragonite. The (010)-cleavage is perfect. The crystals were examined by W. J. Lewis, R. H. Solly, and G. Tschermak. The possible isomorphism of the crystals with those of meneghinite, 4PbS.Sb₂S₃, was discussed by A. Schmidt, J. A. Krenner, H. A. Miers, C. Hintze, G. d'Archiadi, P. Groth, and G. vom Rath. The hardness

is 3. G. vom Rath gave 6.393 for the sp. gr.; R. H. Solly, 6.413; C. Guillemain, 5.480; L. Sipőcz, 6.3842; H. Baumhauer, 6.339 at 25°; S. S. Smirnof, 6.38; and H. Sommerlad, for the artificial crystals, 6.101. H. Sommerlad found that aq. ammonia has no action on the salt, but it is decomposed by hot alkali-lye. R. Bunsen found that potassium sulphide extracts arsenic from the natural sulpharsenites, and L. Sipőcz represented the reaction with jordanite: $Pb_3(As_2S_3)_2 \cdot PbS + K_2S = 4PbS + 2KAsS_2$.

R. H. Solly¹³ described a steel-grey mineral from the Lengenbach quarry, Binnenthal, Switzerland, which he named **lengenbachite**. Analyses by A. Hutchinson correspond with $7PbS \cdot 2As_2S_3$, or $PbS \cdot 2Pb_3(AsS_3)_2$, or **lead trisulphobispyrosulpharsenite**, $(Pb \cdot S \cdot Pb)_3(As_2S_5)_2Pb$. The mineral also contains small amounts of copper, silver, and antimony. The thin-bladed crystals are sometimes curled up like paper; they are probably triclinic. The cleavage parallel to the large face of the crystal is perfect. R. H. Solly gave 5.80 for the sp. gr., and A. Hutchinson, 5.85. This mineral is thought to be identical with the mineral *jentschite* described by R. Köchlin.

W. F. Hillebrand¹⁴ found a massive bluish-grey mineral mixed with zunyite in the zuni mine, Silverton, Colorado, and named it **guitermanite**—after F. Guiterman. The analysis corresponded with $10PbS \cdot 3As_2S_3$, which is so very near **lead orthosulpharsenite**, $3PbS \cdot As_2S_3$, that it is probably this compound with a trace of lead sulphide as an impurity. The sp. gr. is 5.94 at 17.5°; and the hardness 3. A. de Gramont examined the spark spectrum. T. W. Case observed that the mineral is a non-conductor of electricity, and light had no measurable effect. E. T. Wherry studied the crystals as rectifiers of alternating currents, or as radio-detectors. H. Sommerlad obtained a product of the composition of guitermanite by melting together the constituent sulphides. The sp. gr. was 5.86. He thought that the product might not be a chemical individual because aq. ammonia extracted from it arsenic trisulphide; but A. Terreil observed that a boiling 10 per cent. soln. of sodium sulphide gradually extracts arsenic trisulphide from all the lead sulpharsenites. H. Baumhauer described small crystals of a lead-grey mineral from the Lengenbach quarry, Binnenthal, Switzerland. He named it **seligmannite**—after G. Seligmann. The qualitative analysis, and the apparent isomorphism of the crystals with bournonite, and aikinite, indicate that the composition is probably $CuPbAsS_3$, **cuprous lead orthosulpharsenite**, in agreement with G. T. Prior's analysis. W. F. Foshag gave $Cu_2S \cdot 2PbS \cdot As_2S_3$. H. Baumhauer gave $a:b:c = 0.92804 : 1 : 0.87568$ for the axial ratios of the rhombic crystals, and R. H. Solly, $0.92332 : 1 : 0.87338$. The hardness is 3.

J. J. Berzelius¹⁵ obtained what is thought to have been **lead pyrosulpharsenite**, $Pb_2As_2S_5$, as a reddish-brown precipitate, by the action of sodium sulpharsenite on a soln. of a lead salt. H. Sommerlad also obtained it by melting a mixture of the constituent sulphides; and also a mixture of six mols of lead chloride and five mols of arsenic trisulphide. A lead-grey mineral found by A. Damour in the dolomite of Binnenthal, Switzerland, was named **dufrénoysite**—after P. A. Dufrenoy. The analyses reported by A. Damour, J. Berendes, G. vom Rath, H. Baumhauer, and C. Guillemain correspond with $2PbS \cdot As_2S_3$. G. Cesaro said that dufrénoysite corresponds with the general formula $As_2S_3(1+2n-1)R''S$, for these minerals were $n=2$. The corresponding hypothetical acid is $(HS)_2=As-S-As=(SH)_2$. A. Brun found thallium to be present. At first, A. Damour assumed the mineral to belong to the cubic system, and since W. S. von Waltershausen obtained it in rhombic crystals, he called the rhombic form *binnite*—*vide supra*. J. C. Heusser used these two terms. Later, W. S. von Waltershausen reported two other minerals, *arsenomelane* and *sclerodase*. G. vom Rath found three rhombic minerals in this locality; one he identified with A. Damour's dufrénoysite; another with W. S. von Waltershausen's scleroclase, which later came to be called *sartorite*; and the third he named *jordanite*. R. H. Solly added that the arsenomelane of W. S. von Waltershausen is the mineral now called *rathite*. C. F. Rammelsberg's *gottardite*, T. Petersen's

Skleroklas, and P. Groth's *Bleiarsenit* were no doubt samples of dufrénoysite. The measurements of the crystals by A. des Cloizeaux and J. C. G. de Marignac were shown by G. vom Rath to belong to the mineral sartorite. The crystals of dufrénoysite were also examined by R. H. Solly, and H. Baumhauer. G. vom Rath gave $a : b : c = 0.9381 : 1 : 1.5309$ for the axial ratios of the rhombic crystals; but R. H. Solly said that the crystals are monoclinic with the axial ratios $a : b : c = 0.650987 : 1 : 0.612576$, and $\beta = 90^\circ 33\frac{1}{2}'$. The cleavage parallel to the (010)-plane is perfect. J. L. C. Schröder van der Kolk studied the colour of these minerals; and L. J. Spencer, the isomorphism with zinckanite, etc. A. Damour gave 5-549 for the sp. gr.; G. vom Rath, 5-555-5-569, at 21° ; H. Baumhauer, 5-553; W. S. von Waltershausen, 5-52; R. H. Solly, 5-50; and H. Sommerlad, for the artificial crystals, 5-505. The hardness is 3. The compound is readily fused, and at a higher temp., it gives off arsenic trisulphide. A. de Gramont examined the spark spectrum. The compound is somewhat attacked by aq. ammonia; and is decomposed by potash-lye; and by soln. of the alkali sulphides, and acids.

H. Baumhauer¹⁶ obtained a lead-grey mineral, allied to dufrénoysite, from the dolomite of Binnenthal, Switzerland. It was called **rathite**—after G. vom Rath. Analyses reported by H. Baumhauer, W. S. von Waltershausen, G. vom Rath, T. Petersen, G. A. Kenngott, R. H. Solly, and H. Jackson correspond with $3\text{PbS}.2\text{As}_2\text{S}_3$, or **lead orthosulphotetrarsenite**, $\text{Pb}_3\text{As}_4\text{S}_9$. G. Cesaro gave the constitutional formula $\text{As}(\text{S.R.S.As}:\text{S})_3$. The prismatic crystals belong to the rhombic system, and H. Baumhauer gave for the axial ratios $a : b : c = 0.668099 : 1 : 1.057891$, and R. H. Solly, $0.4782 : 1 : 0.5112$. The twinning about the (074)-plane is indicated by numerous fine lamellæ; and there is also a juxtaposed twin about the (0, 15, 1)-plane. H. Baumhauer regards the fine striæ of the macrodomes to be produced by alternate bands of lead sulpharsenite and sulphantimonite, but since the bands occur with crystals containing no antimony, R. H. Solly said that the fine striæ are caused by twin lamellæ parallel to (074). The cleavage parallel to the (010)-face is perfect, and there is a parting parallel to (100). The sp. gr. given by H. Baumhauer is 5.32, and by R. H. Solly, 5.412-5.421. The hardness is 3. T. W. Case found the resistance is greater than a megohm, and that light has no measurable influence. The mineral is soluble in hot nitric acid. W. J. Lewis reported a mineral from the same locality as rathite, and he named it *wiltshireite*—after T. Wiltshire. It is said to occur in tin-white or lead-grey, monoclinic crystals with the axial ratios $a : b : c = 1.5869 : 1 : 1.0698$, and $\beta = 79^\circ 16'$. G. T. Prior showed the similarity of wiltshireite with dufrénoysite. According to R. H. Solly, this mineral is identical with rhandite, and if this is so, the crystals are probably rhombic. Another lead-grey or steel-grey mineral from Binnenthal was called **baumhauerite**—after H. Baumhauer—by R. H. Solly.¹⁷ The analysis corresponds with $4\text{PbS}.3\text{As}_2\text{S}_3$, that is, with **lead sulphohexarsenite**,

The crystals are monoclinic prisms or plates with the axial ratios $a : b : c = 1.136817 : 1 : 0.947163$, and $\beta = 82^\circ 42\frac{1}{2}'$. The (100)-cleavage is perfect. The sp. gr. is 5.330, and the hardness 3. The monoclinic crystals of a mineral, called *liveingite*—after G. D. Liveing—from Binnenthal had an analysis corresponding with $4\text{PbS}.3\text{As}_2\text{S}_3$, or better with $5\text{PbS}.4\text{As}_2\text{S}_3$. E. V. Shannon regards this as analogous with plagonite. The axial angle of the monoclinic crystals is $89^\circ 45\frac{1}{2}'$. G. E. Uhrlaub's mineral of sp. gr. 5.405 is probably the same thing.

H. Sommerlad¹⁸ prepared **lead metasulpharsenite**, $\text{Pb}(\text{AsS}_2)_2$, by melting stoichiometrical proportions of the component sulphides in an atm. of hydrogen sulphide; or by melting a mixture of 3 mols of lead chloride and 4 mols of

arsenic trisulphide. The Binnenthal mineral *scleroclase*—from *σκληρός*, hard; and *κλάειν*, to break—of W. S. von Waltershausen, and G. vom Rath has been mentioned in connection with dufrénoysite. J. D. Dana called it **sartorite**—after W. Sartorius von Waltershausen. Analyses reported by W. S. von Waltershausen, G. A. Kenngott, T. Petersen, H. Baumhauer, and R. H. Solly are in agreement with the formula $\text{Pb}(\text{AsS}_2)_2$, favoured by P. Groth and K. Mieleitner, and C. F. Rammelsberg; H. Baumhauer favoured $3(\text{PbS}.\text{As}_2\text{S}_3).2(\text{PbS})$. The crystals were examined by G. vom Rath, C. O. Trechmann, and H. Baumhauer; they belong to the rhombic system having the axial ratios $a : b : c = 0.5389 : 1 : 0.6188$. The colour is dark lead-grey. The crystal faces may be striated or channelled. The (001)-cleavage is distinct. J. Königsberger studied the anisotropy of the crystals; and L. J. Spencer, the isomorphism with zinckenite (*g.v.*), etc. The hardness is 3. W. S. von Waltershausen gave 5.074–5.469 for the sp. gr.; H. Baumhauer, 5.05; R. H. Jolly, 4.980; G. A. Kenngott, 5.074–5.355; and H. Sommerlad, for the artificial crystals, 4.585. T. W. Case found the mineral is a non-conductor of electricity, and light has no appreciable effect. The mineral is soluble in nitric acid. When the artificial compound is heated in hydrogen sulphide, it forms lead pyrosulpharsenite, and then passes into lead disulphopyrosulpharsenite. It is decomposed by soln. of alkali sulphides or hydroxides, and by hydrochloric or nitric acid.

R. H. Solly¹⁹ discovered a mineral at Lengenbach, Switzerland, and he named it **hutchinsonite**—after A. Hutchinson. Its analysis reported by G. F. H. Smith and G. T. Prior corresponds with **silver thallium lead metasulpharsenite**, $(\text{Tl}, \text{Ag})_2\text{S}.\text{As}_2\text{S}_3.\text{PbS}.\text{As}_2\text{S}_3$, or $\text{Pb}(\text{Tl}, \text{Ag})_2(\text{AsS}_2)_4$. Up to 3 per cent. of copper (ous), and 2.0 per cent. of antimony are present in some samples. The colour is vermilion-scarlet or cherry-red, and it occurs in flattened prisms with numerous small faces of domes and pyramids. R. H. Solly gave for the axial ratios of the rhombic crystals $a : b : c = 0.8172 : 1 : 0.7549$, and G. F. H. Smith and G. T. Prior, 1.6343 : 1 : 0.7549. The (100)-cleavage is good. The hardness is 1.5–2.0, and the sp. gr. 4.6. The optic axial angle $2E = 63^\circ 22'$; $2H = 35^\circ 19'$ for red-light, and $71^\circ 58'$ for yellow-light; and $2V = 19^\circ 44'$, and $37^\circ 34'$. The corresponding indices of refraction were $\alpha = 2.799$, $\beta = 3.063$, and $\gamma = 3.073$; and $\alpha = 3.087$, $\beta = 3.176$, and $\gamma = 3.188$. The birefringence is strong; the optical character negative; and the pleochroism weak.

For **germanium sulpharsenite**, *vide* germanite, 7. 44, 1. -J. J. Berzelius²⁰ found that a mixture of antimony and arsenic trisulphides fuses to an orange-yellow, transparent liquid, but there is here no evidence of the formation of an **antimony sulpharsenite**. When a soln. of a bismuth salt is treated with sodium sulpharsenite, the reddish-brown precipitate was considered to be **bismuth pyrosulpharsenite**, $\text{Bi}_4(\text{As}_2\text{S}_5)_3$. It fuses readily, and gives off arsenic trisulphide when heated to a higher temp. No precipitate of **vanadium sulpharsenite** is formed when an aq. soln. of sodium sulpharsenite is added to a soln. of vanadic sulphate, but the blue liquid becomes colourless. With soln. of chromic salts and sodium sulpharsenite, a dingy, greenish-yellow precipitate is formed which is assumed to be **chromic sulpharsenite**. This precipitate melts when heated, and at a higher temp., gives off arsenic trisulphide. The mixture readily burns when heated in air. Molybdenum salts under similar conditions give a dark brown precipitate of **molybdenum sulpharsenite**, which gives off arsenic trisulphide at an elevated temp. Uranyl salts also give a yellow precipitate of **uranium sulpharsenite** under similar conditions, and it melts when heated and gives off arsenic trisulphide at a higher temp. With manganese salts an aurora-red precipitate of **manganese sulpharsenite** is formed. It behaves when heated like the other sulpharsenites. A soln. of a ferrous salt yields a dark brown precipitate of **ferrous sulpharsenite** soluble in excess of sodium sulpharsenite, forming a yellowish-brown soln.; and a soln. of a ferric salt yields an olive-green precipitate of **ferric sulpharsenite** which dissolves in an excess of sodium sulpharsenite, forming a black soln. Both salts

fuse when heated, and decompose at a higher temp. Cobalt salts under similar conditions give a dark brown **cobalt sulpharsenite** which is soluble in an excess of the sodium sulpharsenite, and decomposes when heated, forming what was thought to be cobaltite or cobalt glance. Nickel salts give a black precipitate of **nickel sulpharsenite** which is also decomposed by heat leaving nickel sulphide as a residue. A soln. of platinic chloride and sodium sulpharsenite gives a dark brown precipitate of **platinum sulpharsenite** which is decomposed by heat.

§ 33. The Sulphoarsenides, Sulpharsenides, or Arsenosulphides

A. Frenzel¹ described a mineral from the copper mines at Lauta, Marienberg; and called it **lautite**. Analyses reported by A. Frenzel, and A. Weisbach agreed

with the formula CuAsS , **copper sulpharsenide**, but about one-fifth of the copper was replaced by silver, $(\text{Cu,Ag})\text{AsS}$. The crystals of the dark steel-grey mineral belong either to the rhombic or the monoclinic system. W. F. de Jong found the X-radiogram to be totally different from that of the arsenopyrite-glaucodote family, so that it is doubtful if isomorphism exists. The hardness is 3.0–3.5, and the sp. gr. 4.96. L. Dürr gave 4.53 at 18°. A. Weisbach considered lautite to be a mixture of arsenic with julianite.

H. and G. Rose² described an arsenical polybasite from Mexico, and S. L. Penfield applied the name **pearceite**—after R. Pearce—to a similar mineral from Aspen, Colorado. Analyses reported by S. L. Penfield, S. H. Pearce, H. Rose, and I. Domeyko agree with the formula $9\text{Ag}_2\text{S.As}_2\text{S}_3$, or **silver hexasulpharsenide**, Ag_9AsS_6 , or $(\text{Ag,Cu})_9\text{AsS}_6$. The black crystals are monoclinic, and, according to S. L. Penfield, have the axial ratios $a : b : c = 1.7309 : 1 : 1.6199$, and $\beta = 89^\circ 51'$. The tabular crystals appear to be pseudo-rhombohedral, and have triangular markings on the basal faces; the twinning is thought to be like that of the micas and chlorites. No cleavage has been observed. The hardness is 3, and the sp. gr. ranges from 6.125 to 6.166. T. W. Case found that the mineral has an electrical resistance less than one megohm, and light has no measurable effect. H. E. McKinstry found that the surface of the mineral is roughened by exposure to the light of an electric arc. Pearceite is readily oxidized, and the powder dissolved by nitric acid.

G. Agricola³ described a mineral which he called *mispickel* as *lapis subtilis atque non fere aliter ac argenti spuma splendens et friabilis*; C. Gesner called the same mineral *Wasserkies* or *pyrites candidus*; J. F. Henckel, **mispickel** or *arsenikalischer Kies*; J. G. Wallerius, *mispickel*, *pyrites albus*, *arsenicum ferro mineralisatum*, etc.; A. G. Werner, A. Cronstedt, C. A. S. Hofmann, and L. A. Emmerling used various designations—*Rauschgelbkies*, *Giftkies*, *Glanzarsenikkies*, *Weisserz*, *dalarnite*, etc. A. Breithaupt called it *plinian*; and E. F. Glocker, **arsenopyrite**. The names *mispickel* and *arsenopyrite* are in common use. A very large number of analyses has been reported.⁴ Some specimens contain little or no cobalt, others—*danaite*—contain up to 10 per cent., and gradually merge into *glaucodote*. Some specimens contain up to 0.28 per cent. of antimony; some bismuth; and some are niccoliferous. The early analyses—e.g. W. A. Lampadius—missed the sulphur, and thus R. J. Haiiy called the mineral *fer arsenical*. The presence of iron, sulphur, and arsenic as essential constituents was demonstrated by M. E. Chevreul, F. Stromeyer, and T. Thomson, who regarded it as a mixture of FeS_2 and FeAs_2 ; while C. F. Rammelsberg regarded it as a mixture of $\text{FeS}_2 + n\text{Fe}_2\text{As}_3$, i.e. of FeAs , Fe_3As_4 , Fe_2As_5 , or FeAs_3 . J. Loczka, and P. Groth represented the constitution of *mispickel* as *marcasite* with part of the sulphur replaced by arsenic, or as *löllingite* with part of the arsenic replaced by sulphur:

N. S. Kurnakoff and N. S. Konstantinoff held similar views. According to F. W. Starke, H. L. Shock, and E. F. Smith, (i) when *mispickel* is heated in hydrogen, all the sulphur is expelled as hydrogen sulphide, whilst the iron and practically all the arsenic remain; this indicates that the sulphur is less intimately combined with the iron than is the arsenic. Pyrites and *marcasite* lose half their sulphur when heated in hydrogen. (ii) Heating with ammonium chloride in nitrogen, and dissolving in water, gives indications of the presence of much ferrous, but only a little ferric iron. (iii) Heating with copper sulphate soln. in sealed tubes and titrating with permanganate shows the presence of much ferrous iron and arsenious acid. (iv) Heating in a current of dry hydrogen bromide showed the presence of about 28 per cent. of ferrous iron, and in dry hydrogen chloride of 30.86, 30.55, 30.16 per cent. Since there is 34.35 per cent. of iron in *mispickel*,

this leaves about 4 per cent. for ferric iron. Consequently, the formula of mispickel is given provisionally as $14\text{Fe}''\text{As}''\text{S}, 2\text{Fe}''\text{As}''\text{S}$. Experiments to determine the mol. wt. by observing the influence of mispickel on the solidification point of alloys were without result. G. A. Behneke, and A. Breithaupt considered the difference in chemical composition, density, and crystal angles is founded on essential differences in composition; and A. Arzruni, and A. Arzruni and C. Barwäld showed that the differences cannot be regarded as being produced by varying proportions of FeS_2 and FeAs_2 regarded as isomorphous compounds; and G. Magel found that as the proportion of sulphur increased so did the axial ratio $a : b$ increase. J. W. Retgers, as well as A. Arzruni, did not consider the FeS_2 and FeAs_2 to be isomorphous, but rather morphotropic. H. de Sénarmont heated, in a sealed tube at 300° , a mixture of iron sulphide with sodium sulpharsenite, and hydrocarbonate and water; or a mixture of precipitated iron sulpharsenite, and sodium hydrocarbonate, and water, and obtained crystals of iron sulpharsenide (mispickel). W. Ipatieff and W. Nikolaieff obtained the crystals by the prolonged action of hydrogen, at a high temp. and press., on iron arsenate. A. N. Winchell discussed the isomorphism of the tetrahedrite-tennantite system.

Mispickel is the most important of the arsenic ores. It occurs in well-defined fissure veins in beds, or threaded bands, and as impregnation deposits in crystalline rocks. It is commonly associated with ores of silver, lead, and tin, and also with pyrite, chalcopyrite, and sphalerite. Mispickel occurs compact and granular, as well as in prismatic or tabular crystals. C. Hintze has given a review of the more important occurrences of the mineral. The colour of mispickel varies from silver-white to steel-grey. C. Linnæus⁵ referred to the cubic crystals, and so did J. B. L. Romé de l'Isle, and J. J. Bernhardt. R. J. Haiiy, however, showed that the crystals are rhombic prisms. A. Arzruni found the axial ratios of the rhombic crystals to be $a : b : c = 0.677726 : 1 : 1.18817$; H. Bücking, $0.6734 : 1 : 1.1921$; and F. Scherer gave $0.69764 : 1 : 1.201$. Twinning occurs about the (110)-plane with contact or penetration twins repeated as with marcasite; and there may be cruciform twins about the (101)-plane. There may be star-shaped trillings crossing at angles 59° and 62° . The brachydomes may be horizontally striated and the (110)-faces may also be finely striated. The (110)-cleavage is distinct; and the (001)-cleavage faint. The crystals were examined by A. Frenzel, P. Groth, F. Scherer, A. Breithaupt, G. Magel, H. Bücking, V. R. von Zepharovich, A. Schmidt, A. des Cloizeaux, M. Weibull, P. von Jeremejeff, K. Jimbo, etc. The effect of variations in the composition on the crystal form were studied by A. Arzruni, A. Arzruni and C. Bärwald, G. Magel, A. Breithaupt, G. A. Behneke, M. Weibull, F. Scherer, L. J. Wallmark, and F. Sandberger. F. Scherer studied the corrosion figures; M. L. Huggins, the space-lattice; and P. F. Kerr,⁶ the X-radiograms. W. F. de Jong found the constants of the space-lattice of the rhombic crystals are $a = 6.44 \text{ \AA}$, $b = 4.76 \text{ \AA}$, and $c = 5.63 \text{ \AA}$; and if there are 4 mols. per cell, the calculated density, 6.28, agrees with the observed value. The hardness is 5-6, and the sp. gr. 5.9-6.2. G. A. Kenngott gave 6.269 for the sp. gr.; A. Vogel, 6.21; J. Potyka, 6.004 for the powder, and 6.095 for the solid; D. Forbes, 6.255; V. R. von Zepharovich, 6.16; L. W. McCay, 6.05-6.07; and A. Breithaupt, 5.84-5.911. E. Madelung and R. Fuchs found for the compressibility, 2.86×10^{12} dynes per sq. cm. F. E. Neumann gave 0.1012 for the sp. ht.; A. Sella, 0.103; and P. E. W. Oeberg, 0.1210. The mineral easily fuses; L. H. Borgström gave 700° for the m.p. of arsenopyrite. At a higher temp., P. Berthier found that in the absence of air mispickel loses half its sulphur, and three-quarters of its arsenic; and J. Loczka observed that almost all the arsenic is sublimed, and ferrous sulphamide remains. C. Schubert gave 220° for the temp. at which the decomposition, $\text{FeAsS} = \text{FeS} + \text{As}$, begins, and he found that the reaction is not completed at 670° . A. de Gramont examined the spark spectrum. T. W. Case observed that in darkness arsenopyrite and tetrahedrite have a resistance less than a megohm, and exposure to light has no effect

on the conductivities. Mispickel is a conductor of electricity; and H. Bäckström observed that the thermoelectric force of a combination of two crystals with a copper strip between them gives an e.m.f. of 0.0002410 volt per degree with the (110)-faces; and 0.0002429 volt per degree with the (110)-faces. C. Schubert found that when heated, dissociation begins at 220°. V. Goldschmidt examined some magnetic properties of mispickel. E. T. Wherry found the crystals poor radiodetectors. H. Saito said that arsenopyrite is rapidly oxidized from about 500° subliming arsenic trioxide, and that the best temp. for the trioxide sublimation is 600°. Slower heating and low temp. give iron arsenate which reduces the yield of trioxide. The mineral is attacked by nitric acid with the separation of sulphur and arsenic acid; and with aqua-regia, only a little sulphur separates. F. Scherer observed the corrosion figures with aqua regia. H. Zieler observed a feeble reaction with boiling 10 and 20 per cent. HNO_3 ; with 30–40 per cent. HNO_3 , there is a feeble reaction in the cold when the mixture is shaken, and a vigorous reaction with the boiling acid; and with 50 per cent. acid, agitated, there is a vigorous reaction in the cold. E. F. Smith found that with sulphur monochloride, there is a great rise of temp. but the mineral is decomposed completely only on heating to 140°; and H. B. North and C. B. Conover, that it is decomposed slowly by heating it with thionyl chloride in a sealed tube at 150°–175°. J. Lemberg found that the mineral is oxidized by soln. of bromine in alkali-lye. For the observations of F. W. Starke and co-workers on the action of hydrogen, ammonium chloride, hydrogen bromide, and a soln. of copper sulphate, *vide supra*. V. Lenher found that arsenopyrite is slowly attacked in the cold by selenium oxydichloride; the reaction is faster with hot soln. J. Lemberg found that when mispickel is warmed with a sulphuric acid soln. of silver nitrate at 75°, it is coloured bluish-violet, and some silver is deposited. E. Thomson studied the etching reactions with nitric acid and with soln. of mercurous and ferric chlorides.

The mineral *pacite* obtained by A. Breithaupt⁷ from La Paz, Bolivia, resembles mispickel in general appearance. Its composition approximates $\text{Fe}_5\text{S}_2\text{As}_3$, *i.e.* $\text{Fe}(\text{As}_2\text{S})_2$. The sp. gr. is 6.297–6.008. The *glaucopyrite* obtained by F. Sandberger from Guadalcanal, Spain, approximates $\text{Fe}_{13}\text{S}_2\text{As}_{24}$ in composition, and is usually regarded as a variety of löllingite. Its sp. gr. is 7.181.

J. G. Wallerius,⁸ and A. Cronstedt referred to *cobaltum cum ferro sulfurato et arsenicato mineralisatum* as *Glantz kobolt*, or *cobolt glance*, *Kobolterz*, or *Koboltmalm*. J. B. L. Romé de l'Isle called it *mine de cobalt arsenicosulfureuse*; R. J. Haiüy, *cobalt gris*; E. F. Glocker, *Kobaltkies*, and **cobaltite**; and F. S. Beudant, *cobaltine*. It is the *sehta* of the Indian jewellers. The first quantitative analyses was made by M. H. Klaproth,⁹ and his analyses as well as that of B. M. Tassart, gave too small a proportion of sulphur. F. Stromeyer's analysis came nearer the mark, and this with numerous others corresponded with the idealized $\text{CoS}_2\cdot\text{CoAs}_2$, or **cobalt sulpharsenide**, CoAsS . Iron is present in some samples, and was called *Stahlcobalt* by C. F. Rammelsberg; *Staglerz*. by T. Münster; and *ferrocobaltite*, by J. D. Dana. According to P. Groth, the sp. gr. favours the view that ferrocobaltite is a variety of cobaltite. The crystals of cobaltite were mentioned by C. Linnæus,¹⁰ and B. G. Sage; while J. E. L. Romé de l'Isle, and R. J. Haiüy observed that the cubic crystals are pyritohedral. They commonly occur in cubes or pyritohedra or combinations of these, and with the faces striated as with pyrites. The cubic cleavage is nearly perfect. The crystals were examined by A. von Hubert, P. Groth, F. von Kobell, G. A. Kenngott, W. H. Miller, C. F. Naumann, etc. L. S. Ramsdell found the X-radiograms corresponded with the pyritic structure with arsenic occupying alternate positions with respect to the sulphur. The unit cubic cell has a side 5.58 Å.; this agrees with the results obtained by W. H. and W. L. Bragg, and M. Mechling. H. Schneiderhöln found that all the crystals he examined were rhombic. This may mean that the rhombic structure of cobaltite is so near cubic that the X-ray data cannot distinguish the one from the other; or it may mean that cobaltite is dimorphous and that one

form is metastable at ordinary temp. The data were discussed by M. L. Huggins. The colour may be silver-white, inclining to red; steel-grey with a violet tinge; or greyish-black when much iron is present. P. F. Kerr examined the X-radiogram of cobaltite. W. Flörke found the anisotropic mineral became isotropic when heated for an hour at 800° – 900° —the reverse change was not observed. The hardness is between 5 and 6; the sp. gr. between 6.0 and 6.4. According to A. Schrauf and E. S. Dana, crystals with a higher sp. gr. than 6.30 are usually octahedral, and those with a smaller sp. gr. than 6.1 are cubes. E. Madelung and R. Fuchs gave for the compressibility, 3.06×10^{12} dynes per sq. cm. P. W. Bridgman represented the linear compressibility at 30° by $\delta l/l_0 = 0.0_62519p - 0.0_{11}101p^2$; and at 75° , by $\delta l/l_0 = 0.0_62559p - 0.0_{11}101p^2$; and the vol. compressibility at 30° by $\delta v/v_0 = 0.0_6756p - 0.0_{11}285p^2$; and at 75° by $\delta v/v_0 = 0.0_6768p - 0.0_{11}282p^2$ for press., p ranging up to 12,000 kgrms. per sq. cm. H. Fizeau gave for the linear coeff. of thermal expansion, 0.0_5919 at 40° . F. E. Neumann found the sp. ht. to be 0.107; P. E. W. Öberg, 0.097; and A. Sella, 0.099. A. de Gramont studied the spark spectrum. T. W. Case said that the mineral is practically a non-conductor of electricity in the dark, and light has no measurable influence. W. G. Hankel found the octahedral crystals from Tunaberg to be thermoelectrically positive towards copper, the cubic crystals negative. This subject was investigated by H. Marbach, G. Rose, and P. Curie. According to A. Schrauf and E. S. Dana, generally, not always, the denser crystals richer in cobalt are usually octahedral, and negative, while the less dense crystals are cubic and positive. H. Bäckström showed that the (111)- and (100)-faces have the same thermoelectric force towards copper. E. T. Wherry found the crystals to be poor radio-detectors; and J. Forrest studied their magnetic qualities. Warm nitric acid dissolves the mineral with the separation of sulphur and arsenic acid. E. F. Smith found that cobaltite must be heated to 180° before it is completely decomposed by sulphur monochloride. J. Lemberg observed that cobaltite is oxidized by a soln. of bromine in alkali-lye, forming cobalt peroxide; that with a soln. of potassium ferricyanide and hydrochloric acid, cobalt ferricyanide is formed; and that with a sulphuric acid soln. of silver sulphate there is very little action until the soln. is boiled—the reaction of smaltite with this soln., resulting in the deposition of silver, is much faster. E. Thomson studied the etching reactions with nitric acid, and soln. of mercurous and ferric chlorides. H. B. North and C. B. Conover said that it is not attacked by thionyl chloride at 150° – 175° .

The cobaltiferous mispickel from Franconia, New Hampshire, was called *danaite*—after J. D. Dana—by A. Hayes;¹¹ T. Scheerer, and F. Wöhler called the cobaltiferous mispickel from Skutterud, *Kobaltarsenikies*; A. Breithaupt called the cobaltiferous mispickel from Hausco, Chili, **glaucodotite**—from $\gamma\lambda\alpha\upsilon\kappa\acute{o}\varsigma$, blue—in allusion to its use for making smalt, and another variety from Hakansboda, Sweden, *akontite*. Analyses were reported by A. Hayes, F. Wöhler, T. Scheerer, C. F. Rammelsberg, G. Tschermak, C. Schnabel, F. von Kobell, G. C. Hoffmann, A. Breithaupt, I. Domeyko, and J. D. Dana. Hence, G. Tschermak showed that glaucodotite and danaite are members of an isomorphous series with FeAsS and CoAsS as terminal members. The members of the series are represented by the formula $(\text{Fe},\text{Co})\text{AsS}$. F. Becke gave for the axial ratios of the rhombic crystals of danaite $a : b : c = 0.6732 : 1 : 1.1871$; and W. J. Lewis for those of glaucodotite, $0.6942 : 1 : 1.1925$. The habit of the crystals resembles that of mispickel, being commonly prismatic. The (100)-faces are usually striated vertically, the brachydomes, horizontally. Twinning occurs about the (110)- and (101)-planes; these are cruciform twins, and also trillings. The (001)-cleavage is nearly perfect, the (110)-cleavage less so. The crystals were also examined by M. Weibull, A. Sadebeck, W. H. Miller, G. A. Kenngott, A. Breithaupt, and I. Domeyko. The X-radiogram was examined by L. S. Ramsdell, and M. L. Huggins. W. F. de Jong found that the space-lattice of glaucodotite resembles that of arsenopyrite, but with $a = 6.67 \text{ \AA}$., $b = 4.81 \text{ \AA}$., and $c = 5.73 \text{ \AA}$., with the calculated

density, 6.0, in agreement with that observed on the assumption that there are 4 mols. per unit cell. The hardness is 5; and the sp. gr. is usually between 5.9 and 6.0—T. Münster gave 5.958–5.983; G. Tschermak, 5.973; A. Breithaupt, 5.975–6.059; A. Hayes, 6.214; and G. C. Hofmann, 5.988. L. H. Bergström gave 480°–700° for the m.p.; and J. Joly, 190° for the temp. at which sublimation occurs. F. Beijerinck found that the mineral is a good conductor of electricity; the increase of conductivity is regular as the temp. rises from 17° to 215°. A. Schrauf and E. S. Dana found the thermoelectric force of danaita from Franconia is positive, and negative with glaucodotite from Modum, Skutterud, and Hakansboda. Crystals from Hakansboda have a negative skin of sp. gr. 6.011 and a positive core of sp. gr. 5.905. E. T. Wherry found the crystals to be fair radio-detectors. J. Lemberg said that when the mineral is heated to 60° with a sulphuric acid soln. of silver sulphate, it is rapidly coloured blue; and it is rapidly oxidized with a soln. of bromine in alkali-lye.

A. Cronstedt¹² described *niccolum ferro et cobalto arsenicatis et sulphuratis mineralisatum*, or kupfernickel as he called it; but in 1818, C. H. Pfaff showed that *ein neues Nickelerz* is involved which was called *nickel glance* or *white nickel ore*. F. von Kobell called a variety *Nickelarsenikglanz*, and *amosbite*—from ἀμοιβή, exchange; E. F. Glocker, *Nickelarsenikkies*; F. S. Beudant, *sulfoarsenure de nickel*, and *disomose*; A. Breithaupt, *tombazite*; J. D. Dana, *dobschawite*, and *plessite*; and A. Löwe, **gersdorffite**—after A. von Gersdorff. According to C. H. Pfaff's analysis, the composition was $2\text{NiAs}_2\cdot\text{FeS}_2$, but J. J. Berzelius¹³ represented his analysis by $\text{NiS}_2 + \text{NiAs}_2$. Numerous other analyses have been reported, and the results agree with the idealized formula NiAsS , **nickel sulph-arsenide**. M. Hörnes showed that some varieties have a significant proportion of iron, and a small proportion of sulphur. The analyses are somewhat discordant—the nickel, for example, ranges from 19.59 to 37.34 per cent., and some indeed approach smaltite or chloanthite in composition. This is taken to mean that the normal gersdorffite is mixed with other minerals. There is probably a trimorphous series $\text{FeAsS}-\text{CoAsS}-\text{NiAsS}$.

The mineral varies in colour from tin-white to steel-grey. It occurs massive in various imitative shapes, and crystalline. J. C. L. Zincken¹⁴ described the first crystals; he regarded them as tetragonal, but G. Rose, and F. von Kobell showed that the crystals are pyritohedral and belong to the cubic system. The cubic cleavage is nearly perfect. S. von Olshausen studied the X-radiograms, and inferred that there is a simple cubic lattice of side $a=5.719 \text{ \AA}$. L. S. Ramsdell found the X-radiogram to be in agreement with the pyritic pattern with arsenic atoms occupying alternate positions with the sulphur. The unit cube had a side of length 5.68 Å. The lattice structure was also examined by M. L. Huggins. The hardness is near 5. J. C. L. Zincken gave for the sp. gr. 6.097–6.300; C. F. Rammelsberg, 5.61–6.415; A. Bäumlér, 6.2; M. Hörnes, 6.72–6.87; F. Pless, 6.641; L. Sipöcz, 6.1977; D. Forbes, 5.49–5.65; C. H. Pfaff, 6.129; and G. C. Hofmann, 6.231; and V. R. Zepharovich, 6.514. J. Joly said sublimation occurs at 450°–480°. A. de Gramont examined the spark spectrum. The mineral is a good conductor of electricity; T. W. Case said that the resistance is less than a megohm, and exposure to light has no effect. It is decomposed by nitric acid, forming a green soln. with the separation of sulphur and arsenic acid. E. F. Smith found that gersdorffite is completely decomposed when heated to 170° with sulphur monochloride. J. Lemberg found that the mineral is oxidized by a soln. of bromine in alkali-lye, and with a sulphuric acid soln. of silver sulphate there is a separation of silver, and the colour becomes dark blue. E. Thomson studied the etching reactions with nitric acid, and with soln. of mercurous and ferric chlorides.

§ 34. Arsenic Pentasulphide

There is an unexplored gap in the f.p. curves of the binary system: As-S, Fig. 43, corresponding with **arsenic pentasulphide**, As₂S₅. A. Gélis¹ said that the dark yellowish-green, plastic mass obtained by fusing stoichiometrical proportions of the constituent elements, gradually hardens and forms a lemon-yellow powder. By digesting the product with aq. ammonia, pale yellow flocculent sulphur remains undissolved, and when the yellow soln. is treated with acids, arsenic pentasulphide is deposited. If the horny product of the fusion of the two elements be distilled, sulphur first passes off, then arsenical sulphur, and the colour of the distillate changes in colour from yellow to orange and then to red. If the distillation be stopped as soon as the colour change begins, and the residue be digested with aq. ammonia, it is almost completely soluble in aq. ammonia, and consists of arsenic pentasulphide. Numerous investigations have been made on the conditions which favour the formation of arsenic pentasulphide by precipitation from a soln. containing arsenic acid, or an arsenate. For instance, J. J. Berzelius,

B. Brauner and F. Tomicek, R. Bunsen, L. W. McCay, F. Neher, E. W. Parnell, H. Rose, J. Thiele, F. L. Usher and M. W. Travers, and H. W. F. Wackenroder have worked on this subject, and the results of their work are discussed in connection with the action of hydrogen sulphide on arsenic acid. J. J. Berzelius, and A. F. Fuchs found that the pentasulphide is also precipitated when hydrochloric acid is added to a boiling dil. soln. of sulpharsenate. L. F. Nilson said that the decomposition is here not quantitative since soluble oxysulpharsenates are formed. If the precipitation is made in the cold, the product may contain free sulphur. R. Bunsen washed out the free sulphur with hydrogen sulphide, but B. Brauner and F. Tomicek said the extraction is incomplete. F. V. von Hahn did not obtain a colloidal soln. of arsenic pentasulphide by the hydrolysis of alkali arsenic thio-sulphates owing to the instability of these compounds.

The formula As_2S_5 is in agreement with the analyses of A. Gélis, R. Bunsen, and B. Brauner and F. Tomicek. According to L. F. Nilson, arsenic pentasulphide appears as a lemon-yellow powder somewhat paler than the trisulphide; it can be heated to 95° without change, but if heated to 100° in air for a long time it acquires a surface film of crystals of arsenic trioxide—B. Brauner said that it can be dried at 107° without decomposition; and R. Bunsen, and F. Neher said at 110° . J. J. Berzelius found that the pentasulphide melts at a higher temp. than does sulphur, and when distilled the residue becomes poorer and poorer in sulphur until, as A. Gélis found, the trisulphide is formed. According to V. and C. Meyer, the pentasulphide dissociates at 500° into the trisulphide and sulphur. The pentasulphide holds adsorbed water very tenaciously; L. F. Nilson found that the water is expelled at 90° to 95° , and he suggested that a hydrate, $As_2S_5 \cdot H_2O$, is formed, or possibly the acids $HAsS_3$ and $HAsOS_2$, but L. W. McCay could not confirm this. H. Rose said that the pentasulphide is reduced by hydrogen, and this also occurs when the pentasulphide is melted with sodium carbonate in hydrogen gas. R. Bunsen found that the pentasulphide is insoluble in water, and J. J. Berzelius observed that blue litmus paper is reddened by the pentasulphide warmed in a current of steam. When the pentasulphide is boiled in water, P. de Clermont and J. Frommel observed that a soln. of arsenic trioxide is formed with the separation of sulphur, and since arsenic acid is not formed by the hydrolysis of the pentasulphide, they doubted if the pentasulphide is a definite compound. R. Bunsen said that the pentasulphide is insoluble in hydrochloric acid. H. Zieler observed no reaction with 10 per cent. HNO_3 ; with 20 per cent. HNO_3 , nitric oxide could be detected only with the boiling acid; with 30–40 per cent. acid, agitated, nitric acid could be detected in the cold, and the gas is given off by the boiling acid; and with over 60 per cent. acid, agitated, nitric oxide was given off. H. Rose showed that the pentasulphide is reduced when heated with carbon, or when fused with potassium cyanide and sodium carbonate; and R. Bunsen, that it is insoluble in alcohol, and in carbon disulphide. J. Spiller observed that the pentasulphide is soluble in soln. of citric acid, or alkali citrates. J. J. Berzelius found that the pentasulphide absorbs ammonia, forming a pale yellow solid which loses the whole of its ammonia when exposed to air. The *arsenic aminopentasulphide* is soluble in water, and the soln. gradually deposits a red powder. L. F. Nilson showed that the pentasulphide is soluble in aq. ammonia, and in soln. of alkali hydroxides, carbonates, or hydrosulphides, forming sulpharsenates and oxysulpharsenates. He added that it dissolves in a soln. of potassium arsenate with the separation of sulphur, forming an oxysulpharsenate, and in a soln. of sodium arsenate, forming arsenic trisulphide.

§ 35. The Complex Salts of Arsenic Pentasulphide—The Sulpharsenates

Arsenic pentasulphide plays the part of an acid anhydride in forming a series of complex salts with the basic sulphides, and the products can be regarded as derivatives of a series of hypothetical **sulpharsenic acids** :

Orthosulpharsenic acid	H_3AsS_4
Metasulpharsenic acid	$HAsS_3$
Pyrosulpharsenic acid	$H_4As_2S_7$
Pentersulphotriarsenic acid ($H_{15}As_3S_{15}$ less $5H_2S$)	$H_5As_3S_{10}$
Pentersulphotetrarsenic acid ($H_{20}As_4S_{20}$ less $5H_2S$)	$H_{10}As_4S_{15}$

A small number of the corresponding salts occur in nature—epigenite, enargite, and xanthocone. H. Rose¹ said that the sulpharsenic acids are stronger than the sulpharsenic acids because they develop more heat in combining with ammonium sulphide. J. J. Berzelius, and L. F. Nilson prepared a number of these salts by dissolving the pentasulphide in a warm soln. of the hydrosulphide of the base, and evaporating the soln. in vacuo. Sulpharsenates were also prepared by J. J. Berzelius, and C. Eckert by dissolving arsenic trisulphide in soln. of the alkali polysulphides, or in soln. of sulphur in the alkali hydroxides. L. W. McCay said that J. J. Berzelius, erred in supposing that the sulpharsenates can be produced by dissolving arsenic pentasulphide in soln. of the alkali hydroxides or carbonates or in aq. ammonia because oxysulpharsenates are produced. This was confirmed by R. F. Weinland and P. Lehmann, and F. A. Flückiger. Sulpharsenates were made by J. J. Berzelius by the action of hydrogen sulphide on aq. soln. of the alkali arsenates. The gas is at first slowly absorbed, but afterwards, more quickly. L. W. McCay studied this reaction and found that arsenic pentasulphide is formed when hydrogen sulphide in excess is passed rapidly into a soln. of alkali dihydroarsenate, some trisulphide and sulphur may also be formed. With the ortho-sulpharsenates and dihydrosulpharsenates, the decomposition of the oxysulpho-arsenate which is always formed may produce potassium arsenite and sulphur. The former then yields arsenic trisulphide. J. J. Berzelius also obtained the sulpharsenates by mixing soln. of the alkali arsenates with an excess of ammonium hydrosulphide, and distilling until the free ammonia and excess of ammonium hydrosulphide are expelled; if the arsenate is insoluble in water—e.g. copper arsenate—it is dissolved in hydrochloric acid and the sulpharsenate precipitated by hydrogen sulphide. J. J. Berzelius, and K. Preis obtained some of these sulpharsenates by double decomposition with soln. of sodium sulpharsenate, and a soln. of the metal salt. Impure sulpharsenates were produced by J. J. Berzelius by fusing a mixture of arsenic penta- or trisulphide with an excess of alkali hydroxide, carbonate, or sulphide; L. F. Nilson, by evaporating soln. of arsenic trisulphide in one of alkali carbonate or hydrosulphide; K. B. Edwards, by treating arsenic trisulphide with ammonium or alkali polysulphides; A. Geuther, by heating arsenic disulphide and a soln. of sodium sulphide in a sealed tube at 100°; and R. F. Weinland and P. Lehmann, by the action of sodium ethoxide on arsenic pentasulphide. In most cases, oxysulpharsenates are produced at the same time.

J. J. Berzelius reported that the sulpharsenates are yellow, red, or brown salts. The orthosulpharsenates have a tendency to crystallize, but not so with the pyro- or meta-sulpharsenates. They are permanent in air; and when soluble they taste first hepatic and afterwards bitter. The ortho-salts of the alkalies and alkaline earths can be heated white-hot without decomposition if air be excluded; while the pyro- and meta-sulpharsenates give off sulphur and form sulpharsenites. When heated in air, arsenic trioxide and trisulphide, and sulphur dioxide are evolved and either the metal oxide or sulphate is formed. L. F. Nilson found that the salts are reduced, forming a mirror of arsenic when they are heated in a current of hydrogen. The sulpharsenates of the alkalies and alkaline earths, magnesium, beryllium, and yttrium were found by J. J. Berzelius to be soluble in water, forming colourless or pale yellow liquids; and, added L. F. Nilson, and J. J. Berzelius, the aq. soln. are slowly decomposed, yielding sulphur, arsenic, arsenic pentasulphide, arsenite, thio-sulphate, and sulphate when exposed to air; the oxidation proceeds more slowly, the more conc. the soln., and the lower the temp. J. J. Berzelius said that acids, even carbonic acid, decompose the alkali sulpharsenates, forming arsenic pentasulphide and hydrogen sulphide. Copper hydroxide partly decomposes alkali sulpharsenate, forming alkali arsenate and copper sulphide, and some copper sulpharsenate is produced. L. Storch found that some of the heavy metal sulphides—copper, iron, mercury, cadmium, etc., are soluble in a soln. of alkali sulpharsenate.

According to J. J. Berzelius, when a soln. of arsenic pentasulphide is gently treated with an excess of ammonium hydrosulphide, and agitated with hot alcohol, colourless prisms of **ammonium orthosulpharsenate**, $(\text{NH}_4)_3\text{AsS}_4$, are deposited. These are washed with alcohol, and dried by press. between bibulous paper. The salt is fairly stable in air, but acquires a yellow film on the surface. When heated, the crystals melt and then decompose: $2(\text{NH}_4)_3\text{AsS}_4 = 3(\text{NH}_4)_2\text{S} + \text{As}_2\text{S}_3 + 2\text{S}$. The alcoholic soln. remaining after the separation of the ortho-salt was stated to contain **ammonium metasulpharsenate**, NH_4AsS_3 , but the salt was not isolated; and it was also said that if aq. soln. of the ortho-salt be boiled ammonium hydrosulphide is given off, and the hot liquid deposits an acid salt, $(\text{NH}_4)_2\text{As}_2\text{S}_{61}$, but the product was probably a mixture of ammonium sulpharsenate and arsenic sulphides. J. J. Berzelius reported **ammonium pyrosulpharsenate**, $(\text{NH}_4)_4\text{As}_2\text{S}_7$, to be formed by allowing a soln. of arsenic pentasulphide in aq. ammonia to evaporate spontaneously. The reddish-yellow glutinous mass cannot be dried without decomposing; and when heated, it behaves like the ortho-salt. L. F. Nilson allowed a filtered soln. of arsenic pentasulphide in a soln. of ammonium hydrosulphide to evaporate in vacuo over sulphuric acid, and obtained a yellow amorphous mass of **ammonium penterasulphotriarsenate**, $(\text{NH}_4)_5\text{As}_3\text{S}_{10}$.

J. J. Berzelius reported crystals of **sodium orthosulpharsenate**, $\text{Na}_3\text{AsS}_4 \cdot 8\text{H}_2\text{O}$, to be formed by evaporating a sat. soln. of arsenic pentasulphide in an excess of sodium hydrosulphide. L. F. Nilson used a similar mode of preparation. J. J. Berzelius also prepared it by evaporating spontaneously a soln. of pyrosulpharsenate in sodium hydrosulphide; by adding alcohol to an aq. soln. of the pyrosulpharsenate; by digesting an alcoholic soln. of sodium pentasulphide with arsenic trisulphide; and by crystallizing a soln. of arsenic pentasulphide in soda-lye. L. F. Nilson made it by boiling a soln. of arsenic trisulphide and sodium carbonate; J. J. Berzelius, H. Heubach, and C. F. Rammelsberg, by boiling a mixture of sulphur, arsenic trisulphide and a soln. of sodium carbonate; A. Geuther, by heating arsenic disulphide with a soln. of sodium sulphide at 100° : $5\text{As}_2\text{S}_2 + 6\text{Na}_2\text{S} = 6\text{As} + 4\text{Na}_3\text{AsS}_4$; K. B. Edwards, by the action of a polysulphide on arsenic trioxide or trisulphide, or by the action of a monosulphide on arsenic pentasulphide; H. Heubach, by the action of hydrogen sulphide on a soln. of sodium orthoarsenate: $\text{Na}_3\text{AsO}_4 + 4\text{H}_2\text{S} = \text{Na}_3\text{AsS}_4 + 4\text{H}_2\text{O}$; and L. W. McCay, by mixing an alkaline soln. of sodium hydroarsenate with hydrogen sulphide, pouring the clear liquid into absolute alcohol, and washing the crystals with absolute alcohol. The analyses of J. J. Berzelius, L. W. McCay, H. Heubach, L. F. Nilson, A. Geuther,

and C. F. Rammelsberg correspond nearly with the octohydrate—though in the last cases some results corresponded more nearly with $7\cdot5\text{H}_2\text{O}$; and that of H. Heubach with $7\text{H}_2\text{O}$. According to C. F. Rammelsberg, the colourless or pale yellow crystals are monoclinic with the axial ratios $a : b : c = 0\cdot6676 : 1 : 1\cdot0393$, and $\beta = 100^\circ 00'$. J. J. Berzelius found the dry salt to be stable in air, and even over sulphuric acid, in vacuo, the salt does not give up water until gently heated. H. Heubach said that the crystals of sodium orthosulpharsenate soon acquire a yellow film on their surface when they are exposed to air; when heated, the crystals melt in their water of crystallization and are hydrolyzed: $\text{Na}_3\text{AsS}_4 + 4\text{H}_2\text{O} = 4\text{H}_2\text{S} + \text{Na}_3\text{AsO}_4$. If more strongly heated, J. J. Berzelius and H. Heubach found that some hydrogen sulphide is given off and the salt becomes yellow, and at a still higher temp., the salt melts to a dark red liquid, which, on cooling, solidifies to the anhydrous salt. H. Heubach said that the aq. soln. of sodium orthosulpharsenate is decomposed by air with the separation of sulphur; the separation of arsenic sulphide mentioned by J. J. Berzelius was not observed. When the soln. is boiled hydrogen sulphide is given off without forming sulphuric acid. Alcohol added to the conc. aq. soln. of sodium orthosulpharsenate gives a yellow precipitate which J. J. Berzelius considered to be a basic salt. When carbon dioxide is passed through the soln., hydrogen sulphide is given off, and sulphur is simultaneously precipitated, and then arsenic sulphide is deposited. J. J. Berzelius said that the aq. soln. of sodium orthosulpharsenate is decomposed when heated with copper sulphate, and K. Preis added that when heated cupric sulphide is formed, and in the cold copper sulpharsenate is produced—*vide infra*; and with lead acetate, C. F. Rammelsberg said that a mixture of lead sulphide and arsenate is produced. J. J. Berzelius prepared colourless crystals of **lithium orthosulpharsenate**, $\text{Li}_3\text{AsS}_4 \cdot n\text{H}_2\text{O}$, by adding alcohol to an aq. soln. of the pyrosulpharsenate. The salt is soluble in water, and when the hot aq. soln. is rapidly cooled six-sided prisms are formed, and when slowly cooled, four-sided prisms. By adding alcohol to a soln. of potassium pyrosulpharsenate, J. J. Berzelius obtained a liquid which, when evaporated, furnished a crystalline mass of **potassium orthosulpharsenate**, $\text{K}_3\text{AsS}_4 \cdot \text{H}_2\text{O}$. L. F. Nilson also made it by evaporating in vacuo the liquid obtained by adding to a sat. soln. of arsenic trisulphide in potassium hydrosulphide or sulphide as much again alkali hydrosulphide or sulphide. The pale yellow, four-sided, probably rhombic, prisms are hygroscopic.

J. J. Berzelius prepared **sodium pyrosulpharsenate**, $\text{N}_4\text{As}_2\text{S}_7$, by spontaneously evaporating an aq. soln. of sodium hydroarsenate sat. with hydrogen sulphide. The pale lemon-yellow mass readily fuses to a yellow liquid. The corresponding **lithium pyrosulpharsenate**, $\text{Li}_4\text{As}_2\text{S}_7$, is citron-yellow and non-hygroscopic. It is readily soluble in water. Likewise also with **potassium pyrosulpharsenate**, $\text{K}_4\text{As}_2\text{S}_7$, which forms rhombic plates. The soln. is decomposed by carbon dioxide with the precipitation of arsenic pentasulphide. J. J. Berzelius said that **sodium metasulpharsenate**, NaAsS_3 , is precipitated when alcohol is added to a soln. of the ortho-salt; likewise also with **lithium metasulpharsenate**, LiAsS_3 ; and **potassium metasulpharsenate**, KAsS_3 . A soln. of two mols of potassium hydrosulphide dissolves between a half and one mol of arsenic pentasulphide, and when evaporated in air, acquires a film of sulphur, arsenic pentasulphide separates, and a soln. of the pyrosulpharsenate is formed.

J. J. Berzelius evaporated a mixed aq. soln. of sodium and potassium orthosulpharsenates, and obtained pale yellow or colourless, four-sided plates of the double salt **potassium sodium orthosulpharsenate**; but not so with the mixture of sodium and ammonium salts. The double salt, **ammonium sodium orthosulpharsenate**, $\text{Na}_3(\text{NH}_4)_3(\text{AsS}_4)_2$, however, was made by adding alcohol to a mixture of the two salts in the correct proportions, and also by evaporating a mixed soln. of sodium orthosulpharsenate and ammonium chloride. The salt furnishes colourless or pale yellow six-sided prisms.

A. Breithaupt² reported what he regarded *als neues Mineral*, from Morocochoa, in the Cordilleras of Peru. He called it **enargite**—from *ἐναργής*, clearly visible—

in allusion to its perfect cleavage. The analyses corresponded with **cuprous ortho-sulpharsenate**, Cu_3AsS_4 . C. R. Rammelsberg, and C. Guillemain considered it to be more complex—the former gave $4\text{CuS} \cdot \text{Cu}_2\text{S} \cdot \text{As}_2\text{S}_3$, or $5\text{CuS} \cdot \text{Cu}_2\text{S} \cdot \text{As}_2\text{S}_3$. Analyses of enargite have been reported by F. Sandberger, V. R. von Zepharovich, R. de Neufville, I. Domeyko, A. Knop, F. Field, F. von Kobell, A. Raimondi, C. Guillemain, W. J. Taylor, A. Breithaupt, W. F. Hillebrand, B. S. Burton, P. Krusch, V. Zsivny, F. A. Genth, W. Semmons, B. Silliman, E. W. Root, C. F. Rammelsberg, A. d'Achiardi, A. W. Stelzner, etc. Specimens have been reported from many localities, and some varieties have received special names. Enargite may occur massive, and granular and in prismatic crystals coloured greyish-black to iron-black. The rhombic crystals, according to H. Dauber, have the axial ratios $a : b : c = 0.8711 : 1 : 0.8248$; V. Zsivny gave $0.8711 : 1 : 0.8248$; and L. J. Spencer, $0.8694 : 1 : 0.8308$. The prismatic planes may be vertically striped. Twins may occur about the (320)-plane, and there are sometimes star-shaped trillings resembling chrysoberyl. The (110)-cleavage is perfect; the (100)- and (010)-cleavages are distinct; and the (001)-cleavage indistinct. The crystals were also examined by F. Sandberger, V. R. von Zepharovich, L. V. Pirsson, C. F. Rammelsberg, M. Zettler, A. W. Stelzner, and G. vom Rath. P. F. Kerr studied the X-radiogram. The hardness is 3, and the sp. gr. 4.3–4.5. A. W. Stelzner gave 4.35–4.37. A. Sella gave 0.1202 for the sp. ht. J. Joly gave 290° for the temp. at which sublimation occurs. A. de Gramont examined the spark spectrum. T. W. Case said that the mineral is a non-conductor of electricity and light has no measurable effect. E. T. Wherry, and H. S. Roberts and L. H. Adams examined the properties of the crystals as rectifiers of alternating currents, and as radio-detectors. The compound decomposes when heated; it is soluble in aqua regia. H. Saito found that when enargite is heated in air, most of the arsenic is expelled at a comparatively low temp., and the copper sulphide is then oxidized. The oxidation is analogous to that of a mixture of its components, arsenic pentasulphide being oxidized first, and then the cuprous sulphide. Nearly 75 per cent. of the dearsenicating reaction occurs below 350° , and to complete this action, rapid oxidation at 500° – 600° is necessary because at higher temp. the reaction is hindered. The ore fuses at about 400° , and the amount of copper arsenate which is produced varies with the conditions.

F. Field called a sample of enargite from the Cordilleras of Chili, *guayacanite*; W. Semmons, an arsenical copper ore from Montana, *garbyite*. A. Frenzel's *lautite* from Lauta, Saxony, was shown by A. Weisbach to be a mixture of arsenic with a mineral resembling enargite. A. Weisbach's *luzonite*, from the Island of Luzon, Philippines, was found to have a composition approaching enargite, but to be monoclinic instead of rhombic. G. Bodländer obtained a specimen with the same composition from Famatina, Argentine. The *clarite* of F. Sandberger was obtained from the Clara mine, Baden. It too occurs in monoclinic crystals with the composition of enargite. The analyses of some samples of binnite (*q.v.*) approach that of enargite.

K. Preis³ reported **cupric orthosulpharsenate**, $\text{Cu}_3(\text{AsS}_4)_2$, to be formed by mixing soln. of one part of sodium sulpharsenate and three parts of cupric sulphate, and drying the washed precipitate at 100° . A boiling soln. of cupric sulphate furnishes cupric sulphide. The reddish-brown salt when heated loses arsenic trisulphide and sulphur. J. J. Berzelius reported that soln. of sodium sulpharsenate and a cupric salt give a dark brown precipitate of **cupric pyrosulpharsenate**, $\text{Cu}_2\text{As}_2\text{S}_7$; and he said that same substance is precipitated by passing hydrogen sulphide through acidic soln. containing copper and arsenic. If arsenic acid is in excess, the brown sulpharsenate is first precipitated, and then yellow arsenic pentasulphide. When the precipitate is treated with ammonium hydrosulphide, E. F. Anthon said that both arsenic and copper sulphide are dissolved. A. Carnot found that ammonium hydrosulphide gives a precipitate of cupric sulphide when added to a soln. of arsenic acid and a copper salt; and the clear liquid gives an orange-yellow precipitate with hydro-

chloric acid. L. Gmelin observed that dil. aq. ammonia extracts arsenic sulphide while a conc. soln. dissolves both arsenic and copper sulphides. As a matter of fact the reaction between copper sulphate and alkali sulpharsenate is not so simple—*vide supra*. H. Heubach represented the reaction by a set of equations involving: $3\text{CuSO}_4 + 2\text{Na}_3\text{AsS}_4 = \text{Cu}_3(\text{AsS}_4)_2 + 3\text{Na}_2\text{SO}_4$, and $3\text{CuSO}_4 + 2\text{Na}_3\text{AsS}_4 = 3\text{CuS} + \text{As}_2\text{S}_5 + 3\text{Na}_2\text{SO}_4$; the arsenic pentasulphide reacts: $\text{As}_2\text{S}_5 + 5\text{CuSO}_4 + 8\text{H}_2\text{O} = 2\text{H}_3\text{AsO}_4 + 5\text{CuS} + 5\text{H}_2\text{SO}_4$; and the sulphuric acid reacts: $2\text{Na}_3\text{AsS}_4 + 3\text{H}_2\text{SO}_4 = 3\text{Na}_2\text{SO}_4 + \text{As}_2\text{S}_5 + 3\text{H}_2\text{S}$; and the arsenic acid is reduced by the hydrogen sulphide: $\text{H}_3\text{AsO}_4 + \text{H}_2\text{S} = \text{H}_3\text{AsO}_3 + \text{H}_2\text{O} + \text{S}$, etc., as in the case of silver nitrate—*vide infra*.

J. J. Berzelius prepared **silver orthosulpharsenate**, Ag_3AsS_4 , by adding a soln. of sodium sulpharsenate to one of a silver salt. When the dark brown precipitate is heated in air, it forms silver sulphide by the combustion of the arsenic sulphide; and when heated in a closed vessel, it fuses with the evolution of sulphur and arsenic trisulphide. According to L. F. Nilson, and K. Preis, when a soln. of silver nitrate is added to one of sodium orthosulpharsenate, the reaction is different according as the reaction takes place in aq. or acidic soln., or in ammoniacal soln. of the sodium sulphoarsenate, silver sulphide is precipitated, and the soln. contains arsenic acid, sodium nitrate, and nitric acid, the reaction taking place according to the equation: $\text{Na}_3\text{AsS}_4 + 8\text{AgNO}_3 + 4\text{H}_2\text{O} = 4\text{Ag}_2\text{S} + \text{H}_3\text{AsO}_4 + 3\text{NaNO}_3 + 5\text{HNO}_3$. When, however, silver nitrate is added to an aq. soln. of sodium sulphoarsenate or if the soln. contains nitric acid, silver sulphide is precipitated as before, and arsenious but no arsenic acid is found in the soln., nitric acid and sodium nitrate being formed as before. This reaction takes place according to the two following equations: (i) $\text{Na}_3\text{AsS}_4 + 8\text{AgNO}_3 + 4\text{H}_2\text{O} = 4\text{Ag}_2\text{S} + \text{H}_3\text{AsO}_3 + 5\text{HNO}_3 + 3\text{NaNO}_3 + \text{O}$; and (ii) $\text{Na}_3\text{AsS}_4 + 6\text{AgNO}_3 + 3\text{H}_2\text{O} = 3\text{Ag}_2\text{S} + \text{H}_3\text{AsO}_3 + 3\text{HNO}_3 + 3\text{NaNO}_3 + \text{S}$. The larger the amount of free acid present the more nearly does the reaction conform to equation (i), but in aq. soln., which is neutral at the commencement of the reaction, it conforms more closely to the second equation. The oxygen which is formed according to the first equation is not liberated in the free state, but as the two reactions always take place simultaneously it combines with some of the sulphur thrown down according to the second equation, and is found as sulphuric acid. These reactions take place immediately, and are not affected by the length of time allowed for the precipitation. It is suggested that arsenic acid is a strong acid, whose thermal effect is equal to that of the strongest acids, whilst on the contrary arsenic trioxide possesses feeble acidic properties, and even under certain conditions exhibits basic properties. Therefore, if the reaction takes place in the presence of ammonia, arsenic acid is formed, whilst in the presence of free acid the feebly basic arsenic trioxide is formed. This theory corresponds with the decomposition of silver nitrate by arsine; on passing this gas through neutral silver nitrate soln., arsenious acid goes into soln., whilst if the silver soln. is ammoniacal arsenic acid is formed. The reaction was also examined by H. Heubach, who suggested that the first stage of the reaction proceeds: $2\text{Na}_3\text{AsS}_4 + 6\text{AgNO}_3 = 3\text{Ag}_2\text{S} + \text{As}_2\text{S}_5 + 6\text{NaNO}_3$; the pentasulphide then reacts with the silver nitrate: $\text{As}_2\text{S}_5 + 10\text{AgNO}_3 + 8\text{H}_2\text{O} = 5\text{Ag}_2\text{S} + 2\text{H}_3\text{AsO}_4 + 10\text{HNO}_3$; the nitric acid then decomposes sodium sulpharsenate: $6\text{HNO}_3 + 2\text{Na}_3\text{AsS}_4 = 3\text{H}_2\text{S} + \text{As}_2\text{S}_5 + 6\text{NaNO}_3$; the hydrogen sulphide reduces the arsenic acid: $\text{H}_3\text{AsO}_4 + \text{H}_2\text{S} = \text{H}_3\text{AsO}_3 + \text{H}_2\text{O} + \text{S}$; the sulphur reacts partly with the silver nitrate: $2\text{AgNO}_3 + \text{S} + \text{H}_2\text{O} = \text{Ag}_2\text{S} + 2\text{HNO}_3 + \text{O}$; and is partly oxidized to sulphuric acid.

A. Breithaupt⁴ applied the term **xanthoconite**—from *ξανθός*, yellow; *κόνις*, powder—to a yellow pulverulent mineral from the Himmelsfürst mine, Freiberg. Analyses reported by A. Breithaupt, and H. A. Miers agree with the formula Ag_3AsS_4 . F. X. M. Zippe reported crystals of another mineral with a similar composition but containing a little selenium, $\text{Ag}_3\text{As}(\text{Se},\text{S})_4$, and he called it **rittingerite**—after P. Rittinger. The observations of A. Breithaupt, A. L. Parsons, P. Groth, G. A. Kenngott, A. Streng, A. Schrauf, and H. A. Miers have proved that rittingerite

and xanthoconite are the same mineral species. A. Breithaupt regarded xanthoconite as a trigonal mineral with the axial ratio $a:c=1:2.3163$, but H. A. Miers proved that the mineral is monoclinic with the axial ratios $a:b:c=1.9187:1:1.0152$, and $\beta=88^\circ 47'$; and A. Schrauf gave $0.52801:1:0.52934$, and $\beta=89^\circ 26'$. The colour is brown or orange-red, and by transmitted light lemon-yellow, or hyacinth-red. According to H. A. Miers, the crystals are isomorphous with those of pyrostilpnite. Twinning occurs about the (001)-plane; the (001)-cleavage is well-defined; the optic axial angle $2E=125^\circ$ (nearly); and the double refraction is strong. The hardness is between 2 and 3. A. Breithaupt gave 5.158-5.191 for the sp. gr.; H. A. Miers, 5.40-5.68; and A. Schrauf, 5.63. The mineral melts and decomposes when heated, giving a sublimate of arsenic sulphide.

According to J. J. Berzelius,⁵ **gold orthosulpharsenate**, AuAsS_4 , is precipitated when a soln. of a gold salt is treated with sodium orthosulpharsenate. The dark brown precipitate is soluble in water, and the soln. is decolorized by ferrous sulphate and a yellowish-brown precipitate is formed. If sodium pyrosulpharsenate is the precipitant, then **gold pyrosulpharsenate**, $\text{Au}_4(\text{As}_2\text{O}_7)_3$, is obtained as a reddish-brown precipitate, soluble in water.

J. J. Berzelius reported **calcium orthosulpharsenate**, $\text{Ca}_3(\text{AsS}_4)_2 \cdot 20\text{H}_2\text{O}$, to be formed by evaporating the clear liquid obtained by digesting calcium sulphide with a soln. of calcium pyrosulpharsenate, or by precipitation from the same liquid with alcohol. The formula is based on the analysis of L. F. Nilson, who made the salt by crystallization from a soln. of a mol of arsenic trisulphide and 5 mols of arsenic hydrosulphide. The pale-yellow, rhombic crystals are soluble in water, insoluble in alcohol. J. J. Berzelius prepared **strontium orthosulpharsenate**, $\text{Sr}_3(\text{AsS}_4)_2 \cdot n\text{H}_2\text{O}$, by a method similar to that used for the calcium salt; he obtained **barium orthosulpharsenate**, $\text{Ba}_3(\text{AsS}_4)_2 \cdot n\text{H}_2\text{O}$, in a similar way, and also by heating the pyro-salt to redness in a retort when arsenic trisulphide and sulphur sublime. J. J. Berzelius made **calcium pyrosulpharsenate**, $\text{Ca}_2\text{As}_2\text{S}_7 \cdot n\text{H}_2\text{O}$, by adding alkali pyrosulpharsenate to a soln. of a calcium salt. The soln. on evaporation forms a yellow, opaque mass which loses water at 60° , but recovers it again on exposure to air. It is decomposed by heat. The salt is soluble in water and alcohol, and the boiling aq. soln. dissolves very little arsenic pentasulphide. He also made **strontium pyrosulpharsenate**, $\text{Sr}_2\text{As}_2\text{S}_7 \cdot n\text{H}_2\text{O}$, in a similar way; and also lemon-yellow **barium pyrosulpharsenate**, $\text{Ba}_2\text{As}_2\text{S}_7 \cdot n\text{H}_2\text{O}$. He also reported that barium metasulpharsenate, $\text{Ba}(\text{AsS}_3)_2$, remains in soln. when alcohol is added to a soln. of the pyro-salt; but it is decomposed when the soln. is conc. by evaporation. L. F. Nilson evaporated in vacuo a sat. soln. of arsenic pentasulphide in one of calcium hydrosulphide, and obtained a crystalline mass of **calcium penterasulphotetrarsenate**, $\text{Ca}_5\text{As}_4\text{S}_{15} \cdot 12\text{H}_2\text{O}$, which is freely soluble in water, and decomposed by hot hydrochloric acid. L. F. Nilson also reported that he had made a complex salt, **barium orthosulphopyroarsenate**, $\text{Ba}_3(\text{AsS}_4)_2 \cdot \text{Ba}_2\text{As}_7\text{O}_5 \cdot 8\text{H}_2\text{O}$, by crystallization from the mother-liquor used in preparing barium pyrosulpharsenite; **strontium orthosulphopyroarsenite**, $\text{Sr}_3(\text{AsS}_4)_2 \cdot \text{Sr}_2\text{As}_2\text{S}_5 \cdot 8\text{H}_2\text{O}$, was prepared in a similar way. L. F. Nilson at first considered the barium salt to be $5\text{BaS} \cdot 2\text{As}_2\text{S}_3 \cdot 6\text{H}_2\text{O}$. He also obtained it from a conc. soln. of barium hydrosulphide sat. with arsenic pentasulphide. The salt can be recrystallized from hot water. It gives yellow monoclinic prisms isomorphous with barium pyrosulpharsenite, $\text{Ba}_2\text{As}_2\text{S}_5 \cdot 15\text{H}_2\text{O}$. L. F. Nilson represented the constitution of the salt by the formula :

J. J. Berzelius obtained a soln. of **beryllium sulpharsenate** by digesting the hydroxide with arsenic pentasulphide suspended in water. He reported **magnesium**

orthosulpharsenate, $Mg_3(AsS_4) \cdot nH_2O$, to be formed by treating a soln. of the pyro-salt with magnesium hydrosulphide so long as hydrogen sulphide is evolved, and evaporating in vacuo, or cooling the clear liquid. This compound may be formed as a white porous mass by heating the pyro-salt in a retort. The colourless crystals are hygroscopic. Alcohol extracts arsenic sulphide and leaves a sparingly soluble basic salt as a residue. When a soln. of magnesium and ammonium sulpharsenates is treated with alcohol, needle-like crystals of **ammonium magnesium orthosulpharsenate**, $(NH_4)MgAsO_4 \cdot nH_2O$, are deposited. They lose ammonia and hydrogen sulphide on exposure to air. They are freely soluble in water; alcohol precipitates the original salt from the aq. soln. When the aq. soln. is evaporated, it decomposes, giving off hydrogen sulphide. J. J. Berzelius obtained **magnesium pyrosulpharsenate**, $Mg_2As_2S_7 \cdot nH_2O$, as a non-crystallizable lemon-yellow mass by the action of sodium pyrosulpharsenate on a soln. of a magnesium salt. The pyro-salt is freely soluble in water, and it is not precipitated on adding alcohol to the aq. soln. L. F. Nilson prepared **magnesium penterasulphotetrarsenate**, $Mg_5As_4S_{15} \cdot 3H_2O$, by the method employed for the corresponding calcium salt. The crystals are freely soluble in water, and are decomposed by hydrochloric acid.

According to J. J. Berzelius, **zinc orthosulpharsenate**, $Zn_3(AsS_4)_2$, is precipitated, in pale yellow flakes, when a zinc salt is treated with sodium orthosulpharsenate, and, according to K. Preis, it is formed by mixing a cold soln. of three parts of zinc sulphate with two parts of sodium orthosulpharsenate. He also obtained light yellow **cadmium orthosulpharsenate** by treating a cadmium salt with a sat. soln. of arsenic trisulphide in one of ammonium hydrosulphide. H. Heubach represented the reaction: $2Na_3AsS_4 + 3CdSO_4 = Cd_3(AsS_4)_2 + 3Na_2SO_4$. J. J. Berzelius observed that yellow flakes of **zinc pyrosulpharsenate**, $Zn_2As_2S_7$, are precipitated by adding the corresponding sodium salt to a soln. of a zinc salt; similarly also with **cadmium pyrosulpharsenate**. According to F. Wöhler, hydrogen sulphide precipitates the whole of the zinc as **zinc metasulpharsenate**, $Zn(AsS_3)_2$, from a soln. of zinc and an excess of arsenic acid in an excess of hydrochloric or sulphuric acid; but if the arsenic be in the form of arsenic trioxide, arsenic trisulphide is precipitated without the zinc. H. Heubach found that when sodium orthosulpharsenate is added to a soln. of mercurous nitrate, no hydrogen sulphide is evolved and a black precipitate of mercurous sulphide is deposited, he assumed that the **mercurous orthosulpharsenate**, Hg_3AsS_4 , is immediately decomposed by the action of the excess of mercurous nitrate: $5HgNO_3 + Hg_3AsS_4 + 4H_2O = 4Hg_2S + 5HNO_3 + H_3AsO_4$. K. Preis obtained **mercuric orthosulpharsenate**, $Hg_3(AsS_4)_2$, by mixing soln. of equal parts of mercuric chloride and sodium orthosulpharsenate; washing the orange-yellow precipitate with cold water, and drying at 100° . H. Heubach represented the reaction: $3HgCl_2 + 2Na_3AsS_4 = 6NaCl + Hg_3(AsS_4)_2$. The olive-green powder is decomposed by heat. J. J. Berzelius obtained a black precipitate by adding sodium sulpharsenate to a soln. of a mercurous salt; he assumed that **mercurous pyrosulpharsenate**, $Hg_4As_2S_7$, is formed which, when heated, loses mercury and sublimes as **mercuric pyrosulpharsenate**, $Hg_2As_4S_7$. He also obtained this salt, as a dark yellow precipitate, by adding a soln. of sodium meta- or pyro-sulpharsenate to a soln. of a mercuric salt.

According to L. F. Hawley,⁶ when thallos salts and salts of quinquevalent arsenic are precipitated together by alkaline sulphides, the precipitate varies in colour and properties according to the composition, and mixtures varying from yellow arsenic pentasulphide to a crystalline orange phase can be prepared. Only one phase is present when the composition is that of **thallos orthosulpharsenate**, Tl_3AsS_4 , and from that point onwards, the precipitate is mixed with black thallos sulphide. With acidic soln. it is difficult to prevent the reduction of the arsenic salt. Solid soln. of thallos sulphide and arsenic trisulphide can be transformed into thallos orthosulpharsenate by treatment with sodium polysulphide. Thallos orthosulpharsenate is an orange-coloured precipitate insoluble in dil. alkaline sulphides. On boiling with a conc. soln. of sodium sulphide it is partially decomposed, some

arsenic pentasulphide going into soln. and thalious sulphide remaining. Dil. acids decompose it with the evolution of hydrogen sulphide, thallium going into soln. and arsenic pentasulphide remaining. When washed with water and dried it is perfectly stable in the air at ordinary temp., but it melts with slight decomposition at about 250°. This compound may also be used in the gravimetric determination of thallium in a manner similar to the thallium sulphostannate method.

J. J. Berzelius reported **cerous orthosulpharsenate** to be formed by precipitating a cerous salt soln. with alkali orthosulpharsenate; if alkali hydrosulpharsenate be used then **cerous pyrosulpharsenate** is formed. Both salts appear as pale yellow precipitates. If a ceric salt be treated with the alkali sulpharsenate, then ceric sulpharsenate is formed as a yellowish-white precipitate. He also obtained a soln. of **yttrium sulpharsenate** by digesting yttrium hydroxide with water in which arsenic pentasulphide is suspended. Yttrium salts do not give any turbidity with soln. of sodium sulpharsenates. J. J. Berzelius reported **zirconium sulpharsenate** to be formed as a lemon-yellow precipitate when a soln. of a zirconium salt is treated with sodium sulpharsenate. It is not decomposed by acids. He also obtained **stannous sulpharsenate** as a chestnut-brown precipitate by adding a soln. of sodium sulpharsenate to one of stannous chloride; with stannic chloride a pale yellow, slimy precipitate of **stannic sulpharsenate** is formed. Sodium orthosulpharsenate gives a red precipitate of **lead orthosulpharsenate** when added to a soln. of a lead salt; and with sodium pyrosulpharsenate, dark brown **lead pyrosulpharsenate** is formed—*vide supra*, jordanite. H. Heubach represented the former reaction: $2\text{Na}_3\text{AsS}_4 + 3\text{Pb}(\text{NO}_3)_2 = \text{Pb}_3(\text{AsS}_4)_2 + 6\text{NaNO}_3$.

J. J. Berzelius obtained **antimony sulpharsenate** as a brownish-yellow, fusible precipitate by mixing soln. of sodium orthosulpharsenate and an antimonious salt. He also obtained a dark brown precipitate of **bismuth pyrosulpharsenate**, $\text{Bi}_4(\text{As}_2\text{O}_7)_3$, by adding sodium sulpharsenate to a soln. of a bismuth salt. The precipitate is soluble in an excess of the alkali sulpharsenate. No **vanadium sulpharsenate** is precipitated when a soln. of vanadyl sulphate is treated with sodium sulpharsenate, but the blue liquid becomes colourless. J. J. Berzelius said that chromic salt soln. give a dirty yellow precipitate of **chromic sulpharsenate** when treated with a soln. of sodium sulpharsenate; molybdic salt soln. under similar conditions form a yellowish-brown soln. of **molybdic sulpharsenate**, but no precipitate is formed. According to R. F. Weinland and K. Sommer,⁷ a series of **metasulpharsenatosulphomolybdates** with the general formula $\text{R}_2\text{S}.\text{As}_2\text{S}_5.2\text{MoO}_3$, analogous to the corresponding $\text{R}_2\text{O}.\text{As}_2\text{O}_5.2\text{MoO}_3$, is known, and can be represented graphically:

Another series of **pyrosulpharsenatosulphomolybdates**, with the general formula $2\text{R}_2\text{S}.\text{As}_2\text{S}_5.2\text{MoS}_3.n\text{H}_2\text{O}$, is known. They can be regarded as double salts of metasulpharsenates and pyrosulphomolybdates, $2\text{RAsS}_3.\text{R}_2\text{Mo}_2\text{S}_7$, or as complex salts with the graphic formula $(\text{RS})_2\text{AsS}.\text{S}.\text{AsS}(\text{S}.\text{MoS}_3\text{S})_2$. There are two representatives of the first series, **sodium metasulpharsenatosulphomolybdate**, $\text{NaAsS}_3(\text{MoS}_3).6\text{H}_2\text{O}$, formed by triturating a mol of sodium pyrosulphoarsenatosulphomolybdate with 1.5 mols of salicylic acid, and water; warming the mixture at 40°–50°; and treating the clear soln. with alcohol. The brick-red precipitate was washed with dil. alcohol, and finally with as little cold water as possible. The amorphous powder is insoluble in water, and freely soluble in dil. soda-lye, and aq. ammonia. The other member of the series, **potassium metasulpharsenatosulphomolybdate**, $\text{KAsS}_3(\text{MoS}_3).4\text{H}_2\text{O}$, was obtained in a similar manner.

R. F. Weinland and K. Sommer prepared **sodium pyrosulpharsenatosulphomolybdate**, $\text{Na}_4\text{As}_2\text{S}_7(\text{MoS}_3)_2.14\text{H}_2\text{O}$, by adding molybdenum trisulphide (2 mols) to a soln. of sodium sulpharsenate (1 mol) heated on the water-bath; a portion of the

trisulphide remains undissolved, and a brown by-product is also formed. The filtrate, on evaporation, yields the salt mixed with the brown, amorphous by-product, which, although insoluble in water, is easily soluble in a soln. of the salt; the two are most conveniently separated by dissolving the crude salt in a large quantity of ice-cold water, when the brown by-product remains for the most part undissolved. The salt is also formed on boiling a soln. of sodium pyrosulpharsenate with molybdenum trisulphide, but large quantities of by-products are formed at the same time. It can, however, be easily obtained in a pure state by adding salicylic acid (1 mol) to a soln. of molybdenum trisulphide (1 mol) in sodium sulpharsenate (1 mol), and precipitating the clear filtrate with alcohol. It crystallizes in lustrous, dark red, six-sided prisms, gradually decomposes when dry, and is then no longer entirely soluble in water, is not hygroscopic, and loses its water of crystallization at 105° . It is decomposed by dil. mineral acids with evolution of hydrogen sulphide and precipitation of a reddish-brown sulphide, and gives characteristic coloured precipitates with soln. of metallic salts. This salt is also produced by the action of arsenic pentasulphide on sodium sulphomolybdate. The **potassium pyrosulpharsenatosulphomolybdate**, $K_4As_2S_7(MoS_3)_2 \cdot 8H_2O$, which can be prepared in a similar manner to the sodium salt, crystallizes in bright red, slender needles, is easily soluble in water, insoluble in alcohol, and has properties like those of the sodium salt. The **ammonium pyrosulpharsenatosulphomolybdate**, $(NH_4)_4As_2S_7(MoS_3)_2 \cdot 5H_2O$, is best prepared by adding salicylic acid (4 mols) to a conc. soln. of ammonium pyrosulpharsenate and ammonium sulphomolybdate, and then precipitating with alcohol; it crystallizes in slender, scarlet needles, is very unstable, and cannot be obtained pure. The aq. soln. quickly decomposes with evolution of ammonia and hydrogen sulphide. The **barium pyrosulpharsenatosulphomolybdate**, $Ba_2As_2O_7(MoS_3)_2 \cdot 14H_2O$, is obtained by dissolving arsenic pentasulphide in a soln. of barium sulphomolybdate, and cooling the filtrate to -15° . It cannot be obtained by the action of molybdenum trisulphide on barium sulpharsenate, as under these conditions sulphur is precipitated, and a double salt of barium sulpharsenate and barium sulpharsenite is formed. It crystallizes in slender, red needles, and when recrystallized partially decomposes with separation of sulphur. A reddish-brown precipitate of the **copper salt** was obtained by treating a soln. of a copper salt with the potassium salt. It is soluble in aq. ammonia. Similarly a dark red, **silver salt** insoluble in aq. ammonia and ammonium sulphide; the dark brown **mercuric salt**, and the dark red **zinc salt**, soluble in aq. ammonia were also formed; the **cobalt salt** is brown and does not dissolve in an excess of the complex salt, in aq. ammonia, or ammonium sulphide; the **nickel salt** is reddish-brown. At first ferrous salts give no precipitate, but a dark brown **ferrous salt** forms after some time. No **manganese salt** is precipitated.

According to J. J. Berzelius,⁸ a soln. of sodium sulpharsenate gives a dingy yellow precipitate of **uranyl sulpharsenate** when added to a soln. of a uranyl salt; it dissolves in an excess of the sodium sulpharsenate. An aq. soln. of sodium sulpharsenate does not give a precipitate with manganese salts. If freshly precipitated manganese sulphide and arsenic pentasulphide be suspended in water, **manganese pyrosulpharsenate**, $Mn_2As_2S_7$, is formed—part passes into soln., and part is precipitated as a yellow powder which is soluble in a larger proportion of water. The evaporation of the aq. soln. deposits first sulphur and then a lemon-yellow mass which is the partly decomposed pyrosulpharsenate and does not all dissolve in water. Acids precipitate arsenic pentasulphide from the aq. soln., and hydrogen sulphide is evolved. Manganese pyrosulpharsenate is produced when manganese carbonate and arsenic pentasulphide are boiled in water, but some manganese arsenate is formed at the same time. When the pyrosulpharsenate is digested with conc. aq. ammonia, some arsenic pentasulphide is extracted and a brick-red basic salt is formed. J. J. Berzelius made **ferrous sulpharsenate** as a dark brown precipitate by the action of sodium sulpharsenate on a soln. of ferrous sulphate. It forms a dark brown soln. with an excess of the sodium salt; and when

dried in air it forms a mixture of ferric hydroxide and **ferric sulpharsenate**. A soln. of sodium sulpharsenate precipitates greenish-grey ferric sulpharsenate from soln. of ferric salts, and the precipitate forms a dark brown soln. with an excess of the sodium salt. The precipitate does not decompose on drying; it fuses readily; and decomposes at a higher temp. giving off sulphur.

A steel-grey mineral, from the Neuglück mine, Wittchen, was described by F. Sandberger⁹ as an *Arsenwismuthkupfererz*, and was afterwards named **epigenite**—from *ἐπιγενής*, born afterwards—in allusion to its occurring implanted on barite vein-masses. The analysis by T. Petersen corresponds with **cuprous ferrous sulpharsenate**, $3\text{Cu}_2\text{S}_3\text{FeO}\cdot\text{As}_2\text{S}_5$; P. Groth gave $4\text{Cu}_2\text{S}_3\text{FeS}\cdot\text{As}_2\text{S}_5$; and C. F. Rammelsberg, $9\text{CuS}\cdot 3\text{Cu}_2\text{S}_6\text{FeS}\cdot 2\text{As}_2\text{S}_5$. The rhombic prisms resemble those of arsenopyrite. The hardness is 3 to 4; and the sp. gr. 4.45. A. d'Achiardi described a mineral from the Jucud mine, Cajamarca, Peru, which he called *regnolite*—after C. Regnoli. Its analysis corresponds with **cupric zinc ferrous sulpharsenate**, $5\text{CuS}\cdot\text{FeS}\cdot\text{ZnS}\cdot\text{As}_2\text{S}_5$. The tetragonal crystals were considered by L. J. Spencer to be related to those of binnite.

J. J. Berzelius¹⁰ obtained a dark brown precipitate of **cobalt pyrosulpharsenate**, $\text{Co}_2\text{As}_2\text{S}_7$, by adding sodium sulpharsenate to a soln. of a cobalt salt; the precipitate is soluble in excess; with a nickel salt soln., sodium pyrosulpharsenate furnishes **nickel pyrosulpharsenate**, $\text{Ni}_2\text{As}_2\text{S}_7$, and sodium orthosulpharsenate, **nickel orthosulpharsenate**, $\text{Ni}_3(\text{AsS}_4)_2$, as dark brown precipitates. When a soln. of nickel arsenate in hydrochloric acid is treated with ammonium hydrosulphide, the precipitate is a mixture of nickel sulphide and sulpharsenate. The dark yellow precipitate obtained when sodium ortho- or meta-sulpharsenate is added to hydrochloroplatinic acid is **platinic sulpharsenate**.

§ 36. The Oxysulpharsenites and Oxysulpharsenates

The **arsenic oxysulphides** reported by H. V. Regnault¹ to be formed by the action of steam on arsenic trisulphide; and by C. Cross and A. Higgin, by dissolving arsenic trisulphide in a hot aq. soln. of arsenic trioxide and evaporating the filtrate, are not recognized as chemical individuals. J. F. L. Hausmann, and L. F. Nilson were unable to isolate any definite oxysulphide by melting mixtures of arsenic trioxide and trisulphide.

It is possible to imagine that in the sulpharsenic acids, the sulphur atoms can be replaced by oxygen atoms one by one, so as to give a series of, say, **oxysulpharsenious acids**: H_3AsO_3 , $\text{H}_3\text{AsO}_2\text{S}$, $\text{H}_3\text{AsO}_2\text{S}_2$, and H_3AsS_3 . This exhibition has not been taken very far with the sulpharsenious acids, as is represented by the following sodium and barium salts. L. F. Nilson² reported **sodium oxysulpharsenite**, $\text{Na}_8\text{As}_{18}\text{O}_7\text{S}_{24}\cdot 30\text{H}_2\text{O}$, to be formed when arsenic trisulphide is boiled with a soln. of sodium carbonate. K. Preis obtained the same salt by boiling a soln. of a mol of sodium hydrosulphide and arsenic trioxide, and pouring alcohol over the filtered liquid. The alcoholic soln. on evaporation gives crystals of this salt. He also obtained it by boiling a mixture of a 16 per cent. soln. of one part of sodium hydroxide sat. with hydrogen sulphide, 4 parts of arsenic trioxide, and one part of sulphur. The hot filtrate was cooled; warmed with sodium hydroxide until all was dissolved; and allowed to crystallize. R. F. Weinland and A. Gutmann mixed conc. soln. of equimolar parts of sodium dihydroarsenite and sodium thiosulphate, and allowed the filtrate to concentrate on a water-bath. The liquid furnished garnet-red or purple-red hexagonal plates. The salt is decomposed by water, by hydrochloric acid, boiling soda-lye, and by heating with sodium carbonate. L. F. Nilson's analysis agrees with the above formula, but he gave $\text{Na}_2\text{O}\cdot 2\text{As}_2\text{S}_3\text{O}_2\cdot 7\text{H}_2\text{O}$.

R. F. Weinland and A. Gutmann say that the salt is derived from the ortho-acid, $\text{H}_3\text{As}(\text{S},\text{O})_3]_{18}$, by the abstraction of $23(\text{H}_2\text{S},\text{H}_2\text{O})$. L. F. Nilson also reported **barium oxysulpharsenite**, $\text{Ba}_5\text{As}_4\text{O}_2\text{S}_9 \cdot 6\text{H}_2\text{O}$, to be formed from the mother-liquid remaining after the preparation of barium pyrosulpharsenite. It appears in red needle-like crystals, stable in air, and sparingly soluble in water.

More work has been done on the **oxysulpharsenic acids**, or rather on their salts. None of the acids has been isolated in the solid state, but $\text{H}_3\text{AsO}_3\text{S}$, and $\text{H}_3\text{AsO}_2\text{S}_2$ are known in soln., while H_3AsOS_3 seems to decompose immediately it is formed. Salts of these and of more complex acids are known. L. W. McCay³ prepared a soln. of **trioxysulpharsenic acid**, $\text{H}_3\text{AsO}_3\text{S}$, by the action of hydrogen sulphide on an excess of a cold, dil., acidified soln. of arsenic acid. The finely-divided sulphur formed at the same time was removed by shaking the liquid with finely-divided asbestos and filtration; and some free hydrogen sulphide was removed by a current of air or by adding copper sulphate which does not attack the trioxysulpharsenic acid. He also obtained the acid by decomposing a cold soln. of the salt with an acid. The aq. soln. of the acid remains clear for a long time after addition of sulphuric or hydrochloric acid; it gives no immediate precipitate with hydrogen sulphide, but ultimately yields one. When boiled, it gives a precipitate of pure sulphur, without evolution of hydrogen sulphide or sulphurous anhydride. With hydrogen sulphide, the boiled and cooled liquid gives an immediate precipitate of arsenic trisulphide; it gives no precipitate with copper sulphate; with mercuric chloride it gives immediately a heavy yellowish-white precipitate; with silver sulphate it gives a heavy black precipitate, the filtrate from which contains no arsenious acid. The properties of the soln. of J. Bouquet and S. Cloez's potassium oxysulpharsenate agree with those of trioxysulpharsenic acid.

L. W. McCay prepared **dioxydisulpharsenic acid**, $\text{H}_3\text{AsO}_2\text{S}_2$, by the action of hydrogen sulphide on a soln. of sodium arsenate acidified with mineral acids; by the action of an excess of hydrogen sulphide on a soln. of arsenic acid. A soln. of **oxytrisulpharsenic acid**, H_3AsOS_3 , has not been prepared.

Trioxysulpharsenic acid forms primary, secondary, and tertiary salts, while the other acids have hitherto furnished only the tertiary salts. Salts of ammonium, the alkali and alkaline earth metals are known, but not so with the salts of the heavy metals. The salts of the heavy metals decompose at once into the metal sulphide. The sodium salts are easiest to isolate; the potassium and ammonium salts are very soluble. Salts of a few condensed acids are known. The primary trioxysulpharsenates were prepared by J. Bouquet and S. Cloez by the action of hydrogen sulphide on a cold aq. soln. of the primary arsenate; by L. F. Nilson, by the action of a boiling soln. of arsenic trisulphide and potassium carbonate; by L. W. McCay, by dissolving arsenic pentasulphide in aq. ammonia; by R. F. Weinland and O. Rumpf, by boiling a soln. of a tertiary arsenate with the stoichiometrical proportion of sulphur, by treating the tertiary or secondary salt with thiosulphates, by the action of arsenic pentasulphide or a mixture of arsenic trisulphide and sulphur on the hydroxides of the alkalies or alkaline earths, and by triturating a mixture of the tertiary salt with salicylic acid. K. Preis showed that the secondary and tertiary salts are formed together when arsenic trioxide is boiled with a soln. of sodium monosulphide.

The alkali and alkaline earth salts furnish colourless crystals which are soluble in water; acids liberate the oxysulpharsenic acid as just indicated. An excess of silver nitrate was found by K. Preis to furnish a precipitate containing brown arsenic; and J. Bouquet and S. Cloez said that lead salts give a white precipitate which soon becomes black. Other reactions are indicated in Table X copied from L. W. McCay and W. Foster's memoir. The reagent indicated in the last column of the table is that recommended by R. L. Weinland and P. Lehmann, namely, a soln. of 0.03 grm. of the sodium salt in 10 c.c. of water treated with 2 c.c. of a soln. of 10 grms. of potassium antimonyl tartrate, 20 grms. of potassium sodium hydrotartrate, and 170 grms. of water.

TABLE X.—REACTIONS OF THE TERTIARY SODIUM OXYSULPHARSENATES.

Acid.	A solution of the tertiary sodium salt.					
	HCl	BaCl ₂	SrCl ₂	Magnesia mixture.	AgNO ₃	Weinland's reagent.
H ₃ AsO ₄ , white crystals	—	white pp. in dil. soln.	white pp.	white pp.	brown-red pp.	—
H ₃ AsO ₃ S, known in dil. soln.	turbidity	white pp. in dil. soln.	white pp.	no pp.	black pp.	turbidity with 3 min. boiling
H ₃ AsO ₂ S ₂ , known in every dil soln.	H ₂ S, yellow pp.	0·3 per cent. soln. white pp.	no pp.	no pp.	black pp.	turbidity with 1 min. boiling
H ₂ AsOS ₃ , not known in soln.	H ₂ S + As ₂ S ₅ in cold	0·3 per cent. soln. turbidity 0·5 per cent. soln.	no pp.	no. pp.	black pp.	At 75° orange-red pp.
H ₃ AsS ₄ , not known in soln.	H ₂ S + As ₂ S ₅ in cold	no pp.	no pp.	no pp.	black pp.	in dil. soln. orange-red pp.

L. W. McCay obtained a soln. of **ammonium trioxysulpharsenate**, (NH₄)₃AsO₃S, mixed with ammonium sulpharsenate, by dissolving arsenic pentasulphide in aq. ammonia; and R. F. Weinland and O. Rumpf obtained crystals of the *trihydrate*, (NH₄)₃AsO₃S·3H₂O, by heating under press. on a water-bath a mixture of a soln. of ammonium arsenite and the calculated quantity of finely-divided sulphur. The liquid also contains sulpharsenate and arsenate. The salt can be purified by fractional crystallization from dil. alcohol. The small, colourless plates readily lose ammonia when exposed to air, probably forming **ammonium dihydrotrioxysulpharsenate**, (NH₄)₂H₂AsO₃S. The salt is readily soluble in water, and the soln. decomposes when boiled, forming arsenic trioxide and sulphur with the escape of ammonia. W. H. McLaughlan fused a mixture of equal parts of sulphur and arsenic trioxide, digested the mass in aq. ammonia, and fractionally precipitated the soln. with alcohol. He represented the salt as a *tetrahydrate*, (NH₄)₃AsSO₃·4H₂O; and on adding more alcohol to the mother-liquor, obtained crystals of **ammonium hydrotrioxysulpharsenate**, (NH₄)₂HAsO₃S, which lose ammonia and become yellow when exposed to air. The white colour is restored in an atm. of ammonia.

K. Preis boiled arsenic trioxide with a soln. of sodium sulphide, and, on fractionally crystallizing the resulting liquid, obtained **sodium trioxysulpharsenate**, Na₃AsO₃S·12H₂O, as well as the hydrotrioxysulpharsenate, dioxysulpharsenate, orthoarsenate, and a condensed salt—*vide infra*. R. F. Weinland and O. Rumpf prepared the trioxysulpharsenate by crystallization from the filtered liquid obtained by boiling a conc. soln. of sodium orthoarsenate with the calculated amount of precipitated sulphur; also, by treating sodium arsenite with sodium polysulphide: Na₂S₄ + 3Na₃AsO₃ = Na₂S + 3Na₃AsO₃S, and allowing the warm alcoholic soln. to crystallize—K. B. Edwards used an analogous process; R. F. Weinland and A. Gutmann, by mixing a conc. soln. of sodium orthoarsenite with an equimolar proportion of sodium thiosulphate: Na₃AsO₃ + Na₂S₂O₃ = Na₂SO₃ + Na₃AsO₃S, and crystallizing the aq. soln. of the resulting product—they also used calcium thiosulphate in place of the sodium salt, and sodium hydroarsenite in place of the normal salt: Na₂HAsO₃ + Na₂S₂O₃ = NaHSO₃ + Na₃AsO₃S; and L. W. McCay, by passing a rapid current of hydrogen sulphide through a soln. of 10 grms. of hemihydrated arsenic acid in a litre of water, allowing the mixture to stand 20 mins., filtering the turbid liquid through asbestos, shaking the liquid with

magnesia, precipitating the magnesia from the filtered liquid by potash-lye, adding a barium salt, and converting the soln. of barium trioxysulpharsenate into the sodium salt by means of sodium carbonate; he also prepared sodium trioxysulpharsenate by dissolving 7 grms. of arsenic pentasulphide in 100 c.c. of a 10 per cent. soln. of sodium hydroxide, shaking the product with strontium chloride, and, after standing 24 hrs., boiling with a soln. of sodium carbonate. The required salt was precipitated from the soln. by alcohol. The colourless, four-sided prisms belong to the rhombic system, and, according to R. F. Weinland and O. Rumpf, have the axial ratios $a : b : c = 0.9199 : 1 : 0.6602$. The salt is freely soluble in water, and the aq. soln. reacts as indicated in Table X. R. F. Weinland and co-workers obtained colourless, six-sided, prismatic crystals of **potassium trioxysulpharsenate**, $K_3AsO_3S \cdot 2H_2O$, in an analogous manner to the method used for the sodium salt.

K. Preis obtained **sodium hydrotrioxysulpharsenate**, $Na_2HAsO_3S \cdot 8H_2O$, as indicated above. The clear, colourless, tabular, triclinic crystals had the axial ratios $a : b : c = 1.0334 : 1 : 1.07065$, and $\alpha = 94^\circ 25'$, $\beta = 114^\circ 7'$, and $\gamma = 87^\circ 28'$. The salt loses three-fourths of its water of crystallization when confined over sulphuric acid, and if the product is heated to 100° , it melts, and, when cold, forms an orange-red mass. It is easily soluble in water. R. F. Weinland and O. Rumpf obtained **potassium hydrotrioxysulpharsenate**, $K_2HAsO_3S \cdot 2\frac{1}{2}H_2O$, in colourless, hygroscopic, prismatic crystals, by evaporating over sulphuric acid and potassium hydroxide, a soln. of the dihydrotrioxysulpharsenate with one-seventh more than the stoichiometrical quantity of potassium hydroxide.

R. F. Weinland and O. Rumpf prepared **sodium dihydrotrioxysulpharsenate**, NaH_2AsO_3S , by triturating the normal salt with two molar proportions of salicylic acid, treating the product with 96 per cent. alcohol, in a closed flask so long as the alcohol shows the presence of salicylic acid. The primary salt was separated from the undecomposed tertiary salt by levigation, and dried on a porous tile. The crystalline powder is composed of colourless prisms, and reddens moist litmus-paper. It contains no water of crystallization. The salt is decomposed by water with the separation of sulphur; and it decomposes in the dry state in a few hours: $NaH_2AsO_3S = NaAsO_2 + S + H_2O$ —this reaction is hastened by raising the temp. J. Bouquet and S. Cloez reported **potassium dihydrotrioxysulpharsenate**, $KH_2AsO_3S \cdot H_2O$, to be formed by passing a brisk current of hydrogen sulphide through a cold sat. soln. of potassium hydroarsenate; L. W. McCay used potassium dihydroarsenate, and he also passed hydrogen sulphide through the boiling soln., and continued the passage of the gas until the soln. was cold. The product was washed with alcohol, and then with ether. L. F. Nilson found that the pale yellow mass obtained by boiling arsenic trisulphide in a conc. soln. of potassium carbonate, when washed with alcohol and allowed to stand in a closed vessel, gradually forms crystals of the dihydrotrioxysulpharsenate; he also made the same salt by crystallization from a filtered soln. of arsenic pentasulphide in a sat. soln. of arsenic acid in one of potassium carbonate. R. F. Weinland and O. Rumpf made it by the action of the calculated quantity of salicylic acid on a conc. soln. of the normal salt, and precipitating the salt with alcohol. The colourless, four-sided crystals are stable in air; they lose water at 170° without melting, but they melt at a higher temp., and decompose into arsenic trisulphide, arsenic, etc. The salt is sparingly soluble in cold water, freely soluble in hot water, but not without decomposition. L. W. McCay found that the free acid is obtained by the action of acids on a cold, dil. soln. of the salt, and no hydrogen sulphide is evolved. L. F. Nilson found that the salt is decomposed by acids with the separation of, presumably, sulphur. The salt is soluble in alkali-lye, and decomposed by silver nitrate, forming a soln. of arsenic acid.

According to A. Gutmann, when ammonia is added to a mixed soln. of 3 mols of lithium chloride and one mol of sodium trioxysulpharsenate, prismatic or

acicular crystals of **sodium lithium trioxysulpharsenate**, $\text{Na}_2\text{LiAsO}_3\text{S}\cdot 5\text{H}_2\text{O}$, are formed.

L. W. McCay prepared a colourless, crystalline powder of **barium trioxysulpharsenate**, $\text{Ba}_3(\text{AsO}_3\text{S})_2\cdot 6\text{H}_2\text{O}$, from a soln. of potassium dihydrotrioxysulpharsenate in baryta-water; and K. Preis, and R. F. Weinland and O. Rumpf, by mixing a warm soln. of sodium trioxysulpharsenate with an excess of a soln. of barium chloride, and allowing the mixture to stand for 24 hrs. K. Preis obtained **barium hydrotrioxysulpharsenate**, $\text{BaHAsO}_3\text{S}\cdot 10\text{H}_2\text{O}$, in colourless crystals, from a conc. soln. of barium chloride and sodiura hydrotrioxysulpharsenate. L. W. McCay reported **ammonium strontium trioxysulpharsenate**, $(\text{NH}_4)\text{SrAsO}_3\text{S}\cdot n\text{H}_2\text{O}$, to be formed by adding strontium chloride to a filtered soln. of 5 grms. of arsenic pentasulphide in 20 c.c. of conc. aq. ammonia, after standing 12 hrs., the crystalline precipitate was washed with dil. aq. ammonia, and dried rapidly between bibulous paper because the salt rapidly loses ammonia when exposed to air and becomes yellow; the white colour is restored in an atm. of ammonia. F. R. Weinland and O. Rumpf obtained **sodium barium trioxysulpharsenate**, $\text{NaBaAsO}_3\text{S}\cdot 9\text{H}_2\text{O}$, by mixing a hot, very dil., aq. soln. of sodium trioxysulpharsenate, free from carbon dioxide, with a dil. soln. of barium chloride so long as the precipitate first formed disappears. In the course of cooling for 24 hrs., colourless crystals of the complex salt appear.

A. Gutmann observed that when sodium trioxysulpharsenate is treated with copper sulphate a black precipitate is formed; zinc sulphate gives a white precipitate—presumably **zinc trioxysulpharsenate**, $\text{Zn}_3(\text{AsO}_3\text{A})_2\cdot n\text{H}_2\text{O}$ —soluble in excess, and the soln. decomposes when concentrated on a water-bath, forming zinc sulphide, and arsenite, and sodium sulphate. Cadmium sulphate likewise gives a white precipitate—presumably **cadmium trioxysulpharsenate**, $\text{Cd}_3(\text{AsO}_3\text{S})_2\cdot n\text{H}_2\text{O}$ —which decomposes in a few hours; mercurous nitrate gives a black precipitate; and mercuric chloride a yellow precipitate—presumably **mercuric trioxysulpharsenate**, $\text{Hg}_3(\text{AsO}_3\text{S})_2\cdot n\text{H}_2\text{O}$ —which quickly turns brown, and black. A dil. soln. of the sodium salt forms a white precipitate of **manganese trioxysulpharsenate**, $\text{Mn}_3(\text{AsO}_3\text{S})_2\cdot n\text{H}_2\text{O}$, when treated with manganese sulphate; with ferrous sulphate a dirty green precipitate, presumably of **ferrous trioxysulpharsenate**, $\text{Fe}_3(\text{AsO}_3\text{S})_2\cdot n\text{H}_2\text{O}$, is formed, and it rapidly darkens in colour; cobalt nitrate gives a violet precipitate of **cobalt trioxysulpharsenate**, $\text{Co}_3(\text{AsO}_3\text{S})_2\cdot n\text{H}_2\text{O}$; and a nickel salt a greenish-white precipitate of **nickel trioxysulpharsenate**, $\text{Ni}_3(\text{AsO}_3\text{S})_2\cdot n\text{H}_2\text{O}$.

As indicated above, K. Preis prepared **sodium dioxydisulpharsenate**, $\text{Na}_3\text{AsO}_2\text{S}_2\cdot 10\text{H}_2\text{O}$, by the action of a soln. of sodium sulphide on arsenic trioxide; he also made it by the action of soda-lye on a hot soln. of sodium sulpharsenate: $\text{Na}_3\text{AsS}_4 + 4\text{NaOH} = \text{Na}_3\text{AsO}_2\text{S}_2 + 2\text{Na}_2\text{S} + 2\text{H}_2\text{O}$; R. F. Weinland and O. Rumpf, by the action of equimolar proportions of sodium metarsenite or trioxysulpharsenate and disulphide: $\text{NaAsO}_2 + \text{Na}_2\text{S}_2 = \text{Na}_3\text{AsO}_2\text{S}_2$; and L. W. McCay, by treating the filtrate from the strontium trioxysulpharsenate, obtained in the preparation of sodium trioxysulpharsenate, with barium chloride, and treating the precipitated barium dioxydisulpharsenate with sodium carbonate so as to convert it into the sodium salt. This was precipitated by alcohol from its aq. soln. L. W. McCay also prepared the salt by pouring a soln. of 5 grms. of arsenic acid into a litre of water sat. with hydrogen sulphide; allowing the mixture to stand for 2 hrs.; removing the hydrogen sulphide by a current of air; treating the filtrate with solid strontium hydroxide; allowing the mixture to stand for 12 hrs.; treating the filtrate with barium hydroxide; and treating the resulting barium salt with sodium carbonate. According to K. Preis, the tabular or prismatic crystals belong to the rhombic system and have the axial ratios $a : b : c = 0.769 : 1 : 0.555$. A soln. of barium chloride precipitates the barium salt. The action of acids, etc., has been indicated in Table VIII. R. F. Weinland and O. Rumpf prepared **potassium dioxydisulpharsenate**, $\text{K}_3\text{AsO}_2\text{S}_2\cdot n\text{H}_2\text{O}$, by passing hydrogen sulphide into a soln. of potassium ortharsenate; treating the product with an excess of potash-lye; and evaporating

to soln. so as to obtain yellow, hygroscopic crystals of the impure salt. When the attempt is made to recrystallize the salt from water, it decomposes into arsenate and sulpharsenate. They also prepared **barium dioxydisulpharsenate**, $\text{Ba}(\text{AsO}_2\text{S}_2)_2 \cdot 4$ or $6\text{H}_2\text{O}$, as a white precipitate, by the action of a soln. of the alkali salt on barium chloride; and by boiling a soln. of sodium sulpharsenate with baryta-water.

L. W. McCay and W. Foster prepared **sodium oxytrisulpharsenate**, $\text{Na}_3\text{AsOS}_3 \cdot 11\text{H}_2\text{O}$, by mixing 45 grms. of magnesia, and 26 grms. of freshly precipitated arsenic pentasulphide with water so as to form a thick slurry, and then with 800 c.c. of water; allowing the mixture to stand at 18° for about 6 hrs. until the pentasulphide has disappeared; precipitating the magnesia by an excess of soda-lye; adding alcohol to the filtered soln. until a faint turbidity appears; and cooling the soln. in an ice-chamber. The crystals contain a little trioxysulpharsenate but no dioxydisulpharsenate. To purify the crystals, they are washed in 50 per cent. alcohol; dissolved in 375 c.c. of water; and mixed with strontium chloride. After standing 12 hrs., the filtrate was mixed with barium chloride, treated with the theoretical quantity of sodium sulphate and heated for 15 mins. on a water-bath; allowed to stand 20 hrs.; filtered; and treated with alcohol, etc., as before. He also made this salt by shaking for 20 mins. a mixture of 8 grms. of arsenic pentasulphide, 1.5 grms. of sodium hydroxide in 145 grms. of water, or an eq. amount of aq. ammonia, and treating the strongly alkaline filtrate with alcohol, etc., as before. L. W. McCay and W. Foster also obtained this salt from the products of the action of magnesia on a mixture of arsenic trisulphide and sulphur. The white, feathery crystals rapidly effloresce in a dry, warm atm. When the salt is kept in a closed vessel for some days, it becomes yellow, and then contains sodium sulpharsenate, but it can be kept for a week without change out of contact with air in an ice-chamber. For the general reactions, *vide* Table VIII. Yellow crystals of **potassium oxytrisulpharsenate**, $\text{K}_3\text{AsOS}_3 \cdot 7\text{H}_2\text{O}$, were obtained in an analogous manner. L. W. McCay and W. Foster also prepared **sodium strontium oxysulpharsenate**, $\text{NaSrAsOS}_3 \cdot 10\text{H}_2\text{O}$, by the action of magnesia on arsenic pentasulphide as in preparing sodium oxytrisulpharsenate; treating the product with soda-lye, and then with strontium chloride; adding more strontium chloride to the filtrate; mixing the soln. with alcohol; and cooling. The white crystals are washed first with water, then with alcohol, and dried at 18° . The salt becomes straw-yellow in air in 20 mins., but it can be preserved many days in a closed vessel cooled by ice. A soln. of 3 grms. of the potassium salt in 40 c.c. of recently-boiled water when mixed with a 10 per cent. soln. of barium chloride, and cooled in an ice-chamber, furnishes yellow crystals of **potassium barium oxytrisulpharsenate**, $\text{KBaAsOS}_3 \cdot 7\text{H}_2\text{O}$.

Some oxysulpharsenates of what appear to be condensed acids have been reported. Thus, K. Preis obtained what he represented as a **sodium oxysulphotetrarsenate**, $\text{Na}_{12}\text{As}_4\text{O}_{11}\text{S}_6 \cdot 48\text{H}_2\text{O}$, by the action of a soln. of sodium sulphide on arsenic trioxide; and fractional crystallization. This salt was the least soluble of the products of the reaction—*vide supra*, sodium trioxysulpharsenate. A. Gœuther represented the composition $2(\text{Na}_3\text{AsO}_3 \cdot \text{S} \cdot 12\text{H}_2\text{O})\text{Na}_6\text{As}_2\text{O}_5\text{S}_3 \cdot 24\text{H}_2\text{O}$. He also obtained **sodium pentoxytrisulphodiarsenate**, $\text{Na}_6\text{As}_2\text{O}_5\text{S}_3 \cdot 24\text{H}_2\text{O}$, or $\text{Na}_3\text{AsO}_4 \cdot \text{Na}_3\text{AsOS}_3 \cdot 24\text{H}_2\text{O}$, or

by heating a mixture of arsenic disulphide and soda-lye in a sealed tube at 100° . By rapidly recrystallizing the product from water, and finally precipitating the conc. aq. soln. with alcohol, he obtained the salt in long, colourless needles. L. W. McCay and W. Foster obtained white crystals of **sodium barium oxysulphopentarsenate**, $\text{Na}_2\text{Ba}_7\text{As}_5\text{O}_7\text{S}_{14} \cdot 12\text{H}_2\text{O}$, by mixing a soln. of sodium or sodium strontium oxytrisulpharsenate with barium chloride, washing the product with water and alcohol, and drying at room-temp. The reactions of the salt are like those of the oxytrisulpharsenates.

R. F. Weinland and K. Sommer prepared **sodium pyrosulpharsenatoxymolybdate**, $\text{Na}_4\text{As}_2\text{Mo}_2\text{O}_3\text{S}_{10}\cdot 15\text{H}_2\text{O}$, or

A mol of arsenic pentasulphide was boiled with a soln. containing two mols of ammonium sulphomolybdate and four mols of sodium hydroxide to eliminate ammonium sulphide. The filtrate was evaporated when a crop of the meta-salt, $\text{NaAsS}_3\cdot\text{MoO}_2\text{S}\cdot 5\text{H}_2\text{O}$, was first deposited, and afterwards, on slowly evaporating the mother-liquid, a crop of yellow needles of the required pyro-salt appeared. The product was recrystallized until the salt furnished a clear soln. when dissolved in water. The properties of the sodium salt closely resemble those of the potassium salt. R. F. Weinland and K. Sommer prepared what they called **potassium pyrosulpharsenatoxymolybdate**, $\text{K}_4\text{As}_2\text{Mo}_2\text{O}_3\text{S}_{10}$, or $\text{K}_4\text{As}_2\text{S}_7\cdot\text{Mo}_2\text{S}_3\text{O}_3$, as follows: A mol of arsenic pentasulphide was boiled with a soln. containing two mols of molybdenum trisulphide and four mols of potassium hydroxide, and the liquid filtered from the remaining sulphur. The conc. soln. furnishes red, acicular crystals of potassium pyrosulpharsenatoxymolybdate, and the mother-liquor yields a crop of yellow, six-sided, needle-like crystals of the hexahydrate. They also obtained it by warming a mol of arsenic pentasulphide with a soln. of two mols of molybdenum trioxide and four mols of potassium hydrosulphide—the first crop of crystals consists of the meta-salt, $\text{KAsS}_3\cdot\text{MoO}_2\text{S}\cdot 2\frac{1}{2}\text{H}_2\text{O}$, and the next crop is the required pyro-salt. The product is purified by recrystallization. When a soln. of two mols of potassium sulphomolybdate, prepared by warming ammonium sulphomolybdate with potassium sulphide, is boiled for a long time with potassium hydroarsenate, a dark red fluid and a brown amorphous precipitate are produced. The filtrate yields a crop of crystals of potassium molybdate, $\text{KM}_2\text{O}_3\text{O}_{10}$, and the yellow needles of the *decahydrate*, $\text{K}_4\text{As}_2\text{Mo}_2\text{O}_3\text{S}_{10}\cdot 10\text{H}_2\text{O}$. The hexahydrate is not hygroscopic, it is freely soluble in water, forming a yellow soln. Hydrochloric acid gives a yellowish-brown flocculent precipitate; and acetic acid gives no precipitate, but colours the liquid dark red. A reddish-brown precipitate is obtained with a soln. of a *copper* salt and a dark brown, with a *silver* salt—both precipitates are insoluble in ammonia. Soln. of the *alkaline earths* give no precipitation; and a small proportion of *zinc* sulphate gives no precipitation, but an excess yields a dirty reddish-brown precipitate, soluble in aq. ammonia, and in potash-lye. *Manganese, ferrous, cobalt*, and *nickel* salts slowly form dark brown flocculent precipitates. R. F. Weinland and K. Sommer prepared **magnesium pyrosulpharsenatoxymolybdate**, $\text{Mg}_2\text{As}_2\text{Mo}_2\text{O}_3\text{S}_{10}\cdot 16\text{H}_2\text{O}$, by a process analogous to that used for the sodium salt. The yellow, acicular crystals have properties similar to those of the alkali salts.

R. F. Weinland and K. Sommer prepared **sodium metasulpharsenatoxymolybdate**, $\text{NaAsS}_3\cdot\text{MoO}_2\text{S}\cdot 5\text{H}_2\text{O}$, or

as indicated above as a by-product in the preparation of potassium pyro-salt. The lemon-yellow product is purified by recrystallization a number of times when it appears reddish-yellow. It consists of microscopic cubes somewhat soluble in cold water, freely soluble in hot water. They obtained a fine, orange-red powder, consisting of microscopic crystals of **potassium metasulpharsenatoxymolybdate**, $\text{KAsS}_3\cdot\text{MoO}_2\text{S}\cdot 2\frac{1}{2}\text{H}_2\text{O}$, by the method employed for the sodium salt. It is rather

less soluble in cold water than the sodium salt, but is freely soluble in hot water. The hot conc. soln. deposits the salt as a crystalline powder, the dil. soln. forms a gelatinous mass. Hydrochloric acid deposits a reddish-yellow flocculent precipitate, and the filtrate is free from molybdenum and arsenic; acetic acid gives neither a precipitate nor a colour change. The salt is slowly decomposed at 100° giving off sulphur dioxide. *Ammonium* salts, and salts of the *alkaline earths*, give an amorphous, yellow precipitate insoluble in cold water, but sparingly soluble in hot water, and which is again precipitated as the hot soln. cools; *magnesium*, *zinc*, and *manganese* salts give no precipitate; *ferrous*, *cobalt*, and *nickel* salts in excess give a dirty yellow precipitate; *copper* and *silver* salts give a dirty or brownish-yellow precipitate, and, in excess, a dark brown precipitate.

§ 37. Arsenic Sulphates

Arsenic trioxide behaves like a base towards the stronger acids; but the earlier chemists did not succeed in making an arsenic sulphate. According to A. Vogel,¹ when sulphuric acid is heated with arsenic, sulphur dioxide is given off, and a residue containing arsenic trioxide, but no pentoxide, is formed; arsenic trioxide crystallizes from a soln. of that oxide in sulphuric acid; and the distillation of sulphuric acid containing some arsenic trioxide in soln. gives a distillate free from arsenic, and a residue of arsenic trioxide but no arsenic pentoxide—C. F. Bucholz said that a little arsenic pentoxide is formed, and H. W. F. Wackenroder, that a little arsenic is carried into the distillate. According to R. H. Adie, there is an upper and an under limit to the number of SO₃-groups that can combine with arsenic trioxide, for when this oxide is dissolved in excess of hot, liquid sulphur trioxide, under increased press., the compound obtained on cooling is probably As₂O₃.8SO₃; when acid of the conc. approximately represented by the formula H₂SO₄.H₂O is used, the compound obtaining on cooling is As₂O₃.SO₃; if the acid is more dil. than this, no compound of the two oxides is formed. When a considerable excess of arsenic trioxide is dissolved in hot conc. sulphuric acid, the excess of the trioxide separates, on cooling, in combination with sulphur dioxide, the quantity of which varies in accordance with the relative masses of the oxide and acid used; on agitating the mother-liquor, deposition of a definite compound occurs. On recrystallization of the definite compounds from the same acids, the same phenomena are repeated. 100 grms. of H₂SO₄ can hold in soln. and combination 1 grm. of As₂O₃; if there be

more As_2O_3 than this, the excess separates on cooling. As regards the action of heat, the most stable compound of the series examined is $\text{As}_2\text{O}_3 \cdot \text{SO}_3$; this compound is probably partially volatile without decomposition. The compounds of arsenic trioxide and sulphur dioxide do not belong to the category of salts, understanding by this term the metallic derivatives of acids; the method of their production, and their instability towards sulphuric acid, water, and heat, points to a constitution analogous to that of the double salts.

F. Reich, B. Kosmann, F. Ulrich, and C. E. Schafhäütl mentioned the existence of a compound of sulphuric acid and arsenic trioxide occurring in the flues leading from the pyrites burners to the lead-chamber of a sulphuric acid factory. The composition approximated to that of **arsenic sulphatotrioxide**, $\text{As}_2\text{O}_3 \cdot \text{SO}_3$, or

A. Stavenhagen obtained a product with the same composition by dissolving arsenic trioxide in warm, conc. sulphuric acid; evaporating the soln.; and heating the product so long as sulphur trioxide vap. is given off. R. H. Adie said that the same compound is obtained by crystallization from sulphuric acid between $9\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, and $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$. According to F. Reich, the tabular crystals become moist in air and form sulphuric acid which runs away leaving arsenic trioxide behind; and, according to R. H. Adie, the compound, at 225° , gradually loses sulphur trioxide. A. Laurent obtained perhaps the same compound, contaminated with sulphuric acid, by heating arsenic trioxide with conc. sulphuric acid, and pouring off the partially cooled liquor. Crystals with the composition $3\text{As}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot \text{H}_2\text{O}$, or $\text{As}_2\text{O}_3 \cdot \text{SO}_3 \cdot \frac{1}{3}\text{H}_2\text{SO}_4$, were formed. The mother-liquor deposits octahedral crystals of arsenic trioxide.

According to R. H. Adie, crystals of **arsenic disulphatotrioxide**, $\text{As}_2\text{O}_3 \cdot 2\text{SO}_3$, are formed from a soln. of 98 per cent. sulphuric acid, sat. with arsenic trioxide; and by crystallizing the trisulphatotrioxide from conc. sulphuric acid. The compound is stable at 150° , but decomposes at 170° . A. Stavenhagen found crystals of **arsenic trisulphatotrioxide**, or **arsenic sulphate**, $\text{As}_2\text{O}_3 \cdot 3\text{SO}_3$, or $\text{As}_2(\text{SO}_4)_3$, occurring in the flues of a pyrites-burner of a sulphuric acid works; and R. Weber obtained the crystals by warming arsenic trioxide with sulphur trioxide at 100° , and driving off the excess of sulphur trioxide at this temp. C. Schultz-Sellack reported needle-like crystals of **arsenic tetrasulphate**, or **arsenic tetrasulphatotrioxide**, $\text{As}_2\text{O}_3 \cdot 4\text{SO}_3$, to be formed by heating arsenic trioxide and sulphuric acid which, according to R. H. Adie, should contain 88.3 per cent. of sulphuric anhydride. R. Weber reported **arsenic hexasulphatotrioxide**, $\text{As}_2\text{O}_3 \cdot 6\text{SO}_3$, to be formed by warming at 60° a mixture of arsenic trioxide and sulphur trioxide; and R. H. Adie, **arsenic octosulphatotrioxide**, or **arsenic octosulphate**, $\text{As}_2\text{O}_3 \cdot 8\text{SO}_3$, by heating a mixture of arsenic trioxide and sulphur trioxide in a sealed tube at 100° . G. Karl considered that *les anhydrides mixtès* are represented by:

A. Stavenhagen obtained hexagonal prisms of **potassium decasulphatarzenite**, $\text{K}_3\text{AsO}_3 \cdot 10\text{K}_2\text{SO}_4$, by evaporating and slowly cooling an aq. soln. of 21.8 grms. of potassium sulphate and 3 grms. of potassium arsenite. H. Köhl obtained **potassium tetrasulphatarzenite**, $2\text{K}_2\text{O} \cdot \text{As}_2\text{O}_3 \cdot 4\text{SO}_3$, by heating a soln. of arsenic trioxide and potassium sulphate in conc. sulphuric acid so as to drive off the sulphuric acid. Similarly with **calcium trisulphatarzenite**, $\text{CaO} \cdot \text{As}_2\text{O}_3 \cdot 3\text{SO}_3$, but the corresponding *barium and strontium trisulphatarzenites* could not be so obtained. Lead sulphate, however, gave **lead disulphatarzenite**, $\text{PbO} \cdot \text{As}_2\text{O}_3 \cdot 2\text{SO}_3$. C. Freidheim and J. Mozkin prepared **ammonium hydrosulphatarzenate**, $2(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 2\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{NH}_4(\text{H}_2\text{AsO}_4) \cdot \text{NH}_4(\text{HSO}_4)$, or $(\text{NH}_4)_2\text{H}[\text{AsO}_3(\text{SO}_4)]$, or $\text{HO} \cdot \text{AsO}(\text{ONH}_4) \cdot \text{O} \cdot \text{SO}_2 \cdot \text{ONH}_4 + \text{H}_2\text{O}$, or $(\text{NH}_4\text{O})(\text{NH}_4\text{SO}_4)\text{As}(\text{OH})_3$, by crystallizing from a soln. of two mols of ammonium dihydroarsenate and a mol of sulphuric acid. The first crop

of crystals is ammonium hydrosulphate. They also prepared **ammonium hydrosulphatarsenate**, $\text{NH}_4(\text{H}_2\text{AsO}_4) \cdot \text{H}_2\text{SO}_4$. They obtained in a similar manner **potassium hydrosulphatarsenate**, $2\text{K}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 2\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{HO} \cdot \text{AsO}(\text{OK}) \cdot \text{O} \cdot \text{SO}_2\text{OK} + \text{H}_2\text{O}$, or $\text{K}_2\text{H}[\text{AsO}_3(\text{SO}_4)] \cdot \text{H}_2\text{O}$, from a soln. of 2 mols of potassium dihydrarsenate and a mol of sulphuric acid; from equimolar parts of potassium dihydroxarsenate and sulphuric acid; **potassium tetrasulphatarsenate**, $5\text{K}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 8\text{SO}_3 \cdot 6\text{H}_2\text{O}$, or $\text{KO} \cdot \text{As}(\text{KSO}_4)_4 \cdot 3\text{H}_2\text{O}$, from equimolar parts of potassium dihydrarsenate and sulphuric acid; and **sodium hydrosulphatarsenate**, $2\text{Na}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 3\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{Na}_2\text{H}[\text{AsO}_3(\text{SO}_4)] \cdot \text{H}_2\text{O}$. J. Setterberg reported a double salt, $\text{Na}_2\text{SO}_4 \cdot 2\text{Na}_2\text{HAsO}_4$, to be deposited by a soln. of eq. quantities of sodium sulphate and hydroarsenate; and E. Mitscherlich, $2\text{Na}_2\text{SO}_4 \cdot \text{Na}_3\text{As}_6\text{O}_{10}$, from a soln. of 3 mols of sodium hydrarsenate and a mol of sulphuric acid. J. Setterberg also obtained **silver sulphatarsenate**, $3\text{Ag}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot \text{SO}_3$, by driving off the excess of acid from a mixture of sulphuric acid and silver ortharsenate. It is decomposed by water with the formation of sulphuric acid and silver ortharsenate.

J. F. Vogl² reported a mineral from Eliaszeche, Joachimsthal, which he called **lindackerite**. Its analysis corresponded with **copper nickel hydroxysulphatarsenate**, $\text{Cu}_6\text{Ni}_3(\text{OH})_4\text{SO}_4(\text{AsO}_4)_4 \cdot 5\text{H}_2\text{O}$. The rhombic crystals occur in rhombohedral plates grouped in rosettes and reniform masses. The colour is verdigris-green or apple-green. E. S. Larsen said the optical axial angle is 73° , the optical character negative, and the indices of refraction $\alpha=1.629$, $\beta=1.662$, and $\gamma=1.727$. The hardness is 2.0-2.5; and the sp. gr., 2.0-2.5. It is slowly dissolved by hydrochloric acid. Another brownish-red mineral from Laurion, Greece, was described by L. Milch; ³ he called it **lossenite**. The analysis corresponds with **lead iron hydroxysulphatarsenate**, $2\text{PbSO}_4 \cdot 6\text{As}_2\text{O}_3(\text{FeOH})_3 \cdot 24$ or $27\text{H}_2\text{O}$; that is, $\text{PbSO}_4(\text{FeOH})_9(\text{AsO}_4)_6 \cdot 12\text{H}_2\text{O}$. The rhombic crystals occur in acute pyramids resembling scorodite. The axial ratios are $a : b : c = 0.843 : 1 : 0.945$. The crystals are optically positive. E. S. Larsen gave $\alpha=1.783$, $\beta=1.788$, and $\gamma=1.818$; the optical character is positive; the optic axial angle $2V=50^\circ$. The mineral named **beudantite**—after F. S. Beudant—was described by A. Lévy; ⁴ and a variety from Cork, Ireland, was called **corkite** by M. Adam, and a variety from Dernbach, **dernbachite**. Analyses were reported by J. Percy, C. F. Rammelsberg, R. Köchlin, F. Sandberger, and E. G. J. Hartley. The formula is doubtful. C. F. Rammelsberg regarded it as a **lead ferric hydroxysulphatophosphatarsenate**, $4\text{Fe}_2\text{O}_3 \cdot 2\text{PbO} \cdot 3\text{SO}_3 \cdot (\text{As}, \text{P})_2\text{O}_5 \cdot 9\text{H}_2\text{O}$; F. Sandberger gave $\text{PbSO}_4 \cdot \text{Pb}_3(\text{PO}_4)_2 \cdot 3\text{FePO}_4 \cdot 24\text{H}_2\text{O}$; E. G. J. Hartley, $3\text{PbSO}_4 \cdot 2\text{FePO}_4 \cdot 6\text{Fe}(\text{OH})_3$; and G. T. Prior, $\text{PbSO}_4 \cdot \text{FePO}_4 \cdot 2\text{Fe}(\text{OH})_3$. The colour may be olive-green, yellowish-green, brown, or black. The acute rhombohedral crystals belong to the trigonal system, and were found by H. Dauber to have the axial ratio $a : c = 1 : 1.1842$. The (0001)-faces are flat and dull; the (10 $\bar{1}$ 1)-faces, bright and curved. The (0001)-cleavage is easy to distinguish. E. S. Larsen gave for the index of refraction of beudantite, 1.96; the optical character is negative. W. T. Schaller regarded beudantite as one member of an isomorphous group of trigonal crystals with the following axial ratios for $a : c$:

Svanbergite	$2\text{SrO}, 3\text{Al}_2\text{O}_3, 2\text{SO}_3, \text{P}_2\text{O}_5, 6\text{H}_2\text{O}$	1 : 1.2063
Hinsdalite	$2\text{PbO}, 3\text{Al}_2\text{O}_3, 2\text{SO}_3, \text{P}_2\text{O}_5, 6\text{H}_2\text{O}$	1 : 1.2677
Corkite	$2\text{PbO}, 3\text{Fe}_2\text{O}_3, 2\text{SO}_3, \text{P}_2\text{O}_5, 6\text{H}_2\text{O}$	1 : 1.1842
Beudantite	$2\text{PbO}, 3\text{Fe}_2\text{O}_3, 2\text{SO}_3, \text{As}_2\text{O}_5, 6\text{H}_2\text{O}$	1 : 1.1842

Following A. Lacroix, and E. Bertrand, corkite is here regarded as a phosphate; beudantite as an arsenate. E. Bertrand found that the optical character is positive; and the index of refraction, medium. The optical character was also examined by E. G. J. Hartley, and H. A. Miers. The sp. gr. is 4.0-4.3; and the hardness, 3.5-4.5. The mineral readily fuses; and it is soluble in hydrochloric acid.

§ 38. The Arsenic Sulphohalides, or Halogenosulphides

According to O. Ruff and K. Thiel,¹ sulphur tetrachloride reacts with arsenic trifluoride, forming yellow crystals of $2\text{AsF}_3 \cdot \text{SCl}_4$, or **arsenic sulphohexafluotetrachloride**, $\text{As}_2\text{SF}_6\text{Cl}_4$. It attacks glass slowly, but decomposes or chars thionyl chloride, carbon tetrachloride, carbon disulphide, alcohol, ether, benzene, and light petroleum.

H. Rose treated arsenic disulphide or trisulphide with dry chlorine, and obtained a brown liquid with a composition approximating $2\text{AsCl}_3 \cdot 3\text{SCl}_2$. It dissolved in nitric acid, giving off nitrous fumes and forming sulphuric, hydrochloric, and arsenic acids; with water, it forms a soln. of hydrochloric, sulphuric, hyposulphurous, and arsenious acids—the hyposulphurous acid is quickly decomposed into sulphur and sulphurous acid; the ammoniacal soln. is rendered turbid by sulphuric acid. L. F. Nilson regarded the product of the action of chlorine on arsenic di-, tri-, or penta-sulphide as a mixture, not a chemical individual.

L. Ouvrard found that dry hydrogen sulphide acts on arsenic trichloride at the ordinary temp., with evolution of hydrogen chloride and formation of a yellow precipitate, which, if the action is continued until the evolution of hydrogen chloride ceases, and the precipitate is washed with carbon disulphide, consists partly of crystalline, and partly of amorphous, material. The proportion of the latter varies, and it can be removed by levigation with carbon disulphide. Both the amorphous and crystalline products consist of **arsenic pentasulphodichloride**, $\text{As}_4\text{S}_5\text{Cl}_2$. This compound is slowly decomposed by boiling water, with formation of arsenic trichloride and amorphous arsenious trisulphide. It melts at about 120° , and volatilizes at about 300° (out of contact with air), with decomposition into arsenic trichloride and trisulphide. If 1 part of the trisulphide and 5 parts of the trichloride are heated at 180° for 24 hrs., and cooled slowly, the pentasulphodichloride, $\text{As}_4\text{S}_5\text{Cl}_2$, is obtained in very small, pale-yellow crystals. If the hydrogen sulphide used in the preparation of the chlorosulphide is not quite dry, the product is simply the ordinary trisulphide, and the same result follows if the reacting substances are heated. Arsenious trisulphide dissolves in the trichloride when heated, but is deposited unchanged on cooling. If, however, a mixture of the two substances is heated in sealed tubes at 150, the trichloride being in excess, the **arsenic sulphochloride**, AsSCl , is obtained in microscopic crystals, which melt and volatilize

readily when heated out of contact with air. It is decomposed by water in the same way as the preceding compound, and is dissolved by soln. of ammonia and alkali carbonates.

V. Auger prepared **arsenic tetracosisulphotriiodide**, $\text{AsI}_3 \cdot 3\text{S}_8$, by mixing soln. of the two components in carbon disulphide. According to L. Ouvrard, dry hydrogen sulphide has no action on dry arsenic triiodide in the cold, but at 200° , some of the triiodide volatilizes in a current of hydrogen sulphide, and crystals of **arsenic pentasulphodiiodide**, $2\text{AsSI} \cdot \text{As}_2\text{S}_3$, are formed; they are less soluble than arsenic triiodide in carbon disulphide. If arsenic trisulphide be melted with an excess of the triiodide, out of contact with air, and the product crystallized from its soln. in carbon disulphide, small acicular crystals of **arsenic sulphotetraiodide**, $\text{AsI}_3 \cdot \text{AsSI}$, are formed. If the arsenic trisulphide be in excess, then **arsenic sulphoiodide**, AsSI , or $\text{As}_2\text{S}_3 \cdot \text{AsI}_3$, is formed. E. R. Schneider obtained it by heating together either a mixture of realgar (1 mol) and iodine (2 atoms) with the least possible access of air, or a mixture of 3 parts arsenious triiodide with 1.6 parts of arsenic trisulphide. N. Tarugi obtained lemon-yellow crystals by heating arsenic triiodide with thioacetic acid. The sulphiodide forms an amorphous, vitreous mass with conchoidal fracture, and is of a dark red or reddish-brown colour. It is not acted on by the air at ordinary temp. When heated at 100° , it softens, and boils at a higher temp. without evolution of iodine vapour, but with partial decomposition into arsenious triiodide and trisulphide. It is insoluble in hot and cold alcohol, ether, carbon disulphide, chloroform, and benzene. E. R. Schneider found that hot water slowly decomposes it with formation of hydriodic acid. Boiling hydrochloric acid slowly decomposes it with evolution of iodine. When boiled with conc. sulphuric acid, it gives off iodine, sulphur, and sulphur dioxide. Potassium and ammonium hydroxides dissolve arsenious sulphiodide to a colourless liquid, from which dil. acids precipitate arsenic trisulphide, whilst the whole of the iodine and parts of the arsenic remain in soln. When treated with an ammoniacal soln. of silver nitrate, it is decomposed, forming silver iodide, sulphide, and arsenite.

According to E. R. Schneider, a soln. of iodine in carbon disulphide is without action on natural arsenic trisulphide (orpiment), but reacts with that precipitated by hydrogen sulphide, forming arsenious iodide and sulphur. Attempts to prepare the compound $\text{As}_2\text{S}_3 \cdot 2\text{AsI}_3$, by heating a mixture of iodine and arsenic trisulphide in the ratio $\text{As}_2\text{S}_3 : 6\text{I}$, were not successful. The mixture fused at a low temp. to a homogeneous mass of a brown colour, which dissolved almost entirely in carbon disulphide; on evaporation of the solvent nothing but arsenic iodide and sulphur crystallized out. On distilling a mixture of arsenic trisulphide and iodine in the ratio $\text{As}_2\text{S}_3 : 6\text{I}$, until two-thirds of the material had passed over, the distillate was found to contain 58.63 per cent. of free iodine, 40 per cent. of arsenic iodide, and 1.37 per cent. of sulphur; the residue consisted of 55.32 per cent. of arsenic trisulphide and 44.04 per cent. of arsenic triiodide. When in place of the former, a mixture of arsenic triiodide and sulphur in the ratio of $2\text{AsI}_3 : 3\text{S}$ was employed, and the distillation continued until half the material had passed over, the distillate contained 69.44 per cent. of free iodine, 28 per cent. of arsenic triiodide, and 2.56 per cent. of sulphur. It therefore follows that whilst a mixture of arsenic trisulphide and iodine is converted at moderate temp. into arsenic triiodide and sulphur, these products again react at a higher temp., reproducing their generators. If the distillate, rich in iodine, is sealed up in a glass tube, which is slightly inclined so that the distillate occupies the higher portion of the tube, and gently heated in a water-bath to a temp. of about 72° , a dark-brown liquid which solidifies on cooling trickles to the bottom of the tube. By repeated liquations in sealed tubes this dark brown mass becomes perfectly homogeneous, crystallizing in hard, brittle plates of a greyish-black colour, and dull lustre. The pure substance melts at 72° , and is **arsenic sulphododecaiodide**, $\text{S}_6 \cdot 2\text{As}_2\text{I}_3$. On pulverizing, it forms a reddish-brown powder which by exposure to the air rapidly loses iodine, whilst the residue,

consisting of a mixture of arsenic triiodide and sulphur, assumes a bright red colour. On fusing a mixture of arsenic trisulphide with iodine in the ratio $\text{As}_2\text{S}_3 : 4\text{I}$, the iodine reacts with only two-thirds of the arsenic trisulphide present. When, as not infrequently happens, the arsenic trisulphide contains arsenious acid, there remains behind, after fusion with iodine and treatment with carbon disulphide, an insoluble pale-yellow powder of **arsenic enneaoxyhexasulphoenneaiodide**, $2\text{As}_2\text{S}_3 \cdot 3(\text{AsI}_3 \cdot \text{As}_2\text{O}_3)$. This substance can also be prepared by heating a mixture of arsenic trisulphide (1 part) and arsenic triiodide (0.2 part) with a large excess (8–10 parts) of arsenic triiodide, or by heating a mixture of arsenic triiodide (4 mols) with arsenic trisulphide (1 mol) with free access of air. Under the microscope, the compound appears to be indistinctly crystalline. On gently heating it, arsenious iodide first sublimes, then arsenious acid, and lastly, arsenic trisulphide. The compound is completely dissolved by soln. of potassium hydroxide and ammonia, and is readily decomposed by the common mineral acids and by boiling water.

§ 39. Arsenic Carbonates, Nitrates, and Phosphates

No *arsenic carbonate* has yet been prepared, although a number of salts with organic acids are known—*e.g.* arsenic acetate, tartrate, cyanide, thiocyanate, have been prepared. *Arsenic nitrate* is unknown; but some complex nitrate-salts are known. J. F. Simon¹ found that **mercurous dinitratarsenate**, $2\text{HgNO}_3 \cdot \text{Hg}_3\text{AsO}_4 \cdot 2\text{H}_2\text{O}$, is produced when a soln. of mercurous hydrarsenate in conc. nitric acid is covered with an equal vol. of water; aq. ammonia poured on that; and all left to stand for some time. The given salt is deposited in warty masses and needles. When the liquids are mixed too rapidly, the product is mixed with a grey powder and with mercurous hydrarsenate. He also made it by adding aq. ammonia with constant agitation to a warm soln. of mercurous hydrarsenate in nitric acid until the hydrarsenate is just about to be precipitated. On cooling the liquid, the complex salt appears in warty masses. This salt is also obtained as a white powder on adding a very small proportion of arsenic acid to a soln. of mercurous nitrate. If too much arsenic acid be used the precipitate turns yellow or orange. The yellowish-white salt gives off nitrous acid—salpetrige Säure—when heated alone or with conc. sulphuric acid, and when its soln. in nitric acid is treated with aq. ammonia, mercurous hydrarsenate is precipitated. K. Haack reported a basic salt, **mercurous dioxydinitratotriarsenate**, $2(\text{Hg}_2\text{O} \cdot \text{HgNO}_3)_2 \cdot 3\text{Hg}_3(\text{AsO}_4)_2$, to be formed by dropping a cold soln. of a mol of sodium hydrarsenate into a cold soln. of nine mols of mercurous nitrate, washing the product with cold water, and drying it in air. The dirty yellow powder is soluble in hydrochloric acid.

J. V. Janowsky² found that when arsenic phosphide is acted on by water, it yields **arsenic dioxydiphosphide**, $\text{As}_3\text{P}_2\text{O}_2$, which is decomposed by chlorine. O. Ruff obtained a violet-black substance, **arsenic dioxyphosphide**, $\text{As}_4\text{P}_2\text{O}_2$, by the action of water on the product obtained by the action of phosphorus on arsenic in the presence of aluminium chloride. No *arsenic phosphate* has been reported, but in view of the isomorphous relationship of the phosphates and arsenates, as might be anticipated, many phosphate-minerals also contain arsenates, and conversely—*e.g.* beudantite, veszelyite, and ferromite previously described.

E. Glatzel obtained **arsenic sulphophosphate**, AsPS_4 , by heating a mixture of arsenic trisulphide and phosphorus pentasulphide—*vide supra*, thiophosphates.

The co-precipitation of arsenic with ammonium phosphomolybdate was studied by A. Frank and F. W. Hinrichsen,³ and J. R. Cain and J. C. Hostetter.

CHAPTER LII

ANTIMONY

§ 1. The History of Antimony

ANTIMONY sulphide was known as a mineral to the people of ancient times, and it was used by them as a medicine, and as a cosmetic. For example, in the Vulgate edition of the *Bible*, *Ezekiel* (23. 40), it says: *te lavisti, et circumlinisti stibio oculos tuos*—thou didst wash thyself, and didst paint thine eyes with stibium; in *II Kings* (9. 30): *Jezebel depinxit oculos suos stibio*—Jezebel painted her eyes with stibium; and in *Jeremiah* (4. 30): *tu pinxeris stibio oculos tuos*. According to X. Fischer,¹ finely-divided lead sulphide was used more frequently than antimony sulphide by the women of ancient Egypt for painting the eyes. In the first century of our era, Dioscorides, in his *De materia medica* (5. 49), applied the term *στίμμι*, *stimmi*, or *stibium*, to the mineral sulphide, and said that in allusion to its use by women for painting their eyes, it was called *πλατυόφθαλμον*, or eye-expander; *καλλιβλέφαρον*, or eye-beautifier; *γυναικείον*, or womankind; etc. About the same time, Pliny, in his *Historia naturalis* (33. 34), described seven remedies derived from *stimmi*; and he spoke of two kinds of *stimmi*—also called *stibium*, *alabastron*, or *larbasis*—which were regarded respectively as male and female. Some commentators have argued that native antimony and antimony sulphide were denoted respectively as female and male *stimmi*; others, that the metal and its oxide were in question.

M. Berthelot obtained a fragment of a vase from some excavations at Tello, and found it to consist of metallic antimony; thus showing that this metal was known to the ancient Chaldeans perhaps 4000 B.C. R. Forrer reported vessels of antimony from old burial grounds near Tiflis; O. Helm and H. V. Hilprecht, and E. Mayer found 3 per cent. of antimony in some bronze vessels of the oldest Babylonian period; O. Stoll found antimony in some old Abyssinian alloys; A. F. von Parly and A. Nies observed 15 per cent. of antimony in some bronzes of the old lake-dwellers; W. Hommel reported antimony in some old Japanese bronzes; H. Oldenberg, in some old Indian bronzes; and B. Bucher, in some old Peruvian alloys.

The scholars tell us that the Hebrew and Arabic word for antimony is *kohl* or *kohl*, which was translated *alcohol* or *alkohol* in other languages. E. O. von Lippmann has quoted a number of examples from the writings of the Middle Ages, where the term *alcohol* was used for substances in the state of a fine powder; only later was the term used for spirit of wine. According to H. Kopp, the word *antimonium* appeared in the Latin translations of Geber's *Summa perfectionis magisterii*; but, added M. Berthelot, it is *une circonstance singulière* that the term antimony does not appear in the reputed twelfth and thirteenth century translations of the Arabian chemists. It does not occur in the writings of Geber, the pseudo-Aristotle, or Avicenna reproduced in the *Theatricum chemicum*, or in the *Bibliotheca chemica*. The terms *marcassite* or *magnesia* are sometimes applied to antimony sulphide, as well as to the other metal sulphides. The term *ἀντεμόνιον* appears

in a practical treatise on the goldsmith's art, written in the Greek characteristic of the Middle Ages, and reproduced in M. Berthelot and C. E. Ruelle's *Collection des anciens alchimistes grecs* (Paris, 2. 6, 1888). The mineral sulphide is called *antimonium*, and not *stimmi*, or *sibium*, in the *Speculum naturale* (8. 49) of Vincent de Beauvais, written towards the middle of the thirteenth century; while Constantinus Africanus, in his *De gradibus*, is said to have employed the same term a century and a half earlier. The word *antimonium* also appears in the *Circa instans* of M. Platearius, about 1150; in the *Tabulæ* of M. Salernus, about 1200; and in the *Antidotarium*, or *Isagogica introductio in artem apothecariatus* of P. Nicolas, about the middle of the twelfth century. Hence, added M. Berthelot, the term *antimonium* appeared in Western Europe about the middle of the eleventh century, and it ultimately displaced the older words.

The origin of the word *antimony* has been the subject of some speculation. It is said that certain monks experimented with antimony on some pigs and discovered that it hastened their fattening. With the desire of avoiding the effects of fasting on themselves, they partook of the same medicament, but with fatal results. Hence the origin of the term *anti*, against; *μόνος*, one who lives alone, a monk. It has also been suggested that the *μόνος* means solitude, and that *antimonos* means opposed to solitude, in allusion to the fact that antimony always occurs in nature associated with other minerals. M. Berthelot said it was not worth while discussing *l'etymologie puerile*, which refers the term antimony to *anti-moine* in allusion to the accidental poisoning of some monks by a preparation of antimony. M. Berthelot continued: E. Littré favours the suggestion that *anti-moine* is derived from the Arabian *athmoud*, *othmoud*, or *ihmid*, eye-paint which in turn is derived from *stimmi* with the addition of the article *al*. Possibly also the Greek word is of Oriental origin, and not borrowed by the Arabians from the Greeks. Many examples of the adaptation of Arabian words to Latin or Greek forms will be found in M. Ruland's *Lexicon alchemice* (Francofurti, 1612). For example, the word *tinkar* becomes *attinkar*, and *antcar*, and *antimonium* is given with the synonym *antistini*.

According to H. Kopp, up to the time of the antiphlogistians, the word *sibium* or *antimonium* was employed in alchemical and chemical writings in place of antimony sulphide. Pliny described a process for preparing *stimmi* for medical purposes by heating it with organic matter in such a way as *ne plumbum fiat*—not to become lead. This is taken to mean that the metal was occasionally obtained by the ancients but not recognized by them as anything different from lead. Dioscorides also mentioned that *stimmi* could be roasted by heating it in a current of air; but if too strongly heated, it melted like lead. Here again it is thought that metallic antimony was formed.

The metal antimony was known to A. Libavius in 1615, to G. E. Stahl, and to D. G. Morhof; while, according to H. von Peters, G. W. von Leibniz made some observations on the metal. A. Libavius obtained antimony by adding iron to a molten mixture of antimony sulphide, salt, and potassium tartrate. The *regulus* so produced had a crystalline or starred surface—hence the terms: *the wonderful star*, *stella antimonii*, *antimonium stellatum*, *regulus stellatus*, *the royal star*, *the philosopher's signet star*, etc. The anonymous Basil Valentine, at the beginning of the seventeenth century, showed that starred and unstarred antimony had the same composition; and he attributed the effect to the use of iron—Mars—in the reduction of the sulphide. Robert Boyle, in his essay *On the unsuccessfulness of experiments* (Oxford, 1661), said:

It may perhaps be from some diversity either in antimonies or irons, that eminent chemists have often failed in their endeavours to make the starry regulus of Mars and antimony. Inasmuch that divers artists fondly believe and teach (what our experience will not allow) that there is a certain respect to times and constellations requisite to the producing of this (I confess admirable) body. Upon this subject, I must not omit to tell you that a while since an industrious acquaintance of ours was working on an antimony, which, unawares to him, was, as we then supposed, of so peculiar a nature, that making a regulus of it alone without iron, the common way (for this manner of operation I inquired of him), he found, to his wonder, and showed me his regulus adorned with a more conspicuous star than I have seen in several stellate reguluses of both antimon and Mars.

N. Lemery, in his *Cours de chymie* (Paris, 1675), argued against the idea that the

planet Mars had anything to do with the stellate crystals on the surface of metallic antimony. In 1546, G. Agricola described the preparation of antimony by heating the sulphide in a belly-shaped pot with perforations in the bottom. This vessel rested on an empty pot. The two vessels were surrounded by earth and coal-dust, and heated from above by burning logs. The metal ran into the lower vessel. In 1574, L. Ercker, and in 1650, B. Rössler, described methods of reducing the sulphide to metal.

A. Libavius said that *antimonium triplex est*, for it is compounded of mercury, arsenic, and sulphur. A. Sala knew that antimony is often associated with arsenic, and cautioned users of medicinal preparations of antimony against that impurity. Basil Valentine called antimony an *Abart des Bleis*, thus regarding it as a degenerate form of a true metal. Analogous views as to the semi-metallic nature of antimony were held by A. von Suchten in 1613; by H. Poppe in 1625; by J. J. Becher in 1669; by N. Lemery in 1675; by J. Kunckel in 1690; and by E. Etmüller in 1693. In 1732, H. Boerhaave classed the sulphide as a *semi-metalla sulphurea*. According to N. Lemery, the fact that antimony comes after gold in resisting attack by aqua regia led to its being regarded by some alchemists as imperfect gold. The use of additions of antimony for purifying molten gold, said J. Chartier, is because the antimony can unite with impurities, thereby forming a scum which can be easily removed. This, and the fact that antimony united with or devoured all the metals then known, with the exception of gold, led to *stimmi, kohl*, or *antimonium* being called in the alchemical literature of the Middle Ages, *judex ultimus, lupus repax, pupus metallorum*—the wolf of the metals—the *red lion*, the *fiery dragon*, the *fiery satan*, the *son of satan*, *balneum regis*—the bath of the king—*der hochste, Richter*, etc. A fanciful analogy with lead—Saturn—and the likening of the mythological appetite of Saturn for infants with the appetite of antimony for other metals, led some alchemists to call antimony *the sacred lead, the lead of the philosophers*, or the *lead of the sages*. Antimony was also called *radix metallorum*, the root of the metals, because it occurs associated with other metals in mines, and it was sometimes designated *protheus* because of the varying colours associated with the products derived from antimony. *Spießglas* or *Spießglanz* was a miners' term for antimony.

J. R. Glauber showed that when antimony sulphide is heated with mercuric chloride, owing to the *attractio electiva duplex*, the metals exchange places to form mercuric sulphide and antimony chloride. With the advent of the antiphlogistian theory, it was recognized that antimony is an element forming sulphides, oxides, etc., as in the case of other metals. According to H. Hyman,

The part played by antimony in the early history of chemistry is generally overlooked, its claim to an all-important position being overshadowed by its great rival, gold. There is a considerable amount of evidence, however, that antimony and its compounds must have proved of fascinating interest to many of the early chemists, and it is indeed probable that the study of this metal led to more developments in the early history of the science than did that of the precious metal. This fascination became in some cases so absorbing that entire life-times were devoted to its study, and the specialization which we are inclined to attribute to the economic conditions of the present era was in force several centuries ago. The result of this intensive study was the publication of several books dealing entirely with this metal, all of which remain as landmarks in the steady progress of the science.

The following monographs on antimony were published after Basil Valentine's *Triumphwagen antimonii* (Leipzig, 1604):

N. Lemery, *Traité sur l'antimoine*, Paris, 1707; E. P. Meuder, *Analysis antimonii*, Paris, 1738; A. von Suchten, *Antimonii mysteria gemina*, Leipzig, 1604; H. Poppe, *Basilica antimonii*, Franckfurt, 1617; T. Bergman, *De antimonialibus sulphuratis*, Upsala, 1782; G. Rolfinck, *De antimonio*, Jenæ, 1691; Le Pere Lamy, *Dissertation sur l'antimoine*, Paris, 1682; G. Pearson, *Experiments and Observations to Investigate the Composition of James's Powder*, London, 1791; R. G. Renault, *Histoire de l'antimoine*, Paris, 1868; L. de Launay, *De la faculte et vertu admirable de l'antimoine, avec response a certaine calomnies*, La Rochelle, 1564; A. Sala, *Anatomia antimonii*, Francofurti, 1617; G. D. Traverso,

L'Antimonio, Alba, 1897; A. Guntz, *Antimoine*, Paris, 1884; C. Y. Wang, *Antimony*, London, 1909; A. Nicolas, *L'Antimoine et ses principaux composés*, Montpellier, 1880.

F. Fittica² said that antimony is a nitrogen derivative of phosphorus, and can be obtained in small quantities together with arsenic by heating amorphous phosphorus with ammonium nitrite and potassium nitrate with or without the addition of ammonium carbonate. He also said that antimony can be similarly obtained from arsenic. C. Winkler, and C. Arnold and F. Murach showed that the arsenic and antimony which F. Fittica obtained must have been derived from impurities in the materials he used—*vide* arsenic.

§ 2. The Occurrence of Antimony

Antimony is regarded as one of the common elements, but it is neither widely nor abundantly distributed in nature. F. W. Clarke and H. S. Washington¹ estimate that the igneous rocks of the earth's crust contain $n10^{-7}$ per cent. of antimony, and J. H. L. Vogt, $n10^{-5}$ per cent. W. Vernadsky gave 0.05_7 for the percentage amount of antimony, and 0.0_{45} for the atomic proportion. According to H. Rowland,² and M. N. Saha, the spectral lines of antimony have not been detected in the spectrum of the sun. Antimony has been observed by G. Trotterelli, B. Silliman and F. S. Hunt, E. Cohen, and E. Cohen and E. Weinschenk in meteorites.

Elemental antimony occurs in nature too rarely for the deposits to be of any elemental importance. The earliest definite record of the occurrence of the element is the *gediget Spitzglas* found at Sala, Sweden, by A. von Swab³ in 1748; and in 1780, J. G. Schreiber found it at Allemont, France. The following analyses of native antimony were reported by M. H. Klaproth, A. Eschka, A. Raimondi, R. A. A. Johnston, and G. F. Kunz, respectively:

	Sb	As	Fe	Ag
Andreesberg	98-00	—	0-25	1-00
Pribram	95-15	4-85	—	—
Macata, Peru	96-36	3-63	—	0-0
Madoc, Ontario	99-80	0-02	trace	—
York County, U.S.A. (fine)	98-19	0-86	0-11	—
„ „ (coarse)	94-15	0-47	0-34	—

The French occurrences of native antimony have been described by R. Hörnes. The deposits in Germany—Andreesberg, Harz; Goldkronach, Bayern; and Pribram, Bohemia—were described by M. H. Klaproth, J. F. L. Hausmann, O. Luedecke, E. Schulze, G. Rose, F. A. Roemer, C. Greifenhagen, W. von Gümbel, C. Hahn, A. E. Reuss, A. Eschka, V. R. von Zepharovich, and F. Katzer; at Kapruk, and Pozsony, in Hungary, by V. R. von Zepharovich, and S. Koch; at Waldenstein, Carinthia, by E. Döll; at Sarrabus, Sardinia, by A. des Cloizeaux; at Chang-Sha, China, by F. R. Tegengren; at Lucknow, New South Wales, by A. Liver- side; in Queensland, by B. Dunstan, and R. W. E. MacIvor; in Chili, by I. Domeyko; in Peru, by A. Raimondi; in Mexico, by G. Leonhard, I. Domeyko, and C. F. de Landero; in California and New Jersey, by J. D. Dana, and C. H. Behre; in North Carolina, by F. A. Genth; in Canada, by C. H. Hitchcock, W. E. Logan, R. A. A. Johnston, and A. Weisbach; and in New Brunswick, by G. F. Kunz.

The chief minerals containing antimony are the sulphides, various antimonides and sulphantimonides of the heavy metals, and oxidized compounds of secondary origin. The arsenic minerals include:

Antimonides.—*Breithauptite*, NiSb; *arite* or *arsenantimonial nickel*, Ni(As,Sb); *dycrasite* or *antimonial silver*, Ag₃Sb; *chanarcillite*, Ag₃(As,Sb)₃; *antimonial copper*; *allemontite*, SbAs₃—*vide arsenic*; *sperrylite*, (Pt,Rh)(As,Sb)₂; *horsfordite*, Cu₃Sb. **Sulphides.**—*Stibnite*, *antimonite*, or *antimony glance*, Sb₂S₃; *metastibnite*, Sb₂S₂. **Mixed antimonides and sulphides.**—*Pyrrargyrite*, Ag₃SbS₃; *polybasite*, Ag₁₀Sb₂S₁₁; *miargyrite*, AgSbS₂; *polyargyrite*, Ag₂₄Sb₂S₁₅; *stephanite*, Ag₅SbS₃; *pyro-stilpnite*, Ag₃SbS₃; *wolf- bergite*, CuSbS₄; *guejarite*, Cu₉Sb₄S₇; *famatinite*, Cu₃SbS₄; *tetrahedrite*, Cu₉Sb₂S₇; *chal- costibite*, CuSbS₂; *eromeyerite*, (Ag,Cu)S; *stylotypite*, (Cu₂,Ag₂,Fe)₃Sb₂S₈; *livingstonite*, HgSb₄S₇; *zinkenite*, PbSb₂S₄; *brongniardite*, (Pb,Ag₂)Sb₂S₅; *boulangerite*, Pb₃Sb₂S₈; *epiboulangerite*, Pb₂Sb₂S₃; *geokronite*, Pb₅Sb₂S₈; *warrenite*, or *domingite*, Pb₂Sb₄S₉; *plagionite*, Pb₆Sb₈S₁₇; *meneghinite*, Pb₄Sb₃S₇; *kobellite*, Pb₂(Bi,Sb)₂S₅; *jamesonite*, Pb₂Sb₂S₅; *freieslebenite*, or *diaphorite*, (Pb,Ag₂)₅Sb₄S₁₁; *bournonite*, (Pb,Cu₂)₃Sb₂S₈; *semseyite*, Pb₇Sb₆S₁₆; *kylindrite*, Pb₆Sn₆Sb₂S₂₁; *frankeite*, Pb₅Sn₃Sb₂S₁₂; *kilbruckenite*, Pb₆Sb₂S₉; *steinmannite*, antimonial galena; *berthierite*, FeSb₂S₄; *dürfeldtite*, a sulphanti- monide of lead, silver, copper, iron, and manganese; *plumbostannite*, a sulphantimonide of lead, tin, and iron; *ullmannite*, NiSbS; *wolfachite*, Ni(As,Sb)S; *korynite*, (Ni,Fe)(As,Sb)S; *ammiolite*, mercury copper tellurantimonide.

Oxides, and oxidized salts.—*Senarmonite*, Sb₂O₃; *valentinite*, Sb₂O₃; *cervantite*, Sb₂O₄; *volgerite*, hydrated antimonous acid, *stibiconite* or *stiblite*, Sb₂O₄·H₂O; *arsenostibnite*, an arsenical hydrate of antimony; *partzite*, hydrated antimonious oxide mixed with copper, lead, and silver oxides; *romeite*, CaSb₂O₇; *atopite*, Ca₂Sb₂O₇, or (Ca,N_a,Fe,Mn)₂Sb₂O₇; *thrombolite*, Cu₃(SbO₃)₂·6H₂O; *barcenite*, mercury antimonate; *bindheimite*, Pb₂Sb₂O₈·4H₂O; *corongite*, silver lead antimonate; *morimolite*, (Pb,Fe,Mn)₃(SbO₄)₂; *tanzite*, bismuth arsenantimonate; *hematostibite*, Mn₃Sb₂O₁₃; *manganostibite*, Mn₁₀Sb₂O₁₅; *tripukhyite*, Fe₂Sb₂O₇; *ochroite*, Pb₃Sb₂O₇·2PbCl₂; *nadorite*, PbSbO₂Cl; *rivotite*, a copper silver antimonate with carbon dioxide; *sarawakite*, antimony chloride; *schneebergite*, calcium antimony sulphate; *stetefeldtite*, hydrated silver copper oxysulphantimonate; *kermesite*, Sb₂S₂O; *stibiatic*, and *ferrostibian*, ferrous manganese antimonate; *langbanite*, manganese iron antimonatosilicate; *arequipite*, lead antimonatosilicate.

There are upwards of fifty minerals containing antimony, but only a few are worked commercially. Stibnite is by far the most important ore of antimony, and metallic antimony not infrequently occurs with stibnite. Thus, antimony is abundant in the lower levels of the stibnite at West Gore, Nova Scotia, and it predominates over the stibnite of Wolfe Co., Quebec; it occurs massive near Sandon, New South Wales; and in nodular masses, at Erskine Creek, Cal. Native antimony impregnates the shales near Vinuela, Spain; and it occurs in the anti- mony veins and detritus of Bidi, British Borneo. Stibnite is associated with cinnabar at San Martino, Corsica; Rohonez, Hungary; Selvena, Italy; Cemernitsa

and Prozer, Yugoslavia; Sandjak-Kale, Asia Minor; Djebel Tayo, etc., Algeria; Tegora, British Borneo; Pulganbar, New South Wales; at Rio Blanco, Mexico; etc. Antimony itself is regarded as an alteration product of stibnite, etc. The antimony ores are often associated with volcanic activity, and were deposited near the surface—e.g. Monte Amiata, Italy; Hsi-Ku'ang-Shan, China; Thabyu, Burma; Bridge River, British Columbia; West Gore, Nova Scotia; Huitzucó, Mexico; and in South Utah. In other cases, particularly with the sulphantimonides, the ores were deposited at intermediate depths at moderate temp., and under great press.—e.g. the antimony ores in Cobalt, Ontario; Slocan, British Columbia; Aspen, Colorado; Park City, Utah; Black Hills, South Dakota; Hillgrove, New South Wales; Bendigo, Victoria; Andreesberg, Harz; Clausthal, Germany; and Příbram, Czechoslovakia. The antimony ores of Bolivia; Zimapán, Mexico; Arabia, Nevada; and Western Australia are thought to have been deposited at high temp. and under great press. The stibnite ores commonly occur in fissure veins with a quartz gangue, and they may or may not be argentiferous and auriferous; they may occur in faults or shear zones in limestone, sandstone, or schist; as irregular masses in limestone being formed by substitution; as impregnations in porous beds of limestone or sandstone; and as sporadic occurrences in lead, zinc, copper, mercury, gold, or silver minerals. The geographical distribution of the ores is illustrated by the map, Fig. 1.

FIG. 1.—Geographical Distribution of the Antimony-bearing Districts.

Europe.—Comparatively little antimony ore was raised in *Great Britain*⁴ from the end of the eighteenth century to 1893, when the mining of antimony ore virtually ceased. The ores occur in Cornwall, Devon, Cumberland, Derbyshire, and the Isle of Man; in the past, in Scotland, ores were mined in Dumfriesshire, and in Ayrshire; and in Ireland, in Monaghan. Before the war, *France*⁵ was the largest producer in Europe; it occurs at La Lucette, Mayenne, Semmon, Isle-et-Vilaine; Massiac, Brioude, etc., Central Plateau; Bresnay, Souvigny; Freycenet, Mercoeur, Valadau, La Licoulne, Haute Loire; Malbosc, Ardèche; Luri Castello, Meria, Metra, and Ersu, Corsica. In *Portugal*,⁶ it occurs in the Basin of the Douro, Braganza, Prata, and Alcoutim. In *Spain*,⁷ Ribas valley, Caurel, Orense, Alemejo, Estremadura, and Vinuela. In *Switzerland*, at Lessnig. In *Italy*,⁸ Sardina, Monte Annata, Selvena, San Martino, Percia Fiorentina, Montauto, Cetine di Cotorniano, Pari, Su Suergiu, and Soana di Campiglia. In *Greece*,⁹ Mytilene, and Chios. In *Russia*,¹⁰ Urals, Amur, and Siberia. In *Austria*,¹¹ Rohoncz. *Czechoslovakia*,¹² Pricov, Schonberg, Mileschen, Kritz, Punnau, Joachimsthal. There are several mines in Slovakia, and ores occur in Ruthenia. In *Yugoslavia*,¹³ there are deposits in Kostainic-Krapanj, in Slovenia, Croatia, Bosnia, Dalmatia, and Serbian Macedonia. In *Germany*,¹⁴ Moben-

dorf, Brück, Westphalia, Nuttler, Böhmisdorf, Wolfsgalgen, and Goldkronach. In *Sweden*, Sala, Westmannland, and Gladhammar.

Asia.—In *Asia Minor*,¹⁵ antimony ores occur in Anatolia, Brusa, Smyrna, and Kordilio. In *Persia*,¹⁶ Afshar. In *Afghanistan*, Kil' Abdullo, Kinchak, and Duligird. In *India*,¹⁷ Mysore, Madras, Bihar, Orissa, Baluchistan, Punjab, in the North-West Provinces. *Burma*. In *British Borneo*,¹⁸ Bidi, Busan, Jambusan, Piat, Orogo, Siktingit, and in the basin of the River Rejang. In *French Indo-China*, near Tonkin. *China*¹⁹ has been the principal producer of antimony for the last quarter of a century; the more important deposits occur in the provinces of Hunan, Hupeh, Yunnan, Kweichow, and Kwangsi. In *Japan*,²⁰ the principal antimony deposits extend from the Province of Yamato in Honshu, through Tosa and Iyo in Shikoku, to Hyuga and Osumi in Kyushu.

Africa.—There has been a small production of antimony from the ore deposits—*Southern Rhodesia*²¹—extending from Hartley to Belingive, and from Gwelo to Selukwe. Ore occurs at Octavi in *Damaraland*; and in the *Transvaal* district in a line of hills extending north-east of Leydsdorp. In *Algeria*,²² Djebel Nador, Sidi-Rgheiss, and Senza.

North America.—There are deposits of antimony ore in *Alaska*²³—Fairbanks, Kanti-ohna, and Seward Peninsula. In *Canada*,²⁴ British Columbia, Ontario, Quebec, Yukon, Nova Scotia, New Brunswick. In *Newfoundland*,²⁵ New World Island, Notre Dame Bay. In the *United States*,²⁶ Arizona, Arkansas, California, Idaho, Montana, Nevada, Oregon, Utah, and Washington. In *Cuba*,²⁷ there is a deposit of argentiferous stibnite in the Isle of Pines. In *Mexico*,²⁸ there are mines in the district of Catorce, Charcas, Altar, and Aueretars. There are deposits in Durango; Tlaxiaco, Oaxaca; and Zimapan, Hidalgo.

South America.—In *Argentina*,²⁹ antimony ore occurs at Charillos, and near La Higuera. In *Bolivia*, in the districts of Oruru, Pulacayo, and Portuagete. In *Peru*, Cajamarca, Liberlad, Ancachs, Junin, Huanaco, Huancavelica, Arequipa, Cuzco, and Puno.

Australia.—In *Australia*,³⁰ there are deposits in Queensland—Chillagoe mineral field; Hungary Hill, Neerdee, in the vicinity of Gympie. New South Wales, in a north-east line from Forbes to Buller. Victoria, in the vicinity of Bendigo, Western Australia, West Oilbara, and East Murchison. Tasmania, Mount Bischoff, Mount Zeehan, Heazelwood River, and Table Cape. *New Caledonia*; ³¹*New Zealand*,³² Endeavour Inlet, Marlborough; Waipori, Cromwell, Alexandra, and Mt. Stoker, Otago; Reefton, Greymouth, Westland; Kawau Island; Bay of Islands, and the Thames and Coromandel Districts.

The World's production of antimony ore, so far as data are available, amounted to 24,114 metric tons in 1913; 83,449 metric tons in 1916; 32,283 metric tons in 1918; 23,363½ metric tons in 1920; 17,301½ metric tons in 1921; and 32,000 metric tons in 1926. The results for individual countries are indicated in Table I. The highest price since 1800 was reached in 1906, *viz.* £135 per ton, and

In England, antimony sulphide ore is bought at so much per unit. On April 18, 1916, it was 11s. per unit, less 2·5 per cent. According to H. K. Masters,³³ the penalties are : Lead, up to 0·3 per cent. free, with an allowance to buyers of 5s. per ton of ore for every one-tenth of 1 per cent. over 0·3 per cent. up to 1½ per cent. ; arsenic, 0·1 per cent. free, with an allowance to buyers of 7s. 6d. per ton of ore for every one-tenth of 1 per cent. in excess of 0·1 per cent. up to 0·5 per cent. Should the ore fall below 60 per cent. in antimony content, an allowance to be made to buyers of 3d. per unit down to 55 per cent. If below 55 per cent. and down to 50 per cent. an allowance of 6d. per unit. If above 60 per cent. an allowance to be made to sellers of 3d. per unit. Copper carries the same deductions as arsenic. Zinc and bismuth should not be present in more than traces.

Antimony is common in the arsenical minerals where part of the arsenic is replaced by antimony—*e.g.* A. Carnot,³⁴ D. Campbell, E. Schmid, W. Hampe, and A. Hilger found it in native arsenic, laucopyrite, and arsenical pyrites ; D. Campbell, P. Berthier, T. Petersen, L. Sipöcz, C. F. Rammelsberg, G. Tschermak, C. Winkler, G. T. Prior, F. Sandberger, and C. Bergemann, in arsenical cobalt, and löllingite ; L. Sipöcz, in arsenical nickel ; G. T. Prior, and G. Tschermak, in jordanite, and proustite—*vide* arsenic. L. Sipöcz, W. Petz, and R. Scharizer found antimony in a number of tellurium minerals, thus, he represented nagyadite by the formula $Au_2Pb_{14}Sb_3(S,Te)_{24}$; C. F. Rammelsberg, L. Sipöcz, F. Becke, and W. Hampe, in zinc blende ; F. Sandberger, W. Hampe, D. Forbes, and P. Kröber, in galena ; C. Winkler, T. Petersen, and A. Carnot, in bismuthinite ; W. Hampe, in copper pyrites ; C. Winkler, in argyrodite ; E. Ebler, in ochre ; F. Mauro, in spinel ; F. Sandberger, in rubellan biotite ; and H. Reinsch, in hausmannite. A. Daubrée found 0·03 grm. of antimony per kilogram in the basalt of Kaiserstuhl, and in some coals. As in the case of arsenic, the presence of antimony in many ores explains its occurrence in many commercial metals—thus, W. Hampe found it in zinc, tin, lead, and copper as well as in electrolytic copper ; A. Ledebur, in iron ; S. P. L. Sörensen, in nickel ; T. Poleck, in phosphorus ; E. R. Schneider, in bismuth ; and G. S. Sérullas, and H. Ramage, in the flue-dust of South Yorkshire coals. Arsenic has been found by A. Buchner in a number of commercial antimonial preparations derived from the use of arsenical antimony sulphide.

A. Daubrée found antimony in sea-water ; and D. Campbell, in a number of rivers and streams. The element has also been detected in a number of springs, thermal water, and in the ochreous deposits therefrom by H. de Sénarmont,³⁵ L. F. Bley, T. Poleck, C. R. Fresenius, E. Ludwig and J. Mauthner, H. Will, F. A. Walchner, E. F. von Gorup-Besanez, N. B. Hardin, F. Garrigou, H. von Fehling, and H. Göttl. W. von Gümbel found the sediment from the Bormio spring had 1·27 per cent. of antimonious oxide ; C. R. Fresenius found the ochre of the springs at Driburg contained 0·007–0·009 per cent. Sb_2O_3 ; E. Reichardt, 0·011 per cent. of Sb_2O_3 in that from Liebenstein, Thüringia ; C. P. Williams found 0·021–0·022 per cent. Sb_2O_3 in 10 litres of the waters of the lead mines of Jasper County, Missouri.

§ 3. The Extraction of Antimony

Stibnite is the commonest ore of antimony; senarmontite and ratentinite are the chief ones at Sidi-Rgherss and Senga in Algeria; stibiconite has been mined at El Altar, Sonora, Mexico; kermesite, in Tuscany, Italy; jamesonite, in South Rhodesia, and Ontario; jamesonite, and tetrahedrite, Ourro, Bolivia, and Santa Rosa, Peru; nadorite, at Djebel Nador, Algeria; and livingstonite, and barcenite, at Huitzucó, Mexico. In the last case mercury was once extracted from the ore and the antimony rejected.

The concentration of stibnite by washing with water is costly because the ore is soft, and of a low sp. gr., 4.5. The crushing produces a large proportion of lime which makes the loss so great that the water concentration is then satisfactory only when the precious metals are present in payable quantities. J. Daniels and C. R. Corey¹ found that low-grade stibnite ores can be successfully concentrated by flotation methods. Fine grinding, and the creosote oils with sulphuric acid give the highest yields with the lowest cost of production.

The more important methods for the extraction of antimony from sulphide ores are: (i) Fusion with iron; (ii) Roasting in shaft furnace, and reducing the oxide with charcoal and alkali; and (iii) Electrolysis of the sulphide dissolved in alkali sulphide. The extraction of antimony from its ores is discussed in the usual books on the metallurgy of the non-ferrous metals. In addition there are a few special monographs on antimony:

W. Borchers, *Zinn, Wiemuth, Antimon*, Halle (Saale), 1924; G. D. Traverso, *L'antimonio*, Alba, 1897; A. Guntz, *Antimoine*, Paris, 1884; C. Y. Wang, *Antimony*, London, 1909; J. Oehme, *Die Fabrikation der wichtigsten Antimon-Präparate*, Wien, 1884; G. Hyvert, *Technologie de l'antimoine*, Carcassonne, 1906.

Liquation processes.—Ores containing over 90 per cent. antimony sulphide are considered to be *crude antimony* or *needle antimony*; those containing more than

40 per cent. and less than 90 per cent. can be liquated for the production of crude antimony. This liquation is possible because of the comparatively low melting temp. of the sulphide. Small-grained ore is not suitable for liquation, presumably because the grains are so close together that the molten sulphide is unable to escape. Pieces the size of a walnut are considered most suited for the liquation process. Fine-grained ore with a low percentage of metal is best reduced to regulus. If the temp. of liquefaction be too high, some antimony sulphide is lost by volatilization; and if too low, a relatively large proportion of sulphide is retained by the residue. Since merchants prefer crude antimony with a radiating structure, the liquated sulphide is allowed to cool slowly. If rapidly cooled, the required crystalline structure is not developed. The liquefaction can be conducted in pots or crucibles made of fireclay and perforated at the base to allow the molten sulphide to trickle into a fireclay receiver placed below. The pots can be heated by direct contact with the fuel, or by flames with the receiver inside or outside the furnace. The process is intermittent; the pots require recharging every 10 hrs. In the continuous process of liquation, tubes are fitted over a perforated slab below which is the receiver. The tube is so arranged that the exhausted charge can be raked from the bottom, and a new charge inserted at the top. Continuous liquation is also conducted in reverberating furnaces. There is a tap-hole at the deepest part of the bed of the furnace for the removal of the liquated sulphide. The liquation residues, if sufficiently rich, are worked up for regulus.

Iron reduction process.—The production of metallic antimony or regulus from crude antimony, or from rich ores, with over 60 per cent. antimony, can be effected by the so-called *precipitation process*, or *iron reduction process*: $\text{Sb}_2\text{S}_3 + 3\text{Fe} = 2\text{Sb} + 3\text{FeS}$. As indicated in connection with the history, this method was used in the Middle Ages. It is not possible to separate the iron sulphide from the antimony, and therefore sodium sulphate and carbon must be added. The resulting sodium sulphide forms a fusible slag with the ferrous sulphide which floats on the surface of the antimony. Common salt can be used instead of sodium sulphate and carbon. The iron is introduced in the form of turnings, shavings, or tin-plate cuttings, for the tin they contain does no harm. The proportion of iron is kept low since arsenides and lead sulphides are reduced by the excess, and the antimony is then unduly contaminated, not only with iron, but also with lead and arsenic. With ores free from arsenic and lead, an excess of iron is used in order to ensure the separation of all the antimony in the ore. The excess of iron is removed by subsequent fusion with crude antimony. The process was discussed by P. Berthier,² J. von Liebig, C. J. B. Karsten, E. Hering, C. Schnabel, E. Rodger, T. C. Sanderson, N. C. Cookson, R. Helmhacher, G. Pautrat, A. H. Imbert, N. Baraboschkin, etc.

The operation on a large scale is carried out in crucibles or in reverberatory furnaces. In the crucible process, the metal produced by the reduction with wrought iron is known as *singles*. It contains, maybe, 91.6 per cent. of antimony, about 7 per cent. of iron, and less than one per cent. of sulphur. The singles is mixed with some liquated or crude antimony and common salt, and heated. The operation is called *doubling*. The product is known as *star bowls*, and contains, say, 99.5 per cent. of antimony, nearly 0.2 per cent. each of iron and sulphur. The refining or *frenching* of the star bowls is effected again by heating the metal with liquated sulphide and a flux. The product is known as *star antimony*, or *French metal*. The reverberatory furnace process involves the fusion with scrap iron to produce crude metal, and a refining fusion.

Formerly the metal or regulus obtained by reducing the grey sulphide was called *regulus antimonii simplex* or *regulus antimonii vulgaris*. When the metal was cast in a mould and the upper surface of the ingots had a stellated structure, it was called *regulus antimonii stellatus*, Fig. 2. When the antimony contained much iron, it was called *regulus antimonii martialis*. When the sulphide was reduced with tin, the product was called *regulus antimonii jovialis*; with lead, *regulus antimonii saturninus*; with copper, *regulus antimonii venereus*; and with silver, *regulus antimonii lunaris*.

Reduction processes.—Formerly the grey sulphide was mixed with charcoal and roasted. There remained a mixture of the trioxide and pentoxide called *calx antimonii grisea*, or *cinis antimonii*. This was then mixed with cream of tartar, or with a mixture of charcoal and sodium carbonate and fused in a crucible at a low red-heat. The slag floated on the surface of the metal, which was then cast in a mould. Modifications of the process were described by P. L. Geiger and A. Reimann,³ J. von Liebig, and A. Duflos. Heating the sulphide with lime and carbon does not give good results: $\text{Sb}_2\text{S}_3 + 3\text{CaCO}_3 + 6\text{C} = 2\text{Sb} + 3\text{CaS} + 9\text{CO}$, but C. G. Fink obtained good results in an electrically heated vacuum furnace. A. Levöl reduced antimony sulphide by melting it with twice its weight of potassium ferrocyanide. H. C. Geelmuyden reduced the sulphide with calcium carbide; and N. Tarugi employed this agent with other antimonial compounds. M. G. Bachimont heated the sulphide with ferric chloride and obtained ferrous sulphide and volatile antimony trichloride. A. Germot heated the sulphide to its temp. of dissociation while protected from oxygen; the sulphur was recovered by sublimation. R. Jahn passed the fumes from the roaster through a reducing flame.

Roasting for tetroxide.—Poor ores, and liqation residues can be roasted to the tetroxide or to the volatile trioxide. In the past, the roasting for the tetroxide has been carried out in muffles, or reverberatory furnaces with rabbling. At about 350°, air converts antimony sulphide into antimony trioxide and sulphur dioxide; a part of the trioxide forms the pentoxide, which, uniting with the trioxide forms the tetroxide. In the presence of metal oxides, antimonates are formed; no antimony sulphate is produced. If the ore contains foreign sulphides which, when roasted alone, form sulphates, antimonates are produced in place of the sulphates. According to L. Bidou,⁴ if the temp. of roasting be less than 350°, the sulphide is not decomposed; if it exceeds 350° a little, the mass sinters together, thereby retarding the access of air to the interior of the mass; and if the temp. be raised still higher, the trioxide volatilizes. The rabbling of the mass hinders the sintering. The richer the ore the more difficult it is to roast it in this way because of the tendency to sinter; the presence of gangue hinders the balling or sintering. If the admission of air be restricted during the roasting, the volatile trioxide, not the tetroxide, is formed.

Roasting for volatile trioxide.—In 1844, A. Bobierre, F. A. H. F. de Ruobz and M. Rousseau proposed to obtain antimony trioxide by the volatilization process; and the idea was applied by M. de Franceschi, W. Glass, H. L. Herrenschmidt, J. Oehme, E. Hering, R. Helmhacker, E. Chatillon, J. Woolford, A. S. Plews, E. Rasse-Courbet, and the Miniere e Fonderie d'antimonie Società Anonima, Genoa, Italy. The process was studied by J. A. de Cew. In the volatilization process poor ores and residues from the manufacture of crude antimony can be treated by roasting them in a furnace at a sufficiently high temp. to volatilize the antimony as trioxide, and collect it in suitable chambers. The product contains very little antimony tetroxide, or pentoxide, and is used partly in the preparation of paint, and partly for reduction to antimony by melting it with coal and fluxes. J. Oehme prepared the trioxide for use as paint by roasting the sulphide in a restricted supply of air and steam. The air roasting for the volatile sulphide is effected (i) in E. Chatillon's furnace. This consists of two rectangular cupolas charged with alternate layers of fuel and ore; these cupolas communicate with two smaller cupolas where hot air is produced and where the last traces of antimony trioxide are produced from scoræ. The volatile trioxide is collected in sheet-iron tanks acting as a filtration chamber, or bag-house. The roasting is also effected (ii) in H. L. Herrenschmidt's furnace which consists of a rectangular shaft which is fitted with a step-grate of iron bars. The upper part of the furnace communicates with a series of condensing chambers provided with condensation tubes of corrugated iron. The air and dust is drawn through these chambers by an exhaust fan. Beyond the condensing chamber is a coke-tower down which water trickles so as to arrest the last traces of uncondensed oxide.

Reducing the oxides to regulus.—The products obtained in the roasting of sulphide ores—tetroxide, or volatile trioxide—or the natural oxidized ores are reduced to antimony regulus. Coal alone is unsuitable as a reducing agent because so much antimony is lost by volatilization as trioxide, and any sulphide which has escaped oxidation will also escape reduction. Hence, fluxing agents are added to form a protective cover preventing undue volatilization, to assist in the formation of fusible slags, and to help the separation of the metal from the sulphide. Fluxes like alkali sulphates and carbonates also help to remove impurities from the antimony, and to serve as a refining medium. With rich ores, crude antimony, or the volatilized oxide, when only a small quantity of metal is required, the reduction is carried out in crucibles or pots; the reduction, however, is more economically effected in reverberatory furnaces or in shaft furnaces. The processes were described by E. Hering, L. and G. Simonin, J. Rössner, A. F. Wendt, C. Winkler, C. A. M. Balling, L. A. Pelaton, E. Basse, etc.

The direct reduction of the ore in a blast-furnace.—W. R. Schoeller described a process for the direct smelting of stibnite, slag, and liquation residues containing 25–40 per cent. of antimony. No iron is used in the reduction. The molten sulphide dissolves the trioxide formed in the blast: $2\text{Sb}_2\text{S}_3 + 9\text{O}_2 = \text{Sb}_4\text{O}_6 + 6\text{SO}_2$, and there is then a reaction: $\text{Sb}_4\text{O}_6 + \text{Sb}_2\text{S}_3 = 6\text{Sb} + 3\text{SO}_2$. This self-reduction also occurs during the roasting of lead sulphide ores. The current of sulphur dioxide which is at the same time evolved acts as inert gas in that it does not reduce antimony trioxide, and it takes no active part in the liberation of the metal. The reaction does not occur in an inert gas, for if the oxide-sulphide mixture be melted under a layer of salt, the metal is not obtained. The fused mixture of oxide and sulphide is the so-called *antimony glass*. In order to reduce the loss by volatilization, a tall shaft is required, and it should be connected with a suitable condenser. E. Hering observed that no antimony is formed when a mixture of the sulphide and tetroxide is heated in the roasting furnace, but the mixture forms a red glass; K. Brückner made some observations on this reaction. Water-jacketed furnaces were used by H. L. Herrenschildt, and A. Germot used a converter. R. Jahn described a process in which the volatilized oxide is at once reduced by a reducing gas; and A. P. Hernandez heated the sulphide with carbon and nitrate: $\text{Sb}_2\text{S}_3 + 8\text{KNO}_3 + 6\text{C} = 2\text{Sb} + 3\text{K}_2\text{SO}_4 + \text{K}_2\text{CO}_3 + 4\text{CO}_2 + \text{CO} + 4\text{N}_2$. W. Buddëus reduced the ore with silicon or silicides.

Extraction by lixiviation processes.—Many proposals have been made for the extraction of antimony, from poor ores and liquation products, by wet methods, but none has yet had much success. J. Hargreaves and T. Robinson⁵ extracted the powdered ore with hot hydrochloric acid, neutralized the liquid with lime; and precipitated the antimony with tin or zinc. The precipitated metal was washed, and fused with alkali. R. F. Smith employed a somewhat similar process; and E. Hering treated the hydrochloric acid soln. of liquation residues either with water to precipitate the oxychloride, or with hydrogen sulphide to precipitate the sulphide. J. S. MacArthur treated the pulverized ore with a 2 per cent. soln. of sodium hydroxide at 100°; and passed carbon dioxide through the filtered soln. The precipitated antimony sulphide was collected on a filter, and the alkali carbonate was causticized for further use by the lime from the kiln furnishing the carbon dioxide. The process was therefore continuous. F. Leyser also extracted the ore with alkali-lye. J. Simpson and E. W. Parnell proposed soln. of alkali sulphides as solvent. N. W. Edwards lixiviated the ores with a 7 per cent. soln. of sodium sulphide; the antimony sulphide in the filtered soln. was precipitated by carbon dioxide, and the hydrogen sulphide evolved was used to regenerate calcium sulphide by bubbling it through milk of lime. Any gold or silver in the antimony ore remained undissolved and was recovered by ordinary methods. H. L. Herrenschildt also employed a soln. of sodium sulphide as solvent, but precipitated the antimony sulphide by sulphur dioxide. L. A. Pelaton and D. Lévat reported on this process. F. Kessler, and A. Loir also used sodium sulphide as solvent;

evaporated the filtered soln. to dryness; fused the product, and precipitated the antimony with iron. R. Koepp used a soln. of ferric chloride as solvent for the antimony sulphide: $6\text{FeCl}_3 + \text{Sb}_2\text{S}_3 = 6\text{FeCl}_2 + 2\text{SbCl}_3 + 3\text{S}$. The presence of hydrochloric acid or of halide salts hastens the process of dissolution. The antimony can be readily precipitated from the soln. The antimony was recovered by electrolysis. J. Gitsham used a soln. of alkali cyanide-lye. M. Haremann roasted the ore with alkali carbonate and carbon, and on lixiviating the product with water, lead and the precious metals remained undissolved, while antimony sulphide was precipitated from the soln. by adding sulphuric acid. F. M. Lyte roasted the ore with chlorides and condensed the vapour of antimony chloride in a soln. of common salt. The antimony was precipitated from the liquid by iron or zinc.

Electrolytic processes.—Several methods have been proposed for the extraction of antimony electrolytically, but with no marked commercial success. According to W. Borchers,⁶ low-grade antimony ores can be leached with soln. of sulphides of the alkalis or alkaline earths, to form a soln. of sulphantimonite or sulphantimonate. He found that with the same expenditure of current, the same quantity of antimony is deposited whether the soln. of sulphantimonite or sulphantimonate is used. Hydrogen was liberated along with antimony at the cathode; and at the anode, oxidation products of sodium sulphide, oxygen, sulphur, and antimony sulphide are formed. The reactions occurring during the electrolytic process are not clear; they have been studied by F. W. Durkee, A. Scheurer-Kestner, H. Ost and W. Klapproth, A. Engelenberg, and D. I. Demorest. R. Koepp leached the ore with a soln. of ferric chloride as indicated above, and electrolyzed the soln. at 50° between lead plates. A. G. Betts studied a similar process. E. W. von Siemens and J. G. Halske extracted the ore with alkali sulphides, hydrosulphides, or polysulphides: $3\text{Sb}_2\text{S}_3 + 6\text{NaHS} = 6\text{NaSbS}_2 + 3\text{H}_2\text{S}$. The liquor was then electrolyzed in diaphragm chambers with carbon or platinum anodes, and copper or antimony cathodes. At the cathode, the soln. of hydrosulphide is regenerated, and antimony deposited. E. W. von Siemens also used soln. of magnesium or alkaline earth sulphides as the extraction liquid. Modifications were devised by I. Izart, and J. von der Ploeg. J. H. Vogel, and T. C. Sanderson used as electrolyte a soln. of antimony trichloride and alkali or ammonium chloride, acidified with hydrochloric acid. F. C. Mathers and K. S. Means recommended a soln. of antimony fluoride in water mixed with an excess of hydrofluoric acid, with a small addition of aloin, resorcinol, α -naphthol, β -naphthol, or salicylic acid, as the best electrolyte for the electrodeposition of antimony; and F. von Hemmelmayr, and J. C. Ghosh and A. N. Kappana, a hydrochloric acid soln. of tartar emetic—the last-named added that if oil of bergamot be present, this bath gives a very smooth, uniform white deposit, which on polishing assumes a silvery appearance. Thin deposits of thickness 0.025 mm. have been found to be quite adhesive; this thickness is quite sufficient for plating purposes. High current densities can be employed (50 milliamperes per cm.) and the current efficiency is as high as 97 per cent.—*vide infra*.

J. Lukas and A. Jilek showed that to obtain bright, firmly-adherent deposits of antimony from acid soln., the substance, containing less than 0.3 g. of antimony, is dissolved in 3 c.c. of conc. sulphuric acid; water is added and the soln. treated with 12.5 g. of ammonium citrate, 2 g. of sodium hydrophosphate, and 2 c.c. of hydrazine hydrate, and electrolyzed for 2 hrs. at 70°–90°, using a current of 1 amp. at 1.6–2.1 volts and a rotating anode. If a stationary anode is employed, the electrolysis should be conducted with 0.5 amp. for 3 hrs. The citrate may be replaced by 11 g. of sodium potassium tartrate, but the deposits then obtained are not quite so brilliant. Good deposits are produced also by using ammonium instead of sodium phosphate and neutralizing the soln. (to methyl-orange) with ammonia before adding the hydrazine hydrate.

The refining of antimony.—R. Helmhacker found unrefined antimony prepared by the iron precipitation process had 84.0–94.5 per cent. of antimony; 2.0–5.0 per cent. of sulphur; 3.0–10.0 per cent. of iron; 0.25–1.0 per cent. of arsenic; and traces of gold. That prepared by the reduction of oxidized ores in a shaft-furnace

had 95.0–97.2 per cent. antimony; 0.2–0.75 per cent. sulphur; 2.5–4.0 per cent. iron; and 0.1–0.25 per cent. arsenic. Unrefined antimony contains sulphur, iron, arsenic, copper, and frequently lead. These impurities with the exception of lead can be eliminated partly by oxidizing and slagging agents, and partly by sulphurizing agents, and partly by chlorinating agents. Fusion with alkali, or antimony-glass—*i.e.* antimony oxysulphide—removes sulphur, and converts arsenic with the alkali arsenate. Fusion with antimony sulphide converts copper and iron into sulphides, and the reaction is facilitated by the addition of alkalies or Glauber's salt and charcoal, which form sodium sulphide. These sulphides are removed by antimony glass. Common salt, cryolite, or magnesium chloride volatilize some of the foreign metals as chlorides, and slag others, but at the same time much antimony may be lost by volatilization. The lead can be partly eliminated by the chloridizing agents, but not by the oxidizing or sulphurizing agents since antimony reduces lead from its oxide or sulphide. The refining of antimony is conducted in pot furnaces or in a reverberatory furnace. The refinery slags are treated with the original ore. L. and M. Meyer recovered antimony from its alloys with other metals by adding enough sulphur to form sulphides with all the metals except antimony. The molten antimony can then be separated from the molten sulphides.

R. Helmhacker⁷ studied the purification of antimony by oxidizing agents like manganese dioxide, potassium permanganate, antimony tetroxide and antimony-glass. J. von Liebig purified small quantities of antimony in the following manner:

Fuse in a fireclay crucible a mixture of powdered antimony with one-eighth its weight of sodium carbonate and one-sixteenth its weight of antimony sulphide. The button of metal so obtained is again fused with sodium carbonate for two hours; and a third time with sodium carbonate mixed with a small proportion of potassium nitrate. The sulphur of the antimony sulphide transforms the foreign metals, except lead, into sulphides which dissolve in the scoria. The arsenic compounds form arsenates and sulpharsenates. The nitrate added by J. Schill in the last fusion is to complete the conversion of arsenic with arsenate. If the sample to be purified contains much iron, the proportion of antimony sulphide should be increased. A. Bensch recommended adding iron sulphide to the mixture in cases where the antimony was free from iron, and contained much arsenic. The presence of iron was said to facilitate the removal of arsenic. E. F. Anthon said that the fusions should not be made in carbon crucibles because carbon would reduce arsenates to arsenic.

The subject was discussed by J. A. Buchner, J. A. Buchner and J. E. Herberger, J. F. A. Götting, A. Duflos, T. Martius, C. Meyer, and F. Wöhler. F. Winkler, W. Artus, G. C. Wittstein, and F. Kessler obtained antimony of a high degree of purity by reducing the purified oxychloride with carbon in the presence of alkali; A. Popper reduced the oxychloride with hydrogen. B. Unger purified antimony by first converting it into sodium sulphantimonate. H. Capitaine, F. Kessler, and G. C. Friend and E. F. Smith purified potassium antimonyl tartrate by repeated crystallization, and reduced the product for antimony. T. Martius did not recommend the process. W. P. Dexter reduced sodium antimonate with carbon. J. B. A. Dumas, and J. P. Cooke purified the trichloride by fractional distillation; and F. Mylius and K. Hüttner recommended purifying the pentachloride by first extraction with ether. E. Groschuff examined the different methods used for preparing antimony of a high degree of purity. Technically purified antimony has a higher degree of purity than that obtained by the electrolysis of soln. of antimony sulphide. He recommended the following mode of preparing antimony of a high degree of purity:

Antimony trichloride or pentachloride is purified by distillation, and is then transformed into chlorantimonic acid. This compound is specially adapted to the separation of antimony from all likely metallic impurities. After purification by recrystallization, the chlorantimonic acid is readily hydrolyzed to antimonic acid, which is reduced to metal preferably by melting with potassium cyanide. In a large preparation (about a kilogram) purified in this way, no impurities at all could be detected by qualitative methods.

J. Bongartz, and A. Classen electrolyzed a soln. of a sulphantimonite; and J. B. Alzugaray, a soln. of antimony trichloride. The electro-deposition of antimony has been discussed above. The difficulty is to obtain a deposit which adheres well to

the cathode. The electro-deposition of antimony has also been discussed by many others⁸—*vide infra*, explosive antimony. According to A. Mazzucchelli, the presence of antimony trichloride, tribromide, or triiodide, cannot be prevented by electrolyzing the halide with a soln. containing a colloid. Many colloids, including resorcinol, tannin, molybdic acid, starch, and gum, have no influence on the aspect and properties of the metallic deposit, but the presence of proteins, especially of gelatin, results in the separation of antimony which exhibits increased lustre and fragility and is explosive towards heat, but only slightly so towards shock. Quinine, with which antimony chloride forms a double chloride, sparingly soluble in conc. hydrochloric acid, has an effect similar to that of the proteins; the cationic function of the alkaloid appears to depend on its absorption by the metal. Lowering of the temp. at which the electrolysis takes place renders the metallic deposit pitted and less adherent, owing to an increase in the cathodic evolution of hydrogen. G. F. Taylor described the manufacture of thin filaments of antimony.

The refined metal usually contains over 99 per cent. of antimony, and the surface is covered by a fern-like appearance, Fig. 2. This effect appears only when

FIG. 2.—Star Antimony, or *Regulus antimonii stellatus*.

FIG. 3.—Crystals from a Cavity in Cast Antimony.

the purified molten metal is allowed to solidify slowly beneath a layer of slag. The slag is easily detached from the cold metal by scrubbing with water and sand. This is the commercial *star-metal* or *star-antimony*, and is considered the best quality of refined antimony. Fig. 3 shows some crystals from a cavity in the cast metals. Analyses were quoted by R. Engelhardt,⁹ F. Herz, J. M. M. Dormaar, and A. L. Day, R. B. Sosmann, and E. T. Allen. The main impurities occurring in commercial antimony in appreciable and varying quantities are lead, arsenic, iron, copper, and sulphur. There are also present, in nearly all cases, traces of tin, bismuth, zinc, nickel, cobalt, and other elements; but these impurities are usually present only in negligible quantities, and are rarely included in commercial analysis of the metal. Two of the following analyses are quoted by C. Schnabel; the others have been supplied from private sources.

The commercial brands are "A.S.P.," St. Helen's Smelting Co. (Fig. 2); "C.," and "Tyne," Cookson and Co., Newcastle-on-Tyne; "H.," Hallett and Son, London; "W.C.C.," Wah Chang Trading Corporation, Chang-Sha, China; Lucette Brioude, La Société France-Italienne, Brioude, France. The continental and Chinese brands are very variable in quality. E. A. Smith reported from a trace to 0.0054 per cent. of gold, and 0.008-0.0191 per cent. of silver in star antimony.

§ 4. The Allotropic Forms of Antimony

The ordinary or metallic form of antimony furnishes trigonal or rhombohedral crystals—**trigonal antimony**, or **grey antimony**. G. Rose¹ obtained them by allowing molten antimony to cool in the crucible until a crust had formed on the sides and surface, and after breaking the surface skin, pouring off the molten metal. The sides of the resulting cavity often furnish aggregates of large crystals. J. P. Cooke observed microscopic crystals of antimony are produced when a current of hydrogen and stibine is heated; and J. Durocher, when antimony trichloride is reduced by hydrogen at a high temp. The antimony obtained by electro-position

from various soln. has a crystalline structure—*vide supra*. The *stella antimonii* is produced by the formation of dendritic skeletons during the solidification of the surface layer, and these are thrown into relief by the irregular contraction which occurs during the cooling of the later growth—*vide* Figs. 2 and 3. *Amorphous antimony* is obtained by condensing the vapour of the metal rapidly by contact with a surface cooled by liquid air. According to A. Stock and W. Siebert, and V. Köhlschütter, the effect is due to a deposition of a film, forming minute globules whose size is such that their form is governed by surface tension; similarly with the minute globule obtained by electrical dispersion—sublimation. The properties of ordinary grey antimony are discussed later.

According to E. Cohen and J. C. van den Bosch, when metallic antimony, which has been melted and rapidly cooled, is powdered and examined in a dilatometer, it shows a transition point at about 101° , in agreement with the observation that the sp. gr. of antimony is lowered by heating it for 4 days at 102.5° ; a dilatometer containing antimony which had been heated for 50 mins. at 150° and then examined at 96° showed at first a decrease in vol. followed by a steady increase. It was inferred that at 96° , ordinary antimony is really a mixture of at least three allotropic forms—*vide* 3. 21, 8. E. Jänecke measured the heating and cooling curves of antimony while exposed to a press. of about 3000 kgms., and observed that in 9 mins. the heating curve rose from 80° to 124° ; there was then a break such that in 13 mins. more the temp. was 178° ; the metal cooled from 148° to 137° in $4\frac{1}{2}$ mins. when there was a break, and it then cooled to 111° in $9\frac{1}{2}$ mins. more. These breaks in the two curves at 124° and 137° are taken to represent a transition from an α - to a β -form of antimony. P. W. Bridgman also found a discontinuity in the electrical resistance at about 145° . P. N. Laschtschenko observed no sign of a break on the cooling curve between 680° and 200° .

In virtue of the relationship between the members of this family of elements—phosphorus, arsenic, antimony, and bismuth—G. E. Linck² inferred that an allotropic form should correspond eutropically with yellow phosphorus, and yellow arsenic. A. Stock and O. Guttmann obtained **yellow antimony** by leading a current of air or oxygen into liquid stibine at -90° . The product is very unstable and rapidly changes into ordinary antimony at -50° . The yield of yellow antimony is very small. It is not possible to work at a lower temp. because the stibine freezes at -91° . Purified and dried oxygen has scarcely any action, but if a little ozone be present, the action is faster; if the oxygen contains 2 per cent. of ozone, an explosion occurs. A better yield of the yellow modification of antimony is obtained by the interaction of stibine with a soln. of chlorine in liquid ethane at -100° in red-light: $2\text{SbH}_3 + 3\text{Cl}_2 = 2\text{Sb} + 6\text{HCl}$. The reaction is completed at the temp. of liquid air. The product is not an antimony hydride because under water it passes into a black modification of antimony without giving off hydrogen; and its mode of preparation shows that it does not contain water. The light yellow form of antimony is much more changeable than yellow arsenic; and it blackens above -90° , even in the dark, but more quickly when exposed to light. It dissolves slightly in carbon disulphide at a little above -90° . When yellow antimony, below -50° , is shaken with carbon disulphide, a suspension of insoluble yellow antimony in a colloidal state is produced which above -50° changes in a few seconds into the black modification. H. Staudinger and W. Kreis could not make solid yellow antimony by cooling the vapour to -190° . Yellow antimony probably corresponds with cubic or yellow arsenic.

A. Stock and W. Siebert prepared **black antimony** either by rapidly cooling the vapour of ordinary antimony, or by the action of air or oxygen on liquid stibine at about -40° . The stibine is allowed to evaporate, and freed from oxide by washing it with hydrochloric acid; it is then washed with alcohol, and ether, and dried in vacuo. In the former method of preparation, the metal is distilled from an electrically-heated porcelain tube, at about 300° , in vacuo, and arranged so that the vapour impinges on a surface cooled by liquid air. The black powder appears

to be amorphous ; its sp. gr. is 5.3. It is more volatile than ordinary grey antimony because when the latter is heated in an evacuated glass tube, a mirror of black antimony appears, and afterwards, a mirror of ordinary antimony is formed between the black antimony and the mass being heated. Black antimony is more chemically active than the grey antimony ; it oxidizes and burns in air at ordinary temp. Black antimony is labile at ordinary temp., and at 400°, it passes instantaneously into the grey form ; and in boiling water, the same change occurs more slowly. A. Stock and W. Siebert said that the black antimony obtained by R. Böttger by reducing a soln. of antimony trichloride with aluminium ; and by P. Lebeau, by treating antimonial magnesium with hydrochloric acid, or antimonial sodium with water is a mixture of black and grey antimony. The same remark probably applies to the black powder produced by H. N. Warren by the action of zinc, aluminium, tin, or iron on a soln. of a salt of tervalent antimony—*vide infra*, explosive antimony. Black antimony probably corresponds with monoclinic black arsenic.

G. Gore³ discovered that when a hydrochloric acid soln. of antimony trichloride is electrolyzed with a feeble current, with a copper or platinum cathode, and antimony anode, a form of antimony—**explosive antimony**—is obtained with very peculiar properties. G. Gore used a 17 per cent. soln. of antimony trioxide in hydrochloric acid of sp. gr. 1.12 ; R. Böttger, a 33 per cent. soln. of antimony trichloride in hydrochloric acid ; and F. Pfeifer said that the soln. may have a conc. between 22 and 60 per cent. of antimony trichloride, and a current density between 0.043 and 0.2 ampère. A soln. containing 7 per cent. of antimony trichloride gave only ordinary crystalline antimony with both strong and weak currents ; and soln. with over 60 per cent. of the chloride were bad conductors. E. Cohen and W. E. Ringer obtained explosive antimony with soln. containing between 10 and 86 per cent. of antimony trichloride at 15°. Wide variations in the proportion of hydrochloric acid present were found by F. Pfeifer, A. Popper, and E. Cohen and W. E. Ringer to have little influence on the result ; similarly also with variations of temp. M. y Hernandez said that the current from one Leclanché cell gave the explosive antimony, but that with two such cells, ordinary antimony was deposited ; and R. Böttger added that if the anode is separated from the cathode by a porous cell, no explosive antimony is deposited. G. Gore obtained an *antimony tree*, consisting of branches of amorphous and crystalline nodules, by suspending a horizontal copper wire as cathode on the surface of the trichloride soln. He also found that if the electrolyte is of unequal density, from long-continued working and neglected stirring, and the receiving surface rough or unclean, the smooth deposit of explosive antimony will appear in the lower and denser part of the liquid, while a warty deposit of ordinary antimony will be formed in the upper and lighter part of the liquid. G. Gore obtained explosive antimony by the electrolysis of a soln. of one part antimony trichloride and 3–4 parts of potassium antimonyl tartrate in water and from hydrochloric acid soln. of antimony chloride in the presence of ammonium chloride, or, according to R. Böttger, in the presence of sodium chloride, but A. Bertrand did not obtain explosive antimony by using soln. containing ammonium salts. G. Gore also obtained explosive antimony from hydrobromic acid soln. of antimony tribromide, and hydriodic acid soln. of antimony triiodide. E. Cohen and W. E. Ringer obtained explosive antimony from soln. with 4.3–68.4 per cent. of antimony tribromide. Soln. of antimony trifluoride were found by G. Gore, and E. Cohen and W. E. Ringer to give ordinary, crystalline antimony. According to F. Pfeifer, and A. Popper, the quantity of antimony deposited by the current, from soln. of the trichloride, is proportional to the quantity of silver deposited in the voltameter with the same current. This ratio was independent of the conc. of the antimony trichloride enclosed in the deposited antimony. E. Cohen and co-workers found that the influence of temp. and of the conc. of the hydrochloric acid are negligible ; but the ratio Sb : Ag increases with the conc. of the trichloride in the electrolyte ; thus, as the conc. rises from 2.3 to

83.3 per cent., the electrochemical eq. of the antimony appears to rise from 40.29 to 40.63. A similar increase was found with soln. of antimony trichloride in methyl alcohol, and of the tribromide and trifluoride in water. According to H. N. Warren, when a zinc rod wrapped in a few coils of asbestos-paper is dipped into a soln. of antimony trichloride, containing enough tartrate to prevent the precipitation of basic salts, part of the antimony is deposited in crystals on the asbestos, and part falls as an amorphous black powder of explosive antimony.

The explosive antimony is always associated with combined or occluded antimony halide. G. Gore said that explosive antimony contains about 6 per cent. of antimony chloride; R. Böttger, 3.03–5.8 per cent.; and F. Pfeifer, 4.8–7.9 per cent. E. Cohen and W. E. Ringer found that a minimum proportion of antimony halide must be present before the antimony acquires its explosive properties. If much less than 3 per cent. is present, the electro-deposit is no longer explosive. Besides antimony trichloride, F. Pfeifer found small quantities of hydrogen chloride and water are present, and E. Cohen and W. E. Ringer observed that other substances—sulphuric acid, and ammonium chloride—may be mechanically entangled

FIG. 4.—Relation between the Concentration of the Electrolyte and the Composition of the Deposited Metal.

in the deposit of antimony during electrolysis. R. Böttger, H. Reckleben and J. Scheiber, and F. Pfeifer observed no occluded hydrogen in explosive antimony; the reducing action which it exercises on potassium ferricyanide was attributed by the latter to the antimony trichloride, not to hydrogen. H. Reckleben and J. Scheiber found only traces of free chlorine in explosive antimony. The halide is not mechanically associated with antimony because, said E. Cohen and W. E. Ringer, a mixture of ether and alcohol does not remove the halide from explosive antimony in the finest state of subdivision; and because, said G. Gore, the powdered substance does not redden moist litmus paper. According to F. Pfeifer, the amount of antimony trichloride associated with the explosive antimony increases with the conc. of the soln., with a rise of temp. and with a decrease in the current density. E. Cohen and W. E. Ringer found that the influence of the current density is small but recognizable; while under constant conditions—15°, and current density 0.2–0.3 amp.—the relationship between the conc. of the soln. and the proportion of antimony trichloride by the deposited antimony is:

SbCl ₃ in soln.	3.08	8.06	11.92	18.07	33.05	55.35	86.70
SbCl ₃ in deposit	1.64	1.82	4.82	5.35	6.75	8.24	10.51

The conc. of the trichloride in soln. and deposit are expressed as percentages. The curve obtained by plotting these numbers is discontinuous, Fig. 4, near the point corresponding with a 10 per cent. soln. of the trichloride—the metal deposited from soln. with a smaller proportion of the trichloride is non-explosive. As the temp. is raised, the proportion of the halide retained by the metal decreases as follows:

	0°	30.0°	50.3°	93.5°	0°	30.0°	50.5°	96
SbCl ₃ in deposit	3.81	1.76	1.90	0.17	5.22	5.54	2.64	0.76
SbCl ₃ in soln.	15.6				21.24			

It will be observed that the metal deposited from a 15.6 per cent. soln. at 30° is non-explosive, while that deposited from a 21.24 per cent. soln. at the same temp. is explosive.

G. Gore favoured the hypothesis that explosive antimony is formed by the “comparatively feeble” union of the antimony *in statu nascendi* “with the elements of the electrolyte, in an indefinite and somewhat variable proportion.” He added that “another explanation which has nearly an equal weight of evidence

in its favour, is that the antimony is deposited in the amorphous state, and the chloride or other salt is enclosed with it mechanically in the process of deposition, and that the change consists in the assumption by the metal of the crystalline state, whereby it is converted with an inconceivable number of crystals of insensible size and the imprisoned salt is set free." E. Jordis assumed that explosive antimony is an alloy of antimony with an unknown metallic form of chlorine which when converted with the metalloid form produces an explosion; antimony trifluoride does not give an explosive compound because fluorine has no tendency to form a metallic modification. According to E. Cohen and T. Strengers, explosive antimony is to be regarded as a solid soln. of antimony trichloride, tribromide, or tri-iodide in a metastable form of the metal, referred to as α -antimony. The explosion is the transformation of this α -antimony into ordinary antimony, and the heat of transformation amounts to about 20 cal. per gram. Explosive antimony and non-explosive electrolytic antimony are simply solid soln. of the trichloride, tribromide, or tri-iodide in ordinary antimony. The α -antimony is to be regarded as a monotropic form, for it has been observed that a soln. which ordinarily deposits explosive antimony on electrolysis will deposit the stable form if the latter acts as cathode in the soln. A. Stock and W. Siebert suggested that their black modification of antimony is the same as E. Cohen and T. Strengers' α -antimony. J. Böhm showed that the X-radiogram of explosive antimony shows no crystalline structure; but after it has exploded the product is crystalline.

Explosive antimony is an example of *monotropic allotropy*; for it is in an unstable form at all temp., and the change is not reversible. Other examples are graphite, and the diamond. G. Gore said that explosive antimony has the colour of polished steel, and its fracture is amorphous, smooth, conchoidal, and waxy; F. Pfeifer added that under the microscope the fracture does not show the slightest trace of a crystalline structure. G. Gore said that the texture of explosive antimony is soft and weak, that of ordinary grey antimony is hard and strong. The amorphous metal files easily, the grey with more difficulty. The grey metal, if struck by a hard substance, emits a clear metallic sound, whilst the dark variety gives a more dull tone. The crystallization lines of grey antimony are at right angles to the receiving surface; and, in several experiments where antimony was deposited upon magnets, the direction of those lines did not seem to be altered by the magnetism. The amorphous variety, if gently struck by a hard substance, undergoes a *rapid and intense change* throughout its mass, attended by development of considerable heat; the crystalline kind undergoes no such change, apparently under any circumstances. The change appears to be mol. in its character; and according to this view the crystalline variety of metal must be regarded as being in a state of comparatively stable mol. equilibrium. Fumes of antimony trichloride are evolved during the explosion. The explosion can be produced by scratching the metal, by friction, by contact with a red-hot wire, by an electric spark, or by warming it to about 125°. When gradually heated under water to 100°, or immersed in boiling water, no change could be observed. Explosive antimony can be powdered by trituration under water at 12°, but when scratched under water at 10°, R. Böttger found that an explosion occurs and the water becomes turbid owing to the formation of the oxychloride. E. Cohen and W. E. Ringer found that thin pieces can be pulverized without explosion at ordinary temp. but thick pieces should be cooled to the temp. of solid carbon dioxide. According to G. Gore, light has no action, and specimens showed no perceptible change when kept for a couple of years. If gradually warmed specimens may lose their explosive property, and then they react acid to litmus, and impart a turbidity to water. F. Pfeifer said that the sp. gr. of explosive antimony is smaller the more antimony trichloride it contains; G. Gore gave 5.74-5.83 for the sp. gr.; F. Pfeifer, 5.64-5.907. E. Cohen and T. Strengers observed that the monotropic change of explosive into ordinary antimony is attended by a decrease in vol. of 0.0047 c.c. per gram with a sample containing 5.17 per cent. SbCl_3 . The formation of a solid soln. of ordinary antimony with this amount of antimony

trichloride is attended by a vol. increase of 0.58 c.c. per gram. G. Gore gave 0.06312 for the sp. ht. of explosive antimony, and 0.0543 for the same substance after it had exploded. According to L. von Pebal and H. Jahn, the sp. ht. of explosive antimony between -21° and -75° is 0.0540; between 0° and -21° , 0.0516; and between 0° and 38° , 0.0559. The heat of the explosion was found by L. von Pebal to be 21 cal. per gram; E. Cohen and T. Strengers gave 19.4 cal. per gram, and found that the difference in the heat of reaction between a gram of ordinary and explosive antimony with a soln. of bromine in carbon disulphide, amounts to 19.6 cal. G. Gore found that explosive antimony is electropositive to the crystalline variety when immersed in dil. phosphoric, sulphuric, hydrochloric, and nitric acids; and in aq. soln. of ammonia, potassium hydroxide, sodium carbonate, or ammonium chloride. Explosive antimony is thermoelectrically positive to ordinary antimony. E. Cohen and T. Strengers found that the cell $+Sb_{\text{grey}} | 18 \text{ per cent. soln. } SbCl_3 | Sb_{\text{explosive}}^-$ is 19.4 millivolts. Both explosive and ordinary antimony were found by G. Gore to acquire a coating of dendritic crystals of silver by immersion in a soln. of silver nitrate. The varieties of explosive antimony prepared from soln. of antimony tribromide and triiodide had properties analogous to those of the product obtained from the trichloride.

According to F. Hérard,⁴ when antimony is heated to dull redness in a current of nitrogen, the greenish vapour condenses on the cool parts of the tube in agglomerations of small spheres. This form of antimony is said to melt at 614° , and to have a sp. gr. of 6.22 at 0° , whereas ordinary antimony melts at 440° , and has a sp. gr. 6.73. The fact that this variety of amorphous antimony is not produced by heating antimony in a current of hydrogen is explained by assuming that, in nitrogen, a nitride is formed which decomposes in the cooler parts of the tube. According to E. Cohen and J. Olie, the phenomena described by F. Hérard are not to be observed when pure antimony and pure nitrogen are used. If, on the other hand, the nitrogen is insufficiently purified, these phenomena are reproduced. What F. Hérard described as "amorphous antimony" appears to be nothing else than the ordinary stable antimony contaminated with more or less trioxide.

According to A. Gutbier and N. Kräutle,⁵ **colloidal solutions of antimony**, prepared by the action of sodium hyposulphite on a soln. of potassium antimonate acidified slightly by the addition of tartaric acid, have their stability considerably increased in presence of the extract of *Tubera salep*. The dialyzed soln. may be evaporated to give solid colloids containing about 10 per cent. of antimony which dissolve completely in water. The stability of the protected soln. is not affected by the addition of acids and neutral salts, but alkalinity reduces the stability to a large extent. A. Gutbier and co-workers obtained the colloid by reducing a fine suspension of antimony trichloride in water by means of titanous chloride. G. Wegelin obtained colloidal antimony by a prolonged grinding in an agate mortar. E. Fouard obtained the colloid by electrolyzing a soln. of a salt of the metal containing a pure organic colloid (albumin, starch, or gelatin) with a current of a few milliampères. At the cathode the metal ions are neutralized by the repelled negatively-charged colloid micelles. A colloidal organo-metallic complex is thus formed. The anode is separated by immersion in a collodion cell rendered semi-permeable by precipitated copper ferrocyanide. The cathode should be a bad conductor so as to reduce the frequency with which formation of the complex occurs on the cathode. T. Svedberg obtained a colloidal soln. of antimony in isobutyl alcohol by suspending a thin foil of antimony in liquid and using electrodes of iron or aluminium with a potential difference of 110 volts, and a current density so small that it can scarcely be measured by an ordinary ammeter—3. 23, 10. The soln. is brownish-red in transmitted light, and black in reflected light. It can be kept for 24 hrs. T. Svedberg also prepared a colloidal soln. of antimony in ethyl ether by connecting a glass condenser of 225 sq. cm. surface with an induction coil and attaching the secondary poles to the electrodes, which are immersed in the liquid contained in a porcelain dish. The antimony is used in a granular form or as wire clippings. When the current is passed, sparks play between the metal particles, and in the course of a few minutes dark-coloured soln. are obtained. These contain

no large particles and hence need not be filtered. Colloidal soln. of magnesium, zinc, aluminium, tin, antimony, iron, nickel, and even alkali metals in ether have been obtained. S. S. Bhatnagar and co-workers found that sols of gold or silver are photosensitive in association with antimony trisulphide.

§ 5. The Physical Properties of Antimony

Antimony is a tin-white, or silver-grey crystalline mass, as indicated above; the colloid, in transmitted light is brownish-red. G. E. Linck¹ said that the green vapour of antimony is probably finely-divided cubic antimony. According to F. Hérard, the vapour is grey. R. J. Haüy supposed that native antimony occurs in octahedral and dodecahedral **crystals** belonging to the cubic system, but F. Mohs showed that they are trigonal. The crystals were described by C. M. Marx, F. Hessel, F. C. L. Elsner, G. W. Zenger, O. Mügge, G. W. A. Kahlbaum, J. W. Retgers, F. A. Römer, C. W. C. Fuchs, F. Fouqué and A. Michel-Lévy, C. F. Rammelsberg, H. C. H. Carpenter, etc. G. Rose gave for the axial ratio $a : c = 1 : 1.3068$; and H. Laspeyres, $1 : 1.32362$. **Twinning** occurs about the (0112)-plane in complex groups—fourlings, sixlings, and polysynthetic. O. Mügge produced lamellæ about the (0112)-plane by percussion or pressure. H. Laspeyres said that the (0001)-**cleavage** is perfect; (0112)-, distinct; (0221)-, sometimes distinct; and (1120)-, indistinct. M. L. Huggins studied the relation between the cleavage and the electronic structure. I. V. Obreimoff and L. V. Schubnikoff obtained large single crystals of antimony when the molten metal is contained in a capillary tube, or in a vessel with a capillary exit below, and is cooled from below. Crystallization starts at a single centre in the capillary and extends uniformly throughout, producing a single individual with the external shape of the containing vessel. G. Tammann and Q. A. Mansuri studied the **velocity of crystallization** of molten antimony. W. H. and W. L. Bragg concluded that the atoms of antimony are

arranged like those in the diamond, but with the whole structure distorted along the trigonal axis; but **X-radiograms** by R. W. James and N. Tunstall, showed that the atoms of antimony lie in two interpenetrating face-centred lattices. If for one of the lattices diagonals are drawn parallel to the trigonal axis for each of the eight equal rhombohedral cells into which the unit lattice may be divided, from considerations of symmetry, the atoms of the second lattice must lie in these diagonals; if they lay at the unoccupied corners of the first lattice, the structure would become a simple rhombohedron. This is not in accord with the facts, but if the atoms of the second lattice are all displaced from these corners along the diagonals in the

FIG. 5.—Arrangement of the Eight Atoms in a Unit Rhomb of the Space-lattice of Antimony.

same direction by a distance equal to 0.074 of the length of the diagonal of one of the small cells, all the facts are explained. For the sake of clearness, only one of the small cells is shown in Fig. 5. According to A. Ogg, the edge of the unit antimony rhomb is 6.20 Å., and the shortest distance between two atoms 2.92 Å., and the longest distance 3.37 Å.; $\alpha=86^\circ 58'$. M. L. Huggins made some observations on the electronic structure—*vide* arsenic, Table II, 9. 51, 5; and for the polymorphism of phosphorus, arsenic, antimony, and bismuth, *vide* arsenic, Tables III and IV, 9. 51, 5. P. P. Ewald and C. Hermann collected data respecting the polymorphism of antimony; and the subject was discussed by P. Möller, G. Linck and H. Jung, F. Roll, and R. Neumann. The fracture of antimony

depends on the rate of cooling, and on the purity of the metal. If rapidly cooled, the fracture is granular, and if slowly cooled, flaky. E. Bekier found the ratio of the spontaneous crystallizing power to the linear velocity of crystallization increases with the velocity of cooling; the number of crystallites in a given area increases with the degree of undercooling from 600° to -70° . The size of the crystallites increases at a low temp. The spontaneous crystallizing power thus diminishes, and it is possible that with sufficient undercooling the antimony might be obtained in an amorphous condition, as in the black antimony obtained by condensing its vapour or by oxidizing hydrogen antimonide at -40° . J. A. M. van Liempert discussed the production of single crystals.

The **specific gravity** of native antimony ranges from 6.6 to 6.8—A. Breithaupt² gave 6.6101; A. Eschka, 6.20; F. Mohs, 6.646; G. A. Kenngott, 6.62–6.65; G. F. Kunz, 6.606–6.693; M. J. Brisson, 6.702; and J. F. L. Hausmann, and M. H. Klaproth, 6.720. P. van Muschenbrock's, and T. Bergman's values are rather high, being respectively 6.852, and 6.860. C. J. B. Karsten gave 6.7006 for the sp. gr. of ordinary antimony; C. Hatchett, 6.712; J. Dalton, 6.7–6.8; G. W. Wertheim, 6.697; R. F. Marchand and T. Scheerer, 6.715 at 16° ; W. P. Dexter, 6.6987 to 6.7102, or the mean of three determinations: 6.705 at 3.75° . A. Matthiessen gave 6.713 at 14° ; H. G. F. Schröder, 6.697 at 3.9° in vacuo; J. P. Cooke, 6.6957 to 6.7070 with the average of six determinations, 6.7022; H. Fay and H. E. Ashley, 6.693; E. Maey, 6.67 at $17.5^\circ/4^\circ$; H. G. Dorsey, 6.88 at 20° for cast antimony; F. Winkler, 6.7137 at $4^\circ/4^\circ$; R. von Dallwitz-Wegner, 6.62; and W. Gaede, 6.627. I. I. Saslowsky gave 6.690 for the sp. gr. at room temp., and 18.0 for the at. vol. C. del Fresno studied this subject. W. Herz estimated the sp. gr. of antimony at -273° to be 7.59. According to R. F. Marchand and T. Scheerer, subjecting antimony to a press. of 75,000 kgrms. per sq. mm. makes no appreciable difference to its sp. gr., since a sample before compression had a sp. gr. 6.715, and after, 6.714; on the contrary, W. Spring noticed a marked difference, for a sample not compressed had a sp. gr. 6.675 at 15.5° ; after one compression at 20,000 atm. the sp. gr. was 6.733 at 15° ; and after two compressions, 6.740 at 16° . G. W. A. Kahlbaum and co-workers also found that antimony cast in a mould has a sp. gr. 6.690 at $20^\circ/4^\circ$; antimony distilled in vacuo, 6.61781 at

$20^{\circ}/4^{\circ}$, and after compression at 10,000 atm., 6.6909 under the same conditions. T. M. Lowry and R. G. Parker found the sp. gr. of antimony *en masse* is 6.6908, and in the form of filings 6.6585. E. Cohen gave 6.678 at $25^{\circ}/4^{\circ}$ for the sp. gr. of antimony which had been cast and then annealed at 102.5° . T. M. Lowry said that the sp. gr. is increased by annealing at 100° . According to F. Nies and A. Winkelmann, the sp. gr. of antimony is greater in the liquid state than when solid, at the same temp., though C. M. Marx said that antimony does not expand on freezing. M. Toepler said that there is a 1.4 per cent. contraction when antimony fuses at the m.p. L. Playfair and J. P. Joule gave 6.529–6.646 for the sp. gr. of liquid antimony; G. Quincke, 6.620 for the sp. gr. at 0° , and 6.528 for the molten metal. J. M. Guinchant and H. Chrétien found the sp. gr. to be 6.75 at 13° ; 6.55 at 698° ; and 6.45 at 1156° ; L. L. Bircumshaw gave 6.49 at 640° ; 6.45 at 700° ; 6.38 at 800° ; and 6.29 at 970° ; and P. Pascal and A. Jouniaux gave 6.55 at 631° ; 6.48 at 800° ; 6.36 at 1000° . J. J. van Laar calculated b of J. D. van der Waals' equation, 0.00250; $\sqrt{a}=0.089$; and the valency attraction A , $\sqrt{A}=34$. R. M. Bozorth calculated the **atomic radius** of antimony to be 1.57 Å. when that of oxygen is 0.65 Å. W. L. Bragg gave 1.40 Å. for the at. radius; E. N. Gapon, 1.79 Å.; M. L. Huggins, 2.58 Å.; and W. F. de Jong and H. W. V. Willems, 1.34 Å. H. G. Grimm made observations on the ionic radius.

V. Meyer and H. Biltz³ measured the **vapour density** of antimony and found 12.31 (air unity) at 1437° ; 10.74 at 1572° ; and 9.78 at 1640° —when the value calculated for Sb_3 is 12.43; and that for Sb_2 is 8.29. According to H. von Wartenberg, antimony has monatomic molecules at 2070° . J. M. Guinchant and H. Chrétien found the **molecular weight** of antimony in melted antimony trichloride is 113; and from the effect of antimony on the f.p. of cadmium, C. T. Heycock and F. H. Neville inferred that the molecules are monatomic; and with lead in place of cadmium, diatomic. A. Jouniaux found that calculations based on Trouton's rule agree with the assumption that antimony is monatomic between the m.p. and the b.p., while the b.p. of antimony amalgams show that antimony is monatomic at 357° , but the effect of antimony on the f.p. and b.p. of iodine indicate a polymerization at lower temp.

The **hardness** of antimony on Mohs' scale is 3.0 to 3.5, so that the metal is a soft one. J. R. Rydberg⁴ gave 3.0 for the hardness. P. Ludwik found the pressure hardness with a load applied for 300 seconds at 17° , 64.4; at 51° , 45.6; at 140° , 26.5; at 262° , 14.8; at 306° , 10.0; at 445° , 4.05; and with a load applied for 15 seconds at 17° , 73.0; 20° , 72.8; at 49° , 58.1; at 81° , 45.0; at 128° , 35.2; at 201° , 22.5; at 298° , 14.4; at 434° , 6.20; and at 448° , 5.85. C. A. Edwards and A. M. Herbert gave 58.0 for Brinell's hardness number; F. Sauerwald gave 125.6 at 13° ; 105.1 at 113° ; 87.3 at 212° ; 67.5 at 313° ; 45.3 at 412° ; and 28.9 at 514° . The subject was also studied by F. Sauerwald and K. Knehans. K. Honda and R. Yamada studied the abrasive hardness. The metal is brittle, easily pulverized, and, when compressed, W. Spring found that it takes on its former lustre. C. I. Burton and W. Marshall observed that there is a rise of temp. of 0.248° when the metal is subjected to a press. of 300 atm.; and a fall of temp. of 0.191° when the press. is suddenly released. T. W. Richards gave 2.4×10^{-6} for the average **compressibility** of antimony between 100 and 500 megabars at 20° . P. W. Bridgman found with antimony cooled slowly in graphite, at 30° , $\delta v/v_0 = -10^{-7}(14.69 - 6.2 \times 10^{-5}p)p$; and at 75° , $-10^{-7}(14.80 - 6.3 \times 10^{-5}p)p$; while for another sample rapidly chilled in iron, at 30° , $-10^{-7}(20.41 - 12.9 \times 10^{-5}p)p$; and at 75° , $-10^{-7}(20.50 - 12.9 \times 10^{-5}p)p$. He also found for the compressibility of simple crystals over the range 12,000 kgrms. per sq. cm.; he found $26.99 \times 10^{-7}p - 31.6 \times 10^{-12}p^2$ at 30° ; and $26.55 \times 10^{-7}p - 25.3 \times 10^{-12}p^2$ at 75° . P. W. Bridgman gave for the compressibility, β , of two samples at 30° , 0.0_51469 and 0.0_42041 ; $\delta\beta/\beta\delta p = 0.0_584$, and 0.0_4126 ; and $-\delta\alpha/\alpha\delta p = 0.0_561$, and 0.0_575 , where α denotes the coeff. of thermal expansion. L. H. Adams gave $\delta\beta = -0.65$. E. Madelung and R. Fuchs gave for the compressibility 0.84×10^{12} dynes per sq. cm.

P. W. Bridgman found the **modulus of elasticity**, or **Young's modulus**, for antimony wires to be 7.8×10^{-11} c.g.s. units, and the **rigidity**, 2.0×10^{-11} c.g.s. units—the magnitude is thus of the same order as for ordinary glass. With the compressibility 2.4×10^{-12} c.g.s. units, **Poisson's ratio** becomes 0.18—a value which is probably far too low. He also measured the elastic constants of single crystals. B. MacNutt and A. Concilio measured the load at which a noise was heard in stressed antimony. W. Widder studied the relation between the elastic modulus, the temp., and the m.p. E. Jänecke observed a discontinuity in the press.-temp. curve at 124° – 137° . G. Quincke found the **specific cohesion** to be $a^2 = 9.90$ sq. mm., and the **surface tension**, 317.2 dynes per cm. G. Drath and F. Sauerwald gave :

	750°	800°	900°	1000°	1100°
α^2	11.79	11.71	11.63	11.54	11.44 sq. mm.
σ	368	367	361	355	348 dynes per cm.

and for the temp. coeff. $d\sigma/d\theta = -0.063$. Observations were made by Y. Matuyama. R. von Dallwitz-Wegner calculated for the **cohesion pressure**, 167,184 atm. at 0° , and 130,543 at 100° . L. L. Bircumshaw gave for the surface tension, 350 dynes per cm. at 640° ; 348, at 700° ; 346, at 800° ; and 342, at 970° ; for the sp. cohesion a^2 per sq. cm., 0.1100, at 640° ; 0.1103, at 700° ; 0.1105, at 800° ; and 0.1111, at 970° ; and for the surface energy, 2605 dynes per cm. at 640° ; 2619, at 700° ; 2634, at 800° ; and 2663, at 970° . The temp. coeff. of the surface tension is -0.02 . A. Saito and K. Hayashi measured the fluidity of molten antimony. A. Bienias and F. Sauerwald found the **viscosity** of antimony, η grms. per cm. per sec., to be :

	702°	801°	900°	1002°
η	0.01296	0.01113	0.00999	0.00905

H. Kopp⁵ found the cubical coeff. of **thermal expansion** to be 0.000033 between 12° and 13° and 41° to 43° . A. Matthiessen gave for the vol., v , at θ° , between 0° and 100° , $v = v_0(1 + 0.00002770\theta + 0.07397\theta^2)$; and for the coeff. of linear expansion, 0.05976 at 20° ; and F. C. Calvert and co-workers made some measurements of this constant. According to H. Fizeau, the linear coeff. of crystals parallel to the chief axis is 0.041692 at 40° ; and 0.041683 at 50° ; perpendicular to the chief axis, 0.05882 at 40° , and 0.05895 at 50° ; while the average value is 0.041152 at 40° , and 0.041158 at 50° . M. de Hemptinne gave 0.041150 for the coeff. of expansion of antimony highly purified. R. von Dalwitz-Wegner gave for the coeff. of cubical expansion 0.04277 at 0° and 0.04356 at 100° . H. G. Dorsey gave for cast antimony of sp. gr. 6.88 :

	-170°	-150°	-130°	-110°	-90°	-50°	-10°	10°
α	0.05747	0.05791	0.05841	0.05886	0.05913	0.05956	0.05988	0.06109

A. Schrauf found the ratio of the expansion coeff. for the directions $a : c$ to be as 3 : 2. P. Braesco gave for the linear coeff. between 100° and 300° , 0.0593; and E. Grüneisen, 0.041088 between 17° and 100° , and 0.041022 between 17° and -190° . S. Lussana found between 9° and 72° , 0.041177 at 1 atm. press.; 0.041097 at 1000 atm.; and 0.041055 at 2000 atm. press. For single crystals at room temp. P. W. Bridgman found the coeff. of thermal expansion to be 15.56×10^{-6} when parallel, and 7.96×10^{-6} when perpendicular to the chief axis. According to A. Matthiessen, if the **thermal conductivity** of silver is 100, that of antimony is 26.5. A. Berget found the coeff. of thermal conductivity, k , in absolute units to be 0.042; L. Lorenz, 0.0442 at 0° , and 0.0396 at 100° . G. Gehlhoff and F. Neumeier gave for the metal in the form of compressed powder, 0.0328 at -80° , 0.0290 at 0° , and 0.0250 at 100° ; and for cast electrolytic antimony, 0.106 at -190° , 0.0628 at -77° , 0.0538 at 0° , and 0.0515 at 100° . A. Eucken and co-workers gave 0.0593 at -190° , 0.0445 at -77° , and 0.0381 at 0° . S. Konno obtained :

	0°	100°	200°	300°	400°	500°	600°	650°	700°
k	0.045	0.040	0.038	0.040	0.043	0.048	0.057	0.052	0.050

S. Lussana found the thermal conductivity to be 3.65 per cent. greater at 1500 atm., and 6.34 per cent. greater at 3000 atm than at 1 atm. S. Lussana found that the relation between pressure and thermal conductivity is not linear since the coeff. at atm. press. is $+0.0_5251$, and at 3000 atm., $+0.0_5164$. P. W. Bridgman, on the other hand, found the thermal conductivity decreases with press., and the press. relation to be linear with the coeff. -0.0_421 —a value larger than that for any other metal except bismuth. E. Jannetaz found the sq. root of the ratio of the thermal conductivity in the direction of the base to that in the direction of the chief axis to be 1.591. The thermal conductivity of fine-grained crystals of antimony, 1.41×10^{-4} sq. cm., at -183° and at 0° was found by A. Eucken and O. Neumann to be respectively 0.1925 and 0.1716 watts per cm. per degree; for another sample, 2.27×10^{-4} sq. cm., 0.2025 and 0.1716 watts per cm. per degree respectively; for medium-sized grains, 6.35×10^{-4} sq. cm., 0.2205 and 0.1820 watts per cm. per degree respectively; and for coarse-grained crystals, 0.143 sq. cm., 0.4519 and 0.2452 watts per cm. per degree respectively. Thus, the heat conductivity decreases as the size of grain decreases. It is assumed that the heat-conductivity is composed of a true metallic conductivity, and a non-metallic conductivity due to the crystal structure, and in the limit with extremely fine-grained material, only the metallic conductivity comes into play.

P. L. Dulong and A. J. Petit⁶ found the **specific heat** of antimony to be 0.0507; H. V. Regnault gave 0.05078 between 12° and 97° ; E. Bède, 0.04861 between 13° and 106° ; and 0.04989 between 15° and 27.5° or $c=0.0466+0.000020\theta$; H. Kopp, 0.0518 between 0° and 100° ; R. Bunsen, 0.0528 between 0° and 100° ; L. Lorenz, 0.05162 at 0° ; 0.05174 at 50° ; 0.05070 at 75° ; L. von Pebal and H. Jahn, 0.0495 between 0° and -76° , and 0.0499 between -21° and -76° ; A. Naccari, 0.05004 from 15° to 99° ; 0.05027 from 18° to 172° ; 0.05070 from 22° to 251° ; and 0.05157 from 21° to 322° —or $0.048896+0.016718(\theta-15)$; P. Schübel, 0.0502 between 18° and 100° ; 0.0516 between 18° and 300° ; and 0.0561 between 18° and 600° ; W. Gaede gave for antimony of sp. gr. 6.627, 0.050248 at 17.1° ; 0.050558 at 33° ; 0.050823 at 47.2° ; 0.051028 at 62.4° ; 0.051160 at 77.3° ; and 0.051321 at 92.5° . S. Umino gave:

Sp. ht.	150°	250°	350°	450°	550°	650°	850°	950°
	0.0505	0.0520	0.0537	0.0552	0.0569	0.0656	0.0656	0.0656

H. Jahn gave:

Sp. ht.	-72° to 13.1°	-21° to 15°	55° to 21.7°	303° to 26.3°	500° to 26.5°	625° to 27.7°
	0.049315	0.049368	0.049517	0.050205	0.050496	0.050834

and for temp. between 22° and θ° , sp. ht. $=0.04941078-0.0_513097(\theta-22^\circ)-0.0_5171207(\theta-22^\circ)^2+0.0_{10}245733(\theta-22^\circ)^3$; and $\alpha\theta/\alpha\theta=0.04941078-0.0_526164(\theta-22^\circ)-0.0_7155136(\theta-22^\circ)^2+0.0_{10}982932(\theta-22^\circ)^3$. L. Schüz, 0.05060 and 0.05192, J. Laborde, 0.0509, and U. Behn, 0.0484 for the range between 18° and -79° ; 0.0472 between 18° and -186° ; and 0.0462 between -79° and -186° ; R. Ewald found 0.0477 at -28° , 0.0462 at -39° , and -0.0423 at -135° ; J. Dewar, 0.0240 between -196° and -253° ; T. W. Richards and F. G. Jackson, 0.0469 between 20° and -188° ; H. Schimpf, 0.0503 between 17° and 100° , 0.0482 between 17° and -79° , 0.0450 between 17° and -190° . J. H. Awbery and E. Griffiths also obtained values for the sp. ht. of antimony. For powdered crystals of antimony P. Günther gave 0.0428 at 188° . G. W. A. Kahlbaum and co-workers gave 0.0497 for distilled antimony, and 0.0496 for the same metal after compression at 10,000 atm. The corresponding **atomic heat** ranges from J. Dewar's value 2.89 near -253° to P. Schübel's 6.74 near 600° . P. Günther gave 5.19 for the at. ht. at -194.6° ; 5.22 at -187.4° ; 5.33 at -181° ; and 5.47 at -174.9° . G. N. Lewis gave $C_p=6.0$; $C_v=5.9$ at 20° ; and E. D. Eastman and co-workers examined the effect of temp. on the relation C_p-C_v ; and A. Simon and M. Ruhemann gave $C_p=3.87$ and $C_p=3.89$ at -201.70° ; $C_v=3.90$ and $C_p=3.92$ at -200.93° ; $C_v=4.21$ and $C_p=4.21$ at -191.79° ; and $C_v=4.20$ and $C_p=4.24$ at -191.42° .

The older determinations of the **melting point** of antimony by J. Dalton,⁷ L. B. G. de Morveau, R. Pictet, and A. Ledebur were far too low; they ranged from J. Dalton's 432° to L. B. G. de Morveau's 513°. H. Capitaine made the questionable observation that the higher the degree of purity of antimony the more easily does it fuse. C. T. Heycock and F. H. Neville gave 629·54°; L. Holborn and A. L. Day, 630·5°; L. Holborn, 630·3°; A. L. Day and R. B. Sosman, 629·8°–630°; E. van Aubel, 630°; W. R. Mott, 630·7°; H. Callendar, 629·5°; A. Gautier, 632°; F. Krafft, 635°; F. Winkler, 630°–635°; P. N. Laschtschenko, and J. H. Awbery and E. Griffiths, 630°; E. Groschuff, 630·3°; C. W. Waidner and G. K. Burgess, 630·23°–630·7°; K. Scheel, 630°; and H. Chrétien, 628°. L. I. Dana and P. D. Foote gave 630° for the best representative value; and W. Guertler and M. Pirani, 630·5°. W. Reinders found the metal is much inclined to undercooling. H. Fay and H. E. Ashley gave 624° for the f.p. H. Pélabon found the **freezing point constant** to be 1240°. According to E. Karrer, when antimony is heated at a temp. above its m.p. it becomes bright red; on cooling, the brightness decreases with the temp. until solidification commences, when a sudden increase in brightness occurs, accompanied by an increase in temp. Moreover, the brightness after the flash appears greater for a given temp. than the brightness at the same temp. before the flash. It thus appears to be a case of **crystal luminescence**; the phenomenon is not due to oxidation of the antimony, since it takes place in hydrogen or in a vacuum.

J. von Liebig⁸ said that antimony volatilizes out of contact with air only at elevated temp., but, in a current of air, less heat is required. Antimony volatilizes at a bright red heat or in a current of an inert gas, but not when fused under a layer of salt; if antimony trioxide be ignited with charcoal and alkali carbonates, metallic antimony is formed, but if the alkali be omitted most of the antimony will be volatilized as trioxide, and only a small part will be reduced to the metallic state. When covered with a flux, antimony lost only one-thousandth part of its weight at the strongest white-heat, but in a current of hydrogen, antimony can be distilled at a white-heat. J. A. M. van Liempt found that the **vapour pressure**, p mm., is:

	1075°	1135°	1175°	1225°	1265°	1325°
p . . .	54	107	206	302	407	745

The values can be represented by $\log_{10} p = 6.20 - 9888T^{-1}$. J. Johnston gave for the vap. press., $\log p = -9.010T^{-1} + 8.12$. T. Carnelley and W. C. Williams gave 1090°–1450° for the **boiling point** of antimony at ordinary press. H. F. Wiebe's relation furnished 1961°. V. Meyer and H. Mensching said that evaporation proceeds very vigorously at 1437°; V. Meyer and H. Biltz said that the b.p. lies between 1500° and 1700°, but the metal is volatile at lower temp. F. Winkler gave 965° for the b.p. of antimony at 10 mm. press.; W. R. Mott, 1440°; H. C. Greenwood, 1440° for the b.p. at 760 mm.; J. A. M. van Liempt, 1322°; and O. Ruff and B. Bergdahl, 1325° at 745 mm., and 1330° at 760 mm. E. Demarçay said that antimony readily volatilizes in vacuo at 292°; A. Schuller found that antimony can be readily sublimed in vacuo; and F. Krafft distilled the element at 775°–780° in vacuo; and E. Tiede and E. Birnbräuer, and F. Krafft and L. Bergfeld said that antimony volatilizes readily in the vacuum of the cathode light at 290°–292°, and evaporation occurs even at lower temp. J. Johnston gave 540° for the b.p. at 10^{-3} mm.; 620° at 10^{-2} mm.; 720° at 0.1 mm.; 840° at 1 mm.; 990° at 10 mm.; 1130° at 50 mm.; 1200° at 100 mm.; and 1440° at 760 mm. C. Zenghelis observed that when antimony was placed near a piece of silver-foil in a desiccator, in a few months the surface of the silver was discoloured by the vapour of antimony. W. G. Duffield made estimates of the **rate of vaporization** of liquid antimony. F. Wüst and co-workers found the **heat of fusion** to be 38.9 cal. per gram, or 4.6 Cals. per gram-atom; S. Umino, 40.75 cal. per gram; and J. H. Awbery and E. Griffiths, 24.3 cal. per gram; and W. Herz gave 24.2 cal. per gram. P. N. Laschtschenko gave 4.85 Cals. per gram-atom. J. W. Richards calculated,

with different standard formulæ, 16–27·25 cal. per gram. J. Tate found the latent **heat of vaporization** to be 320 cal. per gram, or 38·5 Cal. per gram-atom. F. S. Mortimer calculated 41·15 Cal.; and J. Johnston, 41·3 Cal. J. A. M. van Liempt gave 45·28 Cal. per gram-atom, and 28·39 for **Trouton's constant**. W. G. Mixer⁹ found the **heat of oxidation** of antimony to the trioxide, (2Sb,3O) = 163·0 Cal. per mol; (2Sb,4O) = 209·8 Cal.; and (2Sb,5O) = 229·5 Cal. J. C. Thomlinson compared the thermochemistry of antimony and arsenic. E. Kordes gave 5·16 (cals.) for the entropy of antimony; and B. Brugs, 12·6 for the entropy at 25°, and 19·6 at the m.p. M. Kawakami measured the heat of mixing pans of the following metals: sodium, potassium, zinc, cadmium, mercury, lead, antimony, and bismuth.

G. Quincke¹⁰ found the **index of refraction**, ω , to be 3·027 for the C-ray; 2·398 for D-ray; 1·832 for E-ray; 1·429 for F-ray; and 1·110 for G-ray; G. Horn gave 2·965 for C-ray; 2·571 for D-ray; 1·962 for E-ray; 1·578 for F-ray; and 1·246 for G-ray; and P. Drude gave 3·19 for C-ray; and 3·04 for D-ray. For the **absorption coefficient**, k , G. Quincke gave 1·490 for the C-ray; 1·899 for D-ray; 2·329 for E-ray; 2·762 for F-ray; and 2·937 for G-ray; G. Horn gave 1·875 for C-ray; 2·090 for D-ray; 2·534 for E-ray; 2·921 for F-ray; and 3·260 for G-ray. P. Drude found 1·56 for C-ray, and 1·63 for D-ray. The optical dispersion of antimony is very large, and the curve shows a point of inflection. W. W. Coblentz found that the percentage **reflecting power** of antimony, 53 per cent. for light of wave-length $0·06\mu$; 55 per cent. for $1·0\mu$; 60 per cent. for 2μ ; 68 per cent. for 4μ ; and 72 per cent. for 10μ . P. Drude gave 70 per cent. for $\lambda=0·589\mu$; and 4·94 for the extinction coeff. A. Ghira gave for the **atomic refraction** 23·69–25·27 for trivalent antimony from the μ -formula, and 11·18–13·01 from the μ^2 -formula. J. H. Gladstone gave 24·5 for the at. refraction. S. Procopiu studied the **electro-optical effect** and the **magneto-optical effect** of antimony powder suspended in toluene.

J. Piccard and E. Thomas¹¹ discussed the colour of antimony ions. Antimony salts give no characteristic **flame spectrum** in the colourless gas flame, although R. Bunsen¹² found that the upper part of the reducing zone acquires a green tinge. H. W. Vogel found that antimony trichloride in the colourless gas-flame gives a continuous spectrum, which shows a few feeble lines in the green; antimony trichloride volatilized in hydrogen also gives a continuous spectrum in the colourless gas-flame. O. Vogel found that antimony and many of its compounds give a band spectrum—*vide infra*—in the oxy-coal gas flame. The **spark spectrum** of antimony was first described by A. Masson in 1851, and since then numerous observations have been made by A. J. Angström, D. Alter, G. Kirchhoff, T. R. Robinson, W. A. Miller, W. Huggins, R. Thalén, L. de Boisbaudran, R. Capron, H. Schippers, A. Hagenbach and H. Konen, L. and E. Bloch, E. O. Hulburt, J. C. McLennan and

FIG. 6.—Spark Spectrum of Antimony.

co-workers, G. Ciamician, J. Parry and A. E. Tucker, W. N. Hartley and co-workers, A. de Gramont, M. C. W. Buffam and H. J. C. Ireton, F. Exner and E. Haschek, J. M. Eder and E. Valenta, P. G. Nutting, J. Herpertz, S. R. Milner, C. E. Gissing, H. Nagaoka and co-workers, and A. Kretzer. The principal lines in the visible spectrum are: 6129— γ , Fig. 6—6079— δ , Fig. 6—6005— α , Fig. 6—and 5792 in the orange-yellow; 5792, and 5639— ϵ , Fig. 6—in the yellow; 5568— β , Fig. 6—5464, 5379, 5353, 5242, 5176— η , Fig. 6—5140, 5113, 5036, and 4949 in the green; 4878, 4785, and 4711 in the blue; with numerous

lines in the ultra-violet. The orange-yellow α -line, and the green β -line, are characteristic in qualitative spectral analysis. The spark spectrum under-water was examined by M. C. W. Buffam and H. J. C. Ireton, and E. O. Hulburt; and *les raies ultimes*, by A. de Gramont. The **arc spectrum** was studied by R. Capron, G. D. Liveing and J. Dewar, J. M. Eder and E. Valenta, F. Exner and E. Haschek, T. Royds, A. Kretzer, J. C. McLennan and co-workers, S. L. Malurkar, J. B. Green, F. M. Walters, etc.; the intermittent arc spectrum by M. Kimura; the **ultra-violet spectrum**, by W. A. Miller, G. D. Liveing and J. Dewar, V. Schumann, L. and E. Bloch, R. J. Lang, F. Exner and E. Haschek, W. Kimura, etc.; the **ultra-red spectrum**, by H. M. Randall, and V. P. Lubovich and E. M. Pearen; and the **band spectrum**, by J. N. Lockyer, W. N. Hartley, J. Stark and R. Küch, C. de Watteville, E. Paterno and A. Mazzucchelli, L. Janicki, A. Kretzer, J. M. Eder and E. Valenta, etc. The **absorption spectrum** of the vapour was examined by J. N. Lockyer and W. C. Roberts-Austen, J. C. McLennan and A. B. McLay, J. G. Frayne and A. W. Smith, A. Terenin, R. V. Zumstein, W. Grotrian, and J. J. Dobbie and J. J. Fox. A. L. Narayan and K. R. Rao found that absorption spectrum of the vapour showed fine lines at 2312 and at 2306; and there was a banded spectrum extending from 2305 to 2250 with a constant interval of 15 Å. The banded spectrum is taken to mean that the molecules are polyatomic. A. Terenin examined the spectrum of the light emitted by the vapour at 1100°. According to J. Formanek, the salt soln. do not react with alkanna. C. R. Crymble examined the absorption spectrum of soln. of antimony chlorides and antimoniates. The influence of *pressure* was examined by W. J. Humphreys; the *self-induction*, by A. de Gramont, E. Néculcéa, and G. A. Hemsalech; the *enhanced lines*, by J. Steinhausen, and M. Kimura and G. Nakamura; and the influence of a *magnetic field*, or the **Zeeman effect**, by J. E. Purvis, and P. A. van der Harst. Attempts to find regularities and series spectra were made by A. Ditte, J. C. McLennan and A. B. McLay, G. Ciamician, H. Kayser and C. Runge, R. J. Lang, and T. van Lohuizen. No series have been identified, although H. Kayser and C. Runge observed several constant difference lines.

The **K-series of X-ray spectra** was found by F. C. Blake,¹³ W. Duane, B. B. Ray, A. Leide, J. M. Cork and B. R. Stephenson, B. Walter, and M. Siegbahn to have the lines $a_2\alpha^1$, 0.472; $a_2\alpha$, 0.468; $\beta_1\beta$, 0.416; and $\beta_2\gamma$, 4.008; the **L-series**, by H. Hirata, D. Coster, K. Chamberlain, K. Chamberlain and G. A. Lindsay, G. Kellstrom, G. I. Pokrowsky, B. B. Ray, A. Dauvillier, A. Jönsson, D. Coster and F. P. Mulder, G. A. Lindsay, Y. Nishina, E. Hjalmar. M. J. Druyvesteyn, and M. Siegbahn to have the lines $a_2\alpha^1$, 3.44075; $a_1\alpha$, 3.43177; $\beta_1\beta$, 3.21836; $\beta_2\gamma$, 3.017; $\gamma_1\delta$, 2.84507; $\beta_4\nu$, 3.184; and $\beta_3\phi$, 3.14514. D. Coster and F. P. Mulder also studied the **M-, N-, and O-series**; P. Günther, the absorption of the K-rays; and A. L. Foley, the effect on the spectrum of antimony of exposing the element to X-rays, or to ultra-violet light.

P. D. Foote and co-workers found 8.5 volts for the **ionizing potential**, and 1.7 and 5.7 volts for the inelastic collision potential of antimony. G. Piccardi gave 8.46 volts for the ionizing potential. C. G. Barkla and co-workers found that the **K-series of X-rays** of wave-length 1.172 Å., from an antimony radiator, have the ratios of the absorption coeff. μ , divided by the density of the absorber carbon, 0.31; aluminium, 1.21; and silver, 56.1. J. Thibaud measured the **β -ray spectrum** of antimony. W. Herz gave 2.90×10^{12} for the **vibration frequency**. A. Bouers measured the intensity of the X-rays from antimony; K. Chamberlain studied the fine structure of the X-ray absorption edges. A. L. Foley observed no definite change occurs when antimony is exposed for a long time to the X-rays in an atm. of nitrogen. E. T. Wherry classed antimony as a poor **radio-detector**. M. Hake, and A. Predvoditeff and A. Witt, studied the **photoelectric effect** with antimony. M. de Broglie examined the photoelectric effects of the γ -rays. M. Levin and R. Ruer found that ordinary antimonious acid

exhibits a feeble **radioactivity**. J. E. P. Wagstaff gave 3.0×10^{12} for the **vibration frequency**; and W. Herz gave 2.90×10^{12} .

K. F. Herzfeld¹⁴ studied the metallic condition of antimony. A. Mattheissen and M. von Bose found that if the **electrical conductivity** of silver be 100, that of antimony is 4.29 at 18.7°. A. Berget gave 2.48×10^4 mhos for the electrical conductivity of antimony at 0°–30°; A. Oberbeck and J. Bergmann, 2610 mhos at 0°; A. Eucken and G. Gehlhoff, 2565 mhos at 0°, 3568 mhos at –79°, and 9560 mhos at –190°; and L. de la Rive, 620 mhos for the solid and 890 mhos for the liquid at the m.p., and 830 mhos for the liquid at 860°. H. Tsutsumi gave 0.67 for the ratio of the resistance of the liquid to that of the solid. The conductivity is very sensitive to the degree of purity of the metal, and A. Eucken and G. Gehlhoff's results may be taken as representing a metal of a high degree of purity. A. Mattheissen and M. von Bose gave for the **electrical resistance** at θ between 12° and 100°, $R = R_0(1 - 0.0039826\theta + 0.0410364\theta^2)$. The data were reviewed by A. Schulze. E. F. Northrup and V. A. Suydam measured the electrical resistance of four samples of antimony. The results for two are illustrated by Fig. 7. The other two curves fall within these extremes. With two curves for the solid, on a rising temp., there are breaks near 450°, and with two others, for the solid, on a falling temp., there are breaks between 117° and 107°. H. Tsutsumi observed no such singular points in his observations. E. F. Northrup and V. A. Suydam gave for the resistance of the liquid, R in microhms per c.c.:

	20°	627°	650°	700°	750°	800°	850°	900°
R	43.47	117.00	117.07	117.65	118.53	120.31	123.54	131.00

FIG. 7.—The Effect of Temperature on the Electrical Resistance of Antimony.

W. Haken gave 43.48 microhms at 18°. Y. Matsuyama gave 115.0×10^{-6} ohm for the sp. resistance of molten antimony. H. Tsutsumi found the ratio of the sp. resistance in the liquid and solid states to be 0.67—*vide* bismuth. W. J. de Haas gave 0.00511 for the *temperature* coeff. of the resistance, and P. W. Bridgman, 0.00478, between 0° and 100°; and he observed a discontinuity in the curve at about 145°. H. Perlitz studied the relation between the space-lattice and the change of resistance with fusion. S. Lussana found the electrical conductivity increases under *pressure* as with normal metals, and the press. coeff. for 3000 atm. at 25° is 0.05874. On the other hand, P. W. Bridgman obtained converse results; he found for the effect of press. over the range 12,000 kgrms. per sq. cm., at 0°, 25°, 50°, 75°, and 100°, the respective values 1.000, 1.113, 1.229, 1.349, and 1.473, with the respective press. coeff., 0.04220, 0.041107, 0.05994, 0.05881, and 0.05768. There was a discontinuity in the curve at about 145°. E. D. Williamson gave 1.1461 for the ratio of the resistance at 12,000 kgrms. per sq. cm. press. to that at 1 kgrm. per sq. cm. P. W. Bridgman found that the electric resistance of antimony wires increases linearly with *tension*. The tension coeff. was +0.0545 for loads up to 80 grms.; with another sample the coeff. was +0.0420, and with another one, 0.0575. For single crystals at 20° he found the sp. resistance to be 35.6×10^{-6} ohm when parallel and 42.6×10^{-6} ohm when perpendicular to the chief axis. O. Jaamaa and Y. E. G. Leinberg studied the resistance of powdered antimony mixed with marble, sulphur, etc. P. Fischer found that cylinders made from compressed mixtures of antimony sulphide and up to 30 per cent. of antimony do not conduct direct or alternating currents; with 40 per cent. antimony, the mixture is non-conducting with a direct current, but has a conductivities of 2.2×10^{-4} mhos with the alternating current, and the cylinder then conducts the direct current.

Mixtures with 50 and 60 per cent. antimony show a similar phenomenon. So also does a mixture of cupric oxide with 50 per cent. antimony. G. Tammann and H. Bredemeier, of thin films; A. Schulze found antimony has a higher resistance for alternating than for direct currents. T. W. Case said that the conductivity of antimony is not affected by *light*. G. Eucken and O. Neumann found that the *grain-size* of the antimony but slightly affected the electrical conductivity, for with fine-grained material, 1.41×10^{-4} sq. cm., the conductivities at -183° and 0° are respectively 8.34×10^{-4} and 2.43×10^{-4} mhos; material of grain-size 2.27×10^{-4} sq. cm., 8.13×10^{-4} mhos respectively; material of mean-sized grain, 6.35×10^{-4} sq. cm., 8.08×10^{-4} and 2.35×10^{-4} mhos respectively; and coarse-grained material, 0.143 sq. cm., 7.89×10^{-4} and 2.32×10^{-4} mhos. The relation of G. Wiedemann and R. Franz—**3**, 21, 5—was for the finest-grained, fine-grained, medium-grained, and coarse-grained material 2.31, 2.46, 2.73, and 5.72 respectively at -183° , and 7.09, 7.20, 7.73, and 10.55 respectively at 0° —*vide infra*, thermal conductivity. Z. A. Epstein, and A. Günther-Schulze studied the relation between conductivity of various metals and the periodic system; P. W. Bridgman, the electrical resistance and thermal e.m.f.

The **thermoelectric force** of antimony against platinum at 100° was found by W. H. Steele¹⁵ to be 4.70 millivolts, and by E. Rudolphi, 4.86 millivolts. The current passes from the cold junction at 0° to the platinum. A. Matthiessen found the thermoelectric power of antimony wire with respect to lead, at 20° , to be 6.0 microvolts; with crystals axially disposed, 22.6 microvolts; and with crystals equatorially disposed, 26.4 microvolts. J. Svanberg found a rod cut parallel to the chief axis is more negative, and one cut perpendicular to that axis is more positive than a rod cut in any other way. R. Franz found a current is produced by warming the junction of a crystal with the (0001)-surface in contact with another surface. C. Matteucci also made observations on this subject. G. Todesco studied the effect of light; and T. Terada and co-workers, the effect with thin films. F. P. le Roux found the **Peltier effect** with the copper-antimony couple to be -5.64 millivolts. For the **Hall effect**, *vide bismuth*. M. Campa found that X-rays of maximum frequency $\gamma = 1.46 \times 10^{19}$ produce a decrease in the Hall coeff. of antimony during solidification. This causes a thermoelectric current in a circuit containing the unexposed metal. The e.m.f. of the couple is 2×10^{-6} volt at 0° to 18.5° , M. Campa also studied the Hall effect with weak fields; C. W. Heaps, the relation between the Hall effect and the thermoelectric power of antimony; and P. W. Bridgman, the relation between the four transverse electro- and thermomagnetic effects. In Table V, **9**, 51, 5, N. C. Little has compared the **thermomagnetic effect** and the **galvanomagnetic effect** of the arsenic family of elements.

The electrodeposition of antimony has been previously discussed. B. Neumann¹⁶ found that the absolute **electrode potential** of antimony in a normal soln. of the chloride is -0.376 volt; K. Jellinek and H. Gordon gave 0.244 volt. K. Elbs and H. Thümmel found that an antimony anode in a soln. of sodium chloride or hydrochloric acid dissolves in the tervalent form. G. Grube and F. Schweigardt obtained a similar conclusion with conc. soln. of alkali hydroxide, without the antimony becoming passive. If the current density exceeds 7.5 amp. per sq. decm., the anode becomes passive by acquiring a film of white non-conducting oxide. A soln. of potassium antimonite is a strong reducing agent and readily absorbs oxygen from the air. The process of its electrolytic oxidation at a polished platinum electrode is not, however, reversible, and it is shown that production of potassium antimonate in this manner is effected not by a direct process of anodic oxidation, but by the oxidizing action of oxygen evolved in the form of gas at the electrode. The **electrode potential**, ϵ , of antimony in a 10*N*-soln. of potassium hydroxide at 20° , the process of soln. being represented by $\text{Sb} + 4\text{OH}' + 3(+)\rightarrow\text{SbO}_2' + 2\text{H}_2\text{O}$, is given by $\epsilon = -0.675 + 0.058/3 \log C_{\text{SbO}_2'}$. For the oxidation process to antimonate, the corresponding equation is

$\text{SbO}_2' + 2\text{OH}' + 2(+)\rightarrow\text{SbO}_3' + \text{H}_2\text{O}$, and the value of ϵ is given by $\epsilon = -0.589 + 0.058 \log (C_{\text{SbO}_3'}/C_{\text{SbO}_2'})/2$. The value of the electrode potential of antimony in a soln. containing a gram-ion of SbO_3' in 10*N*-potassium hydroxide soln. is -0.641 volt. The value of the antimonite-antimonate potential difference is reduced as the alkalinity of the soln. is increased, and is determined by the OH' conc. of the soln. N. T. M. Wilshire gave < -0.466 volt. for the electrode potential of antimony in contact with normal soln. when the hydrogen electrode is zero. M. le Blanc and D. Reichenstein measured the electrode potential of antimony in soln. of potassium hydroxide, and sulphuric acid. R. Schuhmann found the e.m.f. of the cell $\text{Sb} | \text{Sb}_2\text{O}_3, \text{HClO}_{4\text{soln.}} | \text{H}_2$ to be -0.152 volt at 25° ; and the mol. reduction potential, corresponding with the reaction $\text{Sb} + \text{H}_2\text{O} + 3(+)=\text{SbO}' + 2\text{H}'$, was found to be -0.212 volt. From measurements of the e.m.f. of cells with antimony in combination with a soln. of a tartrate, K. Jellinek and H. Gordon observed that in acidic soln., antimony and tartrate ions form the complex $(\text{SbO})\text{COO}.\text{CH}(\text{OH}).\text{CH}(\text{OH}).\text{COOH}$. G. Tammann and J. Hinnüber studied the cell $\text{Sb}|\text{Hg} | \text{SbCl}_{3\text{aq.}}, \text{N-KCl}, \text{HgCl} | \text{Hg}$. A. Günther-Schulze found that antimony exhibits the electrolytic valve action with nearly all electrolytes, and the valve effect is due to a layer of oxide on the surface of the anodic antimony which holds in some cases with a voltage of 600–700. H. von Steinwehr gave 3.8×10^{-12} atm. for the electrolytic **solution pressure** $\text{Sb} \rightarrow \text{Sb}''$. S. Berberich studied the anodic behaviour of antimony in sulphuric, acetic, nitric, and hydrochloric acid, and in potash-lye—*vide infra*, antimony trioxide and pentoxide. N. R. Dhar studied the effect of dilution on the electrode potential of antimony in salt soln. W. Isbekoff studied the decomposition voltages of a number of metal bromides, and hence deduced the **electrochemical series**: Al, Zn, Cd, Ag, Hg, **Sb**, Bi. F. W. Bergstrom found for soln. in liquid ammonia the series: Pb, Bi, Sn, **Sb**, As, P, Te, Se, S, I. A. Thiel and W. Hammerschmidt found the **overvoltage** of antimony to be 0.233 volt with 2*N*- H_2SO_4 at 25° . H. J. S. Sand and co-workers found that the polarization overvoltage of the antimony cathode is lowered by a high concentration of sulphuric acid or alkali-lye; and in alkaline soln., the polarization overvoltage, $\omega = A - 2h$, where a is a constant, and h is the p_{H} voltage. E. Newbery observed a black film is formed on antimony in both acidic and alkaline soln. S. Glasstone measured the cathodic overvoltage of antimony in *N*- H_2SO_4 , and in *N*- NaOH . H. J. S. Sand and co-workers found that in alkaline soln., the overvoltage-current density curves obtained by the direct method show an arrest or inflexion which usually takes place at a voltage not far removed from the maximum given by the commutator method. The decay curves representing the overvoltage at successive short intervals after breaking the current also give indications of this same value, for they sink to, and become constant for a considerable time at, a potential not far removed from it. E. Newbery, A. Günther-Schulze, and W. Winter studied the **electrolytic valve action**; V. Bayerle found that the deposition of antimony from hydrochloric acid soln. proceeds reversibly; but with alkaline soln., it is irreversible. The **solubility product** is $[\text{Sb}''][\text{OH}']^3 = 4 \times 10^{-42}$. G. C. Schmidt examined the **passivity** of antimony. W. B. Nottingham studied the characteristic curves of the antimony arc; H. F. Vieweg, the frictional electricity; and E. Blechschmidt, and A. Günther-Schulze, the cathodic spluttering of antimony.

In 1827, M. le Bailiff¹⁷ observed that antimony is repelled by a magnet, and later, M. Faraday found that antimony is diamagnetic like bismuth. According to H. Knoblauch and J. Tyndall, if the crystals of antimony are ferruginous, the metal may appear to be paramagnetic. A. von Ettinghausen gave -4.5×10^{-6} to -5.6×10^{-6} vol. units for the **magnetic susceptibility** of antimony; L. Lombardo, -3.8×10^{-6} vol. units; S. Meyer, -0.57×10^{-6} mass units; K. Honda, -0.94×10^{-6} mass units at 18° ; M. Owen, -0.815×10^{-6} mass units; and H. Isnardi and R. Gans, -1.346×10^{-6} . C. Nusbaum studied the magnetic susceptibility of single crystals and found 0.497×10^{-6} for the value of the constant parallel to the principal axis,

and 1.38×10^{-6} when vertical thereto. S. Meyer gave -2.28×10^{-6} for the **magnetization number** of antimony in the powdered state, and -33.1×10^{-6} for compact antimony; and he gave -0.069×10^{-6} and -0.59×10^{-6} respectively for the **atomic magnetism** of antimony. P. Pascal gave for the at. susceptibility of trivalent antimony, -259×10^{-7} to -263×10^{-7} ; and for quinquevalent antimony, -669×10^{-7} . J. Forrest studied the variations in the transverse and parallel components of magnetization of crystals of antimony. W. Gerlach studied the magnetic moment of the atoms. B. H. Wilson calculated the magnetic constants from theoretical principles.

§ 6. The Chemical Properties of Antimony

The solubility of the common gases in antimony is probably very small. P. Goerens and J. Paquet¹ found that antimony retained only a small trace of occluded gas—E. Groschuff said that about 0.005 per cent. of gas was present in ordinary antimony; and 0.0005 per cent. in the purified metal. F. Fischer and co-workers observed that no combination occurs when antimony is sparked below liquid **argon**; W. Ramsay and J. N. Collie observed no reaction with **helium** at a red-heat. H. Caron found that molten antimony absorbs **hydrogen**, and gives it up incompletely when further heated. T. Graham observed that when antimony is exposed to hydrogen, both above and below the m.p. of the metal, and afterwards exhausted at dull redness, there is no evidence of the absorption or occlusion of hydrogen. F. H. Newman observed that hydrogen is adsorbed by antimony in an electric discharge tube. R. Böttger found that in the electrolysis of water with an antimony cathode, a little hydrogen was absorbed by the metal; but neither R. Böttger, nor F. Pfeifer observed an appreciable amount of hydrogen in explosive antimony. K. Iwase studied the absorption of hydrogen by antimony. A. J. J. Van-velde said that antimony does not unite directly with hydrogen under the influence of heat, and that antimony volatilizes unchanged in an atm. of hydrogen. F. Winkler observed a slight absorption of hydrogen by antimony. W. P. Dexter said that no difference in the values for the at. wt. were observed with antimony melted in hydrogen, and in **air**. H. Wölbling said that appreciable quantities of **oxygen** are found only in electrolytic antimony. C. F. Schönbein² found that crystalline antimony is not affected by dry air, but, as noted by T. Bergman, J. J. Berzelius, and J. L. Proust, when antimony is exposed to moist air, particularly in light, the surface becomes matte and grey—particularly, said A. Ditte and R. Metzner, if the metal is finely divided. Antimony prepared by the reduction of potassium antimonyl tartrate may contain some potassium, and this behaves differently from ordinary antimony towards air and water. When antimony is heated in air until it boils, it takes fire, and burns with a bright bluish-white flame, and, at a moderate red-heat, with a reddish light yielding antimony trioxide which condenses on cold bodies in the form of *flores antimonii*—flowers of antimony; or *nix stibii*, antimony snow. If the burning antimony contains some arsenic, the odour resembles that of garlic; J. von Liebig, and H. Capitaine said that there is no odour if the antimony is pure; while F. Wöhler, and C. H. Pfaff said that the smell is peculiar but different from that of garlic, and it reminded T. Martius of that of nitric acid. G. Tammann and N. I. Nikitin found that the metal obtained by reducing the oxide at temp. as low as 125° is not pyrophoric since crystallization occurs at a low temp. When strongly ignited and molten antimony is poured on the ground, it separates into small globules which continue to burn. H. B. Baker

also found that antimony burns when heated in thoroughly dried oxygen. C. F. Schönbein found that antimony is oxidized to the pentoxide by **ozone**, and by ozonized ether or turpentine. A. Ditte and R. Metzner showed that antimony precipitated from soln. of its salts by metals, is slowly attacked by **water** exposed to air; and if distilled water comes in contact with purified antimony, in air, the oxide is always found in the liquid. J. Thiele also found that with the precipitated metal, even when the water has been previously boiled, a considerable quantity of antimony passes into soln.; the metal also undergoes oxidation to such an extent that, in spite of the loss experienced in washing, the results sometimes come out too high. According to J. Milbauer and B. Slemr, if air be passed through a boiling suspension of antimony in water, 45 per cent. of the metal is oxidized; at room temp., only 8 per cent. is oxidized, but if tartrates or citrates be present nearly 45 per cent. is oxidized at room temp. O. Ruff and K. Albert also found that antimony is attacked by distilled water, as well as by alcohol and ether, but not, according to E. Cohen and W. E. Ringer, by a mixture of alcohol and ether. A. Barillé found that alloys of lead or antimony with tin are more readily attacked by seltzer water than is either metal alone. J. J. Berzelius, and H. V. Regnault found that water vapour when passed over red-hot antimony forms hydrogen and antimony trioxide. J. Clark found that neutral **hydrogen dioxide** is without action on antimony, but in the presence of alkalies, an antimonate is formed. L. J. Thénard also observed that hydrogen dioxide has no action on bismuth.

H. Moissan³ found that antimony burns vigorously in **fluorine**, forming a white solid. Powdered antimony takes fire in **chlorine**, burning with a reddish light and the emission of sparks, forming antimony pentachloride; and, added H. Rose, antimony trichloride is never formed in this way. Liquid chlorine, at its b.p., was found by V. Thomas and P. Dupuis to have no action on antimony. R. Cowper found that chlorine, thoroughly dried by fused calcium chloride, acts immediately on antimony with the evolution of heat and light. V. Thomas and P. Dupuis found that liquid chlorine, at the b.p., has no action on antimony. C. Willgerodt found antimony and several of its compounds are good catalytic agents in chlorination reactions. According to A. J. Balard, and G. S. Sérullas, antimony takes fire when brought in contact with **bromine**, the metal running about in fused globules on the surface of the bromine—the tribromide is formed. R. Brandes said that antimony and **iodine** unite at ordinary temp., the reaction is accompanied by a great rise of temp., and the evolution of iodine vapour, and even by an explosion if large quantities are used. G. S. Sérullas, J. B. Berthemet, as well as R. Brandes, obtained the triiodide as a product of this reaction. H. Reckleben found that iodine in the presence of a soln. of tartaric acid readily converts antimony into antimonic acid: $2\text{Sb} + 5\text{I}_2 + 8\text{H}_2\text{O} = 2\text{H}_3\text{SbO}_4 + 10\text{HI}$, and free antimony may be readily estimated in this way. L. B. Parsons observed no reaction with iodine and antimony in the presence of water, alcohol, ether, benzene, heptane, quinoline, pyridine, acetone, carbon disulphide, carbon tetrachloride, or chloroform. F. A. Flückiger said that conc. **hydrofluoric acid** has no action on antimony. Neither **hydrogen chloride** nor **hydrochloric acid** acts on antimony in the absence of air; if commercial antimony is attacked by hydrochloric acid, L. J. Chaudet, and H. von der Planitz showed that this is due to the presence of impurities—*e.g.* antimony sulphide, lead, etc. A. Ditte and R. Metzner showed that antimony, precipitated by tin from an acid soln. of antimony trichloride, is not attacked by hydrochloric acid of any conc. at any manageable temp., even in the presence of platinum or gold chloride; but in the presence of air, W. P. Dexter, and J. P. Cooke found that the metal is slowly dissolved—even by water alone. W. L. Clasen, and J. Thiele made similar observations. P. J. Robiquet, and J. P. Cooke found that **aqua regia**, or hydrochloric acid containing a little nitric acid, dissolves antimony. N. A. E. Millon found that if the **aqua regia** is cold, and dilute, it does not attack the metal unless nitrous acid be present. J. W. Retgers observed that antimony is not dissolved by **methylene iodide**.

When a mixture of antimony and **sulphur** is heated, black antimony trisulphide (*g.v.*) is formed. W. Guertler⁴ studied the affinity of antimony for sulphur. J. Spiller said that if a tube containing sulphur and stibine be exposed to sunlight, orange-coloured antimony sulphide is formed. C. Geitner noticed that when a mixture of the two elements with water is heated to 200° in a sealed tube, the black trisulphide is formed; and W. Spring also obtained the same product by compressing a mixture of the elements at 6500 atm. According to H. Pélabon, the reaction with **hydrogen sulphide** is reversible above 360°: $2\text{Sb} + 3\text{H}_2\text{S} \rightleftharpoons 3\text{H}_2 + \text{Sb}_2\text{S}_3$. When the temp. is below the m.p. of the sulphide, the reaction depends only on the temp., and is independent of the press. and of the mass of the solids. When the temp. is above the m.p. of antimony sulphide, this compound dissolves the liberated antimony, and equilibrium is established between two homogeneous systems; the final composition of the gas depends on the conc. of the soln. of antimony in the trisulphide, and therefore on the amount of trisulphide originally present. If an excess of antimony be present, the soln. of metal in its sulphide is always saturated, providing that all the sulphide is not decomposed. The amount of hydrogen sulphide then produced depends solely on the temp. J. Uhl found that when antimony is heated in a current of dry **sulphur dioxide**, antimony trioxide and trisulphide are formed—H. Schiff said that only the trisulphide is produced; and C. Geitner observed that when an aq. soln. of sulphur dioxide and antimony are heated in a sealed tube at 200°, microcrystalline antimony trisulphide is obtained. According to R. Brandes, when antimony is heated with **sulphuric acid**, the products are sulphur dioxide, sublimed sulphur, and antimony sulphate or basic sulphate; cold sulphuric acid, dil. or conc., is without action on antimony. According to R. H. Adie, when sulphuric acid acts on antimony, sulphur dioxide appears at 90°–95° and no hydrogen sulphide is formed. As previously indicated, the resistance of antimony to attack by acids led some alchemists to regard this element as imperfect gold. M. G. Levi and co-workers observed the formation of oxide or basic sulphate by the action of a soln. of **alkali persulphate**. N. Domanicky discussed the reaction with **sulphur monochloride**. According to K. Heumann and P. Köchlin, antimony forms the volatile trichloride, and a non-volatile antimony compound, when it is heated with **chlorosulphonic acid**; with **sulphuryl chloride**, the reaction is symbolized: $2\text{Sb} + 3\text{SO}_2\text{Cl}_2 = 2\text{SbCl}_3 + 3\text{SO}_2$; with **thionyl chloride**: $6\text{Sb} + 6\text{SOCl}_2 = 4\text{SbCl}_3 + \text{Sb}_2\text{S}_3 + 3\text{SO}_2$; and with **pyrosulphuryl chloride**: $2\text{Sb} + 3\text{S}_2\text{O}_5\text{Cl}_2 = 2\text{SbCl}_3 + 3\text{SO}_2 + 3\text{SO}_3$. E. B. Hutchins found that hot, conc. soln. of **telluric acid** attack antimony.

No compound of antimony and **nitrogen** has been obtained by the union of the two elements—*vide* 8. 49, 12. F. H. Newman⁵ studied the adsorption of nitrogen in discharge tubes; and K. Iwase found that antimony does not occlude nitrogen. G. Gore found antimony to be insoluble in liquid **ammonia**. C. A. Kraus observed complex ion formation with antimony in ammonia soln. E. B. Peck showed that the metal dissolves in a soln. of sodium in liquid ammonia—*vide* sodium antimonide. F. W. Bergstrom found that antimony is attacked by **potassium amide**. T. Curtius and A. Darapsky found that an aq. soln. of **hydrazoic acid** slowly attacks antimony, and when the soln. is evaporated in vacuo, antimony trioxide remains. According to J. J. Berzelius, when antimony is treated with **nitric acid**, nitric oxide is given off, and a basic antimony nitrate as well as antimony tetroxide or pentoxide are formed. The colder and the less the conc. of the nitric acid, the greater the proportion of antimony nitrate, and the less the proportion of antimony tetroxide produced. The antimony nitrate will then be mixed with antimony, which remains undissolved when the products of the reaction are digested with hydrochloric acid. H. Rose said that antimony tetroxide is always produced along with the trioxide; and C. P. Conrad found that the oxidation is never complete. The reaction was also studied by J. Lefort. N. A. E. Millon made the remarkable observation that if nitric acid of sp. gr. 1.42–1.51 is completely freed from nitrous acid the attack by nitric acid is very slight at 20°; if a little nitrous

acid be added the reaction progresses continuously—see the action of nitric acid on copper, silver, etc. An acid weaker than that of sp. gr. 1.42 has no marked action on antimony even if it contains nitrous acid. C. Montemartini said that, contrary to the statements of J. Personne, and E. J. Maumené, the action on antimony of nitric acid, varying in concentration from 2 to 70.27 per cent., does not yield appreciable quantities of ammonia; 2 per cent. acid has very little action on the metal. Antimony is not dissolved by nitric acid; a white powder always remains; when 70 per cent. acid is used, this residue seems to have the composition $(\text{SbO})\text{NO}_3$. Nitrogen peroxide is practically the sole gas produced when this metal is used. N. A. E. Millon found that a mixture of nitric and hydrochloric acids has no action if dilute, or at a low temp., but when very dilute, and potassium nitrate is added, the action will begin. A. Quartaroli studied the period of induction. C. C. Palit and N. R. Dhar observed no action with 13 per cent. nitric acid, and a slow action with 26 per cent. acid during 3 hrs. at ordinary temp. There was a slight formation of nitrous acid. P. T. Austen found that antimony does not burn in the vapour of nitric acid. A. Strøng found that antimony readily dissolves in a mixture of nitric and tartaric acids; and A. Czerwek obtained a similar result with mixtures of nitric acid and other polybasic organic acids. P. Sabatier and J. B. Senderens found that **nitrogen peroxide** converts reduced antimony into the trioxide. According to J. J. Sudborough, **nitrosyl chloride** transforms antimony, at ordinary temp., into antimony pentachloride, and the complex NOCl.SbCl_5 , **antimony nitrosyl hexachloride**.

Antimony was shown by B. Pelletier,⁶ and G. Landgrebe to unite readily with **phosphorus**, forming phosphides. E. Baudrimont found that when antimony is heated with **phosphorus pentachloride** it forms antimony and phosphorus trichlorides; and A. Michaelis found that when antimony is heated in a sealed tube with **phosphorus trichloride** at 160°, red phosphorus and antimony trichloride are formed. F. Krafft and R. Neumann obtained an analogous result at 200°; and they found that when antimony is heated for 6 hrs. with **phosphorus trioxide**, 96 per cent. of the theoretical amount of antimony trioxide is formed; with **phosphorus trisulphide**, for 9 hrs. at 325°, almost the theoretical amount of antimony trisulphide is formed; with **arsenic trichloride**, at 200° for 6 hrs., 97 per cent. of the theoretical antimony trichloride is formed; W. Finkelstein found that antimony precipitates arsenic from a soln. of arsenic trichloride in nitrobenzene with **arsenic trioxide**, at 360°, 90 per cent. of the theoretical trioxide is formed: $2\text{Sb} + \text{As}_2\text{O}_3 = \text{Sb}_2\text{O}_3 + 2\text{As}$; and with **arsenic trisulphide**, at 360°, a 90 per cent. yield of antimony trisulphide is obtained. J. J. Berzelius found that antimony reduces **antimony tetroxide** to the trioxide; and a similar result is obtained with **antimony pentoxide**.

F. von Bacho found that antimony begins to react with **carbon dioxide** at about 830°, and at 1100° the reaction is found to occur in accordance with $2\text{Sb} + 3\text{CO}_2 = \text{Sb}_2\text{O}_3 + 3\text{CO}$. The antimony trioxide sublimes at this temp. No evidence of the formation of higher oxides was obtained. K. Iwase found that carbon dioxide and **carbon monoxide** are not dissolved by antimony. W. Fränkel studied the reduction of **carbon dioxide** by antimony between 400° and 900°. The equilibrium: $3\text{CO}_2 + 2\text{Sb} = \text{Sb}_2\text{O}_3 + 3\text{CO}$ is attained in some weeks at 400°; in some days at 500°; in 60 hrs. at 650°; and in 24 hrs. at 900°. A. Cahours found that some organic compounds react with antimony—e.g. the **alkyl iodides** which furnish stibines. Antimony was also found by B. Moritz and C. Schneider to be readily attacked by many **organic compounds** in the presence of air; for instance, by oxalic, malic, tartaric, or citric acid, but not by malonic, succinic, benzoic, or salicylic acid, or by phenol. According to A. Czerwek, antimony trisulphide is soluble in a mixture of nitric acid with **tartaric acid**, or other organic polybasic acid; E. Cohen found that it is not attacked by a mixture of **alcohol** and **ether**; and C. B. Gates, that 0.0014 grm. is dissolved by a c.c. of **oleic acid** in 6 days. According to J. Milbauer and B. Slemr, very finely ground antimony

dissolves fairly rapidly in soln. of tartaric acid, alkali tartrates, citric acid, and alkali citrates if a rapid current of air is passed through the soln., and much more slowly in lactic, hydrofluosilicic, and oxalic acids under the same conditions. Y. Shibata and H. Kaneko studied the oxidation of pyrogallol in the presence of colloidal antimony. A. Korezynsky studied the catalytic action of antimony on the halogenization of aromatic hydrocarbons. H. Moissan observed that **boron** is not attacked when heated with antimony. E. Vigouroux found that when antimony is heated with **silicon**, a silicide is formed, but L. Kahlenberg and W. J. Trautmann observed no reaction at high temp.

A. Joannis⁷ observed the formation of sodium tritantimonide when a soln. of **sodium** in liquid ammonia acts on antimony, and the reaction was studied by E. B. Peck, and C. A. Kraus and H. F. Kurtz. The action of antimony on the **metals** is discussed in connection with the antimonides. The partition coeff. of antimony between zinc and lead was found by G. Tammann and P. Schafmeister to be 1.28 at 535°; between zinc and bismuth, 0.66 at 550°; and between aluminium and lead, 2.22 at 725°. W. Guertler discussed the affinity of antimony for some of the other metals. J. J. Berzelius found that when **mercuric oxide** is heated with antimony, green mercuric antimonate is first formed, and afterwards antimony pentoxide. O. Ruff and K. Albert found that antimony is attacked by aq. soln. of the **alkalies, and of their salts**. K. Jellinek and J. Wolff studied the equilibrium of the molten chlorides of sodium, potassium, barium, and strontium in contact with antimony. Molten **potassium hydrosulphate** was found by M. Websky to attack antimony, forming a basic sulphate and an antimonate. Powdered antimony mixed with an **alkali nitrate** detonates when heated, forming an antimonate. R. Böttger observed the reduction of a soln. of potassium nitrate by antimony. J. B. Senderens found that soln. of **copper nitrate** are reduced covering the antimony with a thin layer of copper. C. Strzyzowsky observed that Fehling's soln. is reduced by antimony. M. Kohn found that the reaction with antimony and ammoniacal soln. of copper salt containing tartaric acid resembles that with arsenic (*q.v.*). T. Polek and K. Thümmel observed that, unlike arsenic, phosphorus, and sulphur, when antimony is placed in a soln. of **silver nitrate**, it does not form a complex salt, but furnishes silver tritantimonide, which is soon converted into antimony trioxide and silver. R. Bartels said that some hydrogen is evolved; but with 0.05*N*-AgNO₃, J. B. Senderens observed no evolution of gas, and the soln. is incompletely reduced since the antimony acquires a protective film of a basic nitrate; with 0.25*N*- or 0.5*N*-AgNO₃, antimony gives a quantitative precipitate of silver, and the soln. contains nitric acid with very little ammonium nitrate. W. P. Dexter found that antimony reduces **gold trichloride** completely to the metal gold. J. B. Senderens observed no reduction of a soln. of **lead nitrate** by antimony. N. W. Fischer said that antimony does not precipitate mercury from soln. of **mercuric chloride**. J. W. Slater found that antimony reduces a soln. of **potassium permanganate**, forming manganese dioxide, and a soln. of potassium antimonate. J. Attfield observed that antimony reduces **ferric chloride**, forming antimony trichloride; and R. Böttger also found that soln. of **ferric sulphate** and of **potassium ferricyanide** are reduced by antimony. H. Lessheim and co-workers discussed the co-ordination number of antimony in its complex salts.

Some reactions of analytical interest.—Soln. of antimonious salts give a precipitate of a basic salt when treated with **water**. According to F. Jackson,⁸ the presence of one part of antimony in 2000 parts of liquid can be so detected. **Alkali hydroxides and carbonates** precipitate antimony trioxide from soln. of its salts; the precipitate is soluble in an excess of the alkali-lye; the precipitate with aq. **ammonia** is not soluble in an excess—*vide infra*, antimony trioxide. H. Demarçay found that the **carbonates of the alkali earths, and magnesium carbonate** precipitate antimony trioxide from salt soln.; the precipitation is incomplete with barium carbonate, some barium antimonite being formed. Soln. of antimonious or antimonie salts do not give a precipitate with **hydrochloric acid**.

The acid soln. precipitates orange-red antimony trisulphide when treated with **hydrogen sulphide**: $3\text{H}_2\text{S} + 2\text{SbCl}_3 \rightleftharpoons \text{Sb}_2\text{S}_3 + 6\text{HCl}$. The trisulphide is soluble in hydrochloric acid, and in the 1 : 1-acid it is soluble under conditions where arsenic trisulphide does not dissolve. Consequently, the soln. from which the trisulphide is to be precipitated **must be weakly acidic**—*vide infra*, antimony trisulphide. F. Neher said that in the presence of 27.69 per cent. hydrochloric acid antimony salts soln. gave no precipitate with hydrogen sulphide. In practice, the soln. of antimony trichloride is not diluted too much at first because of the precipitation of the oxychloride, rather is the gas passed into the liquid, and the soln. then diluted and again treated with gas. The precipitated sulphide is soluble in a soln. of ammonium sulphide, forming ammonium sulphantimonite; antimony trisulphide is also soluble in alkali-lye, forming a mixture of a soluble antimonite and sulphantimonite. The soln. of the sulphantimonites are decomposed by acids with the precipitation of antimony trisulphide. According to C. H. Pfaff, hydrogen sulphide gives an appreciable effect with one part of the salt in 20,000 parts of water; F. Jackson said 1 in 512,000 parts; and H. Reinsch found that one part of potassium antimonyl tartrate in 10,000 parts of water and 5000 parts of hydrochloric acid gives a perceptible cloudiness with hydrogen sulphide; with 15,000 parts of water and 7500 parts of hydrochloric acid, a yellow coloration; and with 30,000 parts of water and 15,000 parts of acid, no visible effect is produced—*vide infra*, antimony trisulphide.

With soln. of antimonie salts, H. Rose assumed that hydrogen sulphide precipitates a mixture of antimony trisulphide and sulphur; but R. Bunsen, G. C. Wittstein, and A. Classen said that the pentasulphide is formed. O. Klenker, T. Willm, and J. Thiele were unable to confirm R. Bunsen's results. O. Bosek studied the action of hydrogen sulphide on antimonie acid by the methods employed by B. Brauner and F. Tomicek with arsenic acid. He found that when an excess of hydrogen sulphide in the form of an aq. soln. acts at once on antimonie salt soln. at ordinary temp., antimony pentasulphide alone is precipitated; and that when hydrogen sulphide acts on soln. of antimonie salts under otherwise similar conditions, the proportion of pentasulphide precipitated is greater the lower the temp., and the more rapid the stream of gas; and the proportion of trisulphide is increased by reversing these conditions. The proportion of pentasulphide increases as the amount of hydrochloric acid increases up to a maximum lying between 10 and 20 per cent. HCl; after that limit the proportion of pentasulphide rapidly decreases as the amount of hydrochloric acid increases. In the presence of chromic salt soln., acidic soln. of antimonie acid are reduced more easily and completely than without such an addition. Antimony trisulphide alone is obtained from antimonie salt soln. only in the presence of chromic acid, and with a slower current of hydrogen sulphide, for a longer time, at a higher temp., the black trisulphide is formed. B. Brauner added that whereas arsenic acid is first converted by hydrogen sulphide into oxysulpharsenic acid, antimonie acid gives a precipitate of the sulphide almost immediately; oxysulpharsenic acid and its stable salts are known, but not so with the oxyantimonates. These facts are, *à priori*, against a complete analogy in the mechanism of the action of hydrogen sulphide on arsenic and antimonie acids. When a soln. of antimonie acid is treated with insufficient quantity of hydrogen sulphide, in a few hours, the antimonie acid is reduced to antimonious acid with the separation of free sulphur. B. Brauner said that the action cannot be explained as a direct reduction: $\text{H}_3\text{SbO}_4 + \text{H}_2\text{S} + \text{Aq.} = \text{H}_3\text{SbO}_3 + \text{H}_2\text{O} + \text{S} + \text{Aq.}$, because (i) hydrogen sulphide as such does not reduce antimonie acid, and that its sulphur probably combines with the antimony as sulphantimonie acid; and (ii), even in the presence of such a strong reducing agent as sulphur dioxide, acting for a long time, only about 75 per cent. of the antimonie acid is reduced to antimonious acid. It is possible that when an excess of hydrogen sulphide is present along with free mineral acid, sulphantimonie acid is first formed: $2\text{H}_3\text{SbO}_4 + 8\text{H}_2\text{S} + \text{Aq.} = 2\text{H}_3\text{SbS}_4 + 8\text{H}_2\text{O} + \text{Aq.}$; followed by the formation of antimony pentasulphide: $2\text{H}_3\text{SbS}_4$

+ $n\text{HCl} + \text{Aq.} = \text{Sb}_2\text{S}_5 + 3\text{H}_2\text{S} + n\text{HCl} + \text{Aq.}$ B. Brauner preferred the assumption that when the antimonious acid is in excess, sulphantimonious acid is first formed, but this, in contact with the excess of free antimonious acid, forms trioxysulphantimonious acid: $\text{H}_3\text{SbS}_4 + 3\text{H}_3\text{SbO}_4 + \text{Aq.} = 4\text{H}_3\text{SbO}_3\text{S} + \text{Aq.}$; this, however, must be a very unstable compound and decompose at once into antimonious acid and sulphur: $n\text{H}_3\text{SbO}_3\text{S} + m\text{HCl} + \text{Aq.} = n\text{H}_3\text{SbO}_3 + n\text{S} + m\text{HCl} + \text{Aq.}$ The existence of the trioxysulphantimonious acid corresponds with the deep orange colour of the liquid first formed, before the formation of antimonious acid and sulphur which occurs when the soln. is allowed to stand for some time. A soln. of an **alkali sulphide** with antimonious salts gives a precipitate of orange-red antimony trisulphide; and orange antimony pentasulphide from soln. of antimonious salts. All salts of antimony when warmed with **sodium thiosulphate** give a precipitate of the sulphide: $2\text{SbCl}_3 + 3\text{Na}_2\text{S}_2\text{O}_3 + 3\text{H}_2\text{O} = \text{Sb}_2\text{S}_3 + 3\text{Na}_2\text{SO}_4 + 6\text{HCl.}$

Antimonious salt soln. are reduced by **hydriodic acid** or **alkali iodides** in acid soln.: $\text{SbCl}_5 + 2\text{HI} = 2\text{HCl} + \text{SbCl}_3 + \text{I}_2$, but not so with soln. of antimonious salts. Alkali iodides gave a yellow precipitate of antimony triiodide when added to a not too strongly acidic soln. of an antimonious salt. According to G. von Knorre, **sulphur dioxide** reduces antimonious to antimonious salts. Unlike the corresponding case with arsenic salts, **stannous chloride** also reduces antimonious to antimonious salts without ever precipitating the metal. Antimonious salts reduce **chromates** to chromic salts; and acid soln. of antimonious salts reduce **manganates** and permanganates to manganous salts. An aq. soln. of silver nitrate gives a heavy black precipitate of silver when treated with a soln. of an antimonious compound in fixed alkali, but with ammoniacal silver nitrate, no precipitate occurs until the ammonia has been expelled. R. Bunsen found that an ammoniacal soln. of **silver nitrate** gives a black precipitate with a soln. of an antimonious salt when evaporated on a water-bath. Antimonates with silver nitrate give a precipitate of silver antimonate soluble in aq. ammonia. Antimonious salt soln. give a white precipitate with **potassium cyanide**, soluble in excess; antimonious chloride, not tartrate, gives a white precipitate, with **potassium ferrocyanide**—soluble in hydrochloric acid or alkali-lye; alkaline soln. of antimonious salts reduce **potassium ferricyanide** to ferrocyanide; soln. of **sodium phosphate** give no precipitate with soln. of antimony salts. The reduction of antimony salts by **nascent hydrogen** resulting in the formation of stibine has been discussed in connection with arsine in the analytical reactions of arsenic. According to A. Pinkus and F. Martin, **cupferron** (nitrosophenylhydroxylamine) gives no precipitate with antimonious salts.

The metallic precipitation of antimony.—According to N. W. Fischer,⁹ **copper** precipitates antimony incompletely from a hydrochloric soln.; K. Seubert and A. Schmidt, F. Faktor, and Z. Roussin found that **magnesium** precipitates black flecks of antimony with the evolution of hydrogen and stibine; if the soln. be too acid, the precipitation is incomplete. H. Rose, J. J. Berzelius, and N. W. Fischer observed that **zinc** precipitates antimony as a black powder, and C. R. Fresenius observed that a 1:1000-soln. gives a brown film in 2 mins.; a 1:20,000-soln., in 15 mins.; and a 1:30,000-soln., in half an hour—*vide infra*, H. N. Warren on explosive antimony. A. Dupasquier observed that some antimony may be evolved as stibine during the reaction with zinc, but not so with iron. H. Hager found that zinc also precipitates antimony from soln. of the alkali antimonites with the evolution of hydrogen, not of stibine. N. W. Fischer found that **cadmium** acts like zinc. W. Schulte, and R. Böttger showed that **aluminium** gives a fine black precipitate and stibine is evolved. The precipitation of antimony by **tin** was observed by N. W. Fischer, E. Pieszczyk, J. L. Gay-Lussac, A. Carnot, and J. H. Mengin; by **lead**, by N. W. Fischer; by **iron**, by J. J. Berzelius, H. Rose, N. W. Fischer, C. Tookey, O. Low, A. Thiel and K. Keller, M. Hoffmann, J. Attfield, W. L. Clasen, J. Thiele, and S. Rideal; by **cobalt**, by N. W. Fischer; and by **manganese**, by O. Prelinger. N. W. Fischer said that the precipitation by **bismuth** is incomplete.

The physiological action of antimony.—There is a traditional belief with some raisers of cattle that a daily dose of antimony (sulphide) will improve the condition and hasten the fattening of, say, horses and pigs. In Brunswick, for example, the breeders of fat geese add a little antimonious oxide to the food as a traditional custom. The old Roman *pocula emetica*, or everlasting emetic cups, were made from an alloy containing much antimony. When wine was allowed to stand therein for a few days, it dissolved some of the metal, and this acted as an emetic, causing any one drinking it to vomit violently. The available evidence is not unequivocal. J. Wohlgemuth and B. Rewald¹⁰ discussed the toxicity of antimony compounds when used in the manufacture of iron enamels. The use of antimony in medicinal preparations was prohibited in France in 1566 because it was considered so poisonous. The edict was repealed in 1650. There is a marked analogy between the symptoms of poisoning by arsenic and by antimony, particularly in cases of acute poisoning. Potassium antimonyl tartrate—tartar emetic—is the commonest antimonial preparation. The first result of swallowing tartar emetic is vomiting due to the direct action of the drug on the walls of the stomach. It is, however, quickly absorbed. The action of the heart is at first quickened, and afterwards slowed, weakened, and paralyzed. The respiration is depressed—inspiration is shortened, and expiration lengthened. Moderate doses cause a feeling of languor, inaptitude for mental exertion, and sleepiness. Antimony is excreted by the urine, bile, sweat, bronchial secretion, milk, and particularly by the fæces. The long-continued use of tartar emetic in small doses may produce fatty degeneration, especially of the liver, and a suppression of the glycogenic function of the liver. The medicinal dose of a soluble antimony salt does not exceed 97·2 mgrms.; a dose of 129·6 mgrms. has proved fatal, and a dose of 48·5 mgrms. has killed a child. A healthy adult, however, can usually take doses up to 194·4 mgrms. Horses can take 5·832 grms. three times a day; and 3·8 grms. are not considered excessive for cattle. 0·38 grm. has been prescribed as an emetic for pigs, and half this quantity for dogs.

According to M. Cloetta, in chronic antimony poisoning, there is, in contradistinction to arsenic poisoning, not only no decrease in absorption, but an absolute and relative increase, which grows with the length of time the administration lasts, and with the strength of the dose. R. G. Fargher and W. H. Gray studied the toxic action of a number of organic compounds of antimony on mice. O. Brunner found that all the more powerfully-acting compounds contain trivalent antimony, and all the feebly-acting ones quinquivalent antimony. No evidence of habituation to either group was observed. According to G. Pouchet, when antimony in the form of tartar emetic is administered for a long time to rabbits and dogs by ingestion, it tends to accumulate in the digestive tract and is found only in very small quantities in the organs and other parts of the body. It therefore differs markedly from arsenic. If antimony is administered with small quantities of arsenic, the toxic effect of the latter seems to be increased, but the distribution of the two elements in the organism is not affected. According to J. Morgenroth and O. Rosenthal, the action of tartar emetic on trypanosomes is more rapid and powerful than any other preparation yet tried, as 0·2 c.c. of a soln. of 1 in 1000 causes a disappearance of this organism. The acquisition of a noticeable resistance to the drug by repeated treatment was not observed. Various antimony compounds, like those of arsenic, are fatal to trypanosomes. According to J. D. Thompson and A. R. Cushny, the best results were obtained with ethyl antimonyl tartrate. The trypanocidal activity of antimony compounds was also studied by C. Voegtlin and H. W. Smith. J. Morgenroth and O. Rosenthal found that potassium hexatantalate counteracts the trypanocidal activity of antimony compounds on mice. G. T. Morgan and E. A. Cooper studied the germicidal action of antimony compounds on the bacillus typhosus. E. von Knaffl-Lenz was unable to find any evidence of the formation of volatile antimony compounds by moulds. In this respect, there is a difference between antimony and the similar elements arsenic, selenium, and

tellurium. The possibility that chronic antimony poisoning is due to the formation of volatile substances is excluded. A. Wöber found antimony compounds are less poisonous to phanerogams than arsenic compounds. J. A. Smorodinceff and F. E. A. Iliin studied the action of antimony compounds on the fermentative action of ptyalin in the organism. H. Eulenberg found that workmen, exposed for long periods to the vapour of antimony oxide, suffer pain in the bladder, and a burning sensation in the urethra; the continued inhalation leads to impotence and wasting of the testicles. There are a few cases on record of poisoning by antimony chloride. A. Stock and co-workers found that stibine is a violent poison. It transforms the oxyhæmoglobin into hæmoglobin and hæmolysis occurs. The action was studied by F. Joly and B. de Nabais. F. Jones said that fishes placed in water through which the gas is passing die in about 2 hrs., but a fish on the point of death is revived when placed in fresh water. A. Stock and co-workers observed that a mouse in an atm. of the gas dies at once; in an atm. with one part of stibine in a 100 parts of air, death occurs in a few seconds; with an atm. having 1 : 1000 of the gas, death occurs in two minutes; and when two mice were placed in an atm. with 1 : 10,000 for 20 mins., one died in 6½ hrs., and the other in 12 hrs. F. Flury¹¹ discussed the noxious properties of enamels containing antimony for cooking vessels.

The antidotes for antimony are infusions containing tannin or allied astringent principles—decoctions of tea, oak-bark, tannic or gallic acid, etc. Unless vomiting is free, it may be encouraged by zinc sulphate or subcutaneous injections of apomorphine, or the stomach-pump may be used. Stimulants may be required as well as hot-water bottles and warm blankets.

Some uses of antimony.—Antimony is used in making a number of alloys—*e.g.* Britannia metal, bearing or antifricition metal; type-metal; and hard-lead—largely because of its property of hardening the softer metals. It is used in making pigments and paints—*e.g.* antimony white as a substitute for white-lead; antimony black as a bronzing powder for metals or plaster; antimony reds—red or orange-red; and kermes, a brownish-yellow pigment; pharmaceutical preparations—tartar emetic, quinine antimonate, etc.; antimony oxide, or sodium antimonate as an opacifying agent for enamels, etc.—this subject was discussed by K. Fuwa, R. R. Danielson and M. K. Frehafer, etc. Naples yellow—a lead antimonate—is used for colouring pottery, tiles, etc.; colouring matter for cloth and paper; as a mordant—*e.g.* antimony oxychloride, potassium antimony oxalate, antimony tannate, and sodium antimony fluoride; and in vulcanizing rubber¹²—antimony pentasulphide; bronzing copper and iron—*e.g.* antimony chloride or fluoride. The sulphide is used in some paints, in making matches, percussion caps, and fireworks. The so-called Bengal signal light used at sea is a mixture of antimony trisulphide with twice its weight of sulphur, and six times its weight of nitre—*cf.* gunpowder. Antimonic acid is used in the manufacture of aniline red and yellow. Antimony sulphochloride is used as a macerating agent for wood; antimony salts are used in conjunction with the colloidal pastes fibrocol; for the manufacture of antiseptic washes, and the *papier couchés* of painters.¹³

§ 7. The Atomic Weight of Antimony

In 1812, J. J. Berzelius¹ recognized that the oxygen contents of the three antimony oxides were related as 3 : 4 : 5, and represented these compounds by the formulæ SbO_3 , SbO_4 , and SbO_5 respectively. On the oxygen 16 basis, and from the ratio $\text{Sb} : \text{SbO}_4$, he calculated the at. wt. of antimony to be 258.0; and from the ratio $\text{Sb} : \text{SbS}_3$, 257.8. In 1826, he recognized that the lowest oxide has the nature of a sesquioxide, and he therefore represented the three oxides by the formulæ Sb_2O_3 , Sb_2O_4 , and Sb_2O_5 . This reduced his values for the at. wt. of antimony one-half. Later workers found J. J. Berzelius' value for the at. wt. to be too large, and that 120 would have been nearer the mark. This number is in agreement with the vapour densities of the volatile antimony compounds; with the sp. ht. rule; with the isomorphism of the antimony compounds of the same family of

elements; and with the position of antimony in the periodic table. J. Dalton gave 40 for the chemical equivalent of antimony.

Antimony is undoubtedly *tervalent* in such compounds as stibine, SbH_3 ; the trihalides, SbCl_3 , SbBr_3 , and SbI_3 ; trimethylstibine, $\text{Sb}(\text{CH}_3)_3$; and triethylstibine, $\text{Sb}(\text{C}_2\text{H}_5)_3$. It is *quinquevalent* in the stibonium salts—e.g. tetraethylstibonium iodide, $\text{Sb}(\text{C}_2\text{H}_5)_4\text{I}$, and hydroxide, $\text{Sb}(\text{C}_2\text{H}_5)_4\text{OH}$ —in pentamethylstibine, $\text{Sb}(\text{CH}_3)_5$, and pentaethylstibine, $\text{Sb}(\text{C}_2\text{H}_5)_5$; and in antimony pentafluoride, SbF_5 . The compounds SbF_5Br , $(\text{SbF}_5)_2\text{I}$, SbF_5I , and SbF_5S , may involve antimony in a valency greater than five; but more probably, fluorine is not always univalent, and the bromine, iodine, and sulphur are attached to the fluorine, not the antimony. Chlorine does not form complexes with the pentafluoride, and this is in agreement with (i) the failure of P. Lebeau to prepare chlorine fluoride, and (ii) the known combinations of fluorine with bromine, iodine, and sulphur. The *quadrivalency* of antimony is discussed in connection with antimony tetroxide. M. Padoa discussed the valency of antimony.

F. Kessler calculated 120.86 for the at. wt. of antimony from the ratio $\text{Sb}_2\text{O}_3 : \text{O}_2$; W. P. Dexter, 122.46, from the ratio $2\text{Sb} : \text{Sb}_2\text{O}_4$, and J. Knop, 122.04; F. Kessler, 121.31, from the ratio $2\text{Sb} : 3\text{O}$; and F. Winkler, 121.448 from the ratio $\text{Sb} : \text{Sb}_2\text{O}_4$. F. Kessler obtained 121.21, from the ratio $2\text{SbCl}_3 : 2\text{O}$; and 119.59, from the ratio $3\{\text{K}(\text{SbO})\text{C}_4\text{H}_4\text{O}_6 \cdot \frac{1}{2}\text{H}_2\text{O}\} : \text{K}_2\text{Cr}_2\text{O}_7$; and 124.26 from the ratio $\text{SbCl}_3 : 3\text{AgCl}$. Assuming the at. wt. of silver to be 107.92, J. P. Cooke obtained 121.86 from the same ratio $\text{SbCl}_3 : \text{AgCl}$; 119.90–119.91 from the ratio $\text{SbBr}_3 : 3\text{AgBr}$; and 119.86 from the ratio $\text{SbI}_3 : 3\text{AgI}$. H. Rose obtained 120.63 from analyses of the trichloride; J. B. A. Dumas, 121.88 from the ratio $\text{SbCl}_3 : 3\text{Ag}$; and J. P. Cooke, 119.90 from the ratio $\text{SbBr}_3 : 3\text{Ag}$. E. R. Schneider obtained 120.41–120.53 from the ratio $\text{Sb}_2\text{S}_3 : 2\text{Sb}$, and J. P. Cooke, 120.22 from the ratio $2\text{Sb} : \text{Sb}_2\text{S}_3$ with the red sulphide, and 120.54 with the black sulphide. B. Unger calculated 119.71 from his value for the ratio $3\text{Na}_2\text{SO}_4 : \text{Sb}_2\text{S}_3$. F. Pfeifer computed 122.36 from his value for the ratio $3\text{Cu} : 2\text{Sb}$, and 121.36 from the ratio $3\text{Ag} : \text{Sb}$, while A. Popper obtained 121.20 from the ratio $3\text{Ag} : \text{Sb}$. E. Cohen and co-workers showed that the electrolytic results obtained by A. Popper, and F. Pfeifer are invalid because the eq. of antimony increases with the conc. of the soln. electrolyzed. J. Bongartz obtained 120.64 from the ratio $2\text{Sb} : 3\text{BaSO}_4$; and G. C. Friend and E. F. Smith, 120.43, from the ratio $\text{K}(\text{SbO})\text{C}_4\text{H}_4\text{O}_6 : \text{KCl}$. H. H. Willard and R. K. McAlpine, and O. Höhnigschmid and co-workers obtained 121.76 by converting the purified metal into the chloride or bromide—Ag, 107.88; Cl, 35.457; and Br, 79.916; P. F. Weatherill gave 121.748 from the ratio $\text{SbCl}_3 : 3\text{Ag}$ with Ag, 107.880; and Cl, 35.458. H. H. Willard and R. K. McAlpine obtained 121.773; and T. Schreiner, 121.73 from the ratio $\text{SbBr}_3 : 3\text{AgBr}$ when the at. wt. of silver is 107.88. Working with the results available in 1907, B. Brauner considered that 120 was the best representative value for the at. wt. of antimony; and F. W. Clarke, in 1910, gave 120.048. The International Table for 1925 gave 120.2 as the best representative value. K. R. Krishnaswami found that the at. wt. of antimony from different sources ranged from 121.744 to 121.754, so that the variation is less than the experimental error.

The **atomic number** of antimony is 51. F. W. Aston found that the mass spectrum of antimony obtained from the trimethide gives lines corresponding with **isotopes** with at. wt. 121 and 123 respectively—the former being 10–20 per cent. more intense than the latter. The results agree with the value obtained by H. H. Willard and R. K. McAlpine. S. D. Muzaffar determined the at. wt. of antimony derived from stibnite from various sources. From the ratio $3\text{SbCl}_3 : \text{KBrO}_3$, he found with Hungarian stibnite, 121.144; Bornean stibnite, 121.563; Peruvian stibnite, 121.720; and Bolivian, 122.374, pointing to a different distribution of the isotopes in different localities. N. Bohr represented the **electronic structure** of antimony by (2) (4, 4) (6, 6, 6), (6, 6, 6) (4, 1). C. D. Niven, M. L. Huggins, J. H. W. Booth, and H. Collins have made some speculations on this

subject. M. Padoa discussed the valencies of the crystal lattices; H. G. Grimm and A. Sommerfeld, the electronic structure; and H. Pettersson and G. Kirsch, **atomic disintegration** by bombardment with α -rays. H. Müller obtained negative results by exposing antimony to an intense α -radiation, and testing for induced radioactivity.

§ 8. The Antimony Hydrides

While studying the electrolytic decomposition of water by means of an antimony cathode, R. L. Ruhland¹ obtained a brownish-black substance which he regarded as a *solid antimony hydride*. R. F. Marchand likewise obtained black flecks in the electrolysis of a soln. of ammonium chloride with an antimony cathode, and with a large current density there was a development of gas which burnt in air with a white flame—maybe with feeble detonations. He regarded the gas as spontaneously inflammable antimony hydride, but R. Böttger showed that the self-accendible properties and the detonations are due to the formation of some nitrogen chloride; the gases evolved at the negative pole are hydrogen and ammonia. E. Wiederhold obtained a powder resembling graphite when an alloy of zinc with one-fifth of its weight of antimony is treated with dil. sulphuric acid. The residue was washed with tartaric acid soln. to remove the antimony trioxide. The analysis corresponded with SbH_2 . Dil. acids and dil. alkali-lye are without action; the hydride decomposes with the evolution of hydrogen at 200° . An alloy of zinc with one-thirtieth of its weight of antimony gave only metallic antimony as a powder. In repeating these experiments, R. C. Engel obtained only arsenic in place of the alleged antimony hydride. A. Stock and O. Güttmann observed no solid antimony hydride was produced by the spontaneous decomposition of liquid stibine; and H. Reckleben and J. Scheiber observed none in their study of the action of the silent discharge on stibine. E. J. Weeks and J. G. F. Druce did not

succeed in preparing a solid hydride of antimony by reducing a soln. of the trichloride by stannous chloride. H. J. S. Sand and co-workers showed that the amounts of stibine formed at an antimony cathode during the electrolysis of soln. of sulphuric acid and sodium hydroxide were related to the temp. and conc. of the electrolyte. Besides stibine, an amorphous deposit containing antimony was deposited in the alkali-electrolyte. E. J. Weeks and J. G. F. Druce showed that the amorphous deposit is **antimony dihydride**, Sb_2H_2 , analogous to arsenic dihydride. When mixtures of stibine and hydrogen are passed through soln. of sodium hydroxide over 5*N*-conc., poor yields of the dihydride were obtained: $\text{SbH}_3 + 3\text{NaOH} = \text{Na}_3\text{Sb} + 3\text{H}_2\text{O}$; followed by $2\text{Na}_3\text{Sb} + 6\text{H}_2\text{O} = 6\text{NaOH} + \text{Sb}_2\text{H}_2 + 2\text{H}_2$. Negative results were obtained with soln. of potassium hydroxide. Better yields were obtained by passing stibine over solid sodium hydroxide, which soon became covered with a grey deposit. This was decomposed by water when hydrogen was evolved. The residual antimony dihydride was treated with dil. hydrochloric acid, washed with water, and dried over calcium chloride in vacuo. The same hydride is produced when stibine is prepared by dropping a soln. of antimony trichloride in conc. hydrochloric acid, diluted with its own vol. of water, into a flask containing zinc and dil. hydrochloric acid. A grey residue of antimony dihydride was formed: $2\text{SbCl}_3 + 8\text{H} \rightarrow 6\text{HCl} + \text{Sb}_2\text{H}_2$. Antimony dihydride is soluble in moderately conc. nitric acid, but is insoluble in other dil. mineral acids, and in conc. sulphuric or hydrochloric acid. It is readily attacked by conc. nitric acid, and dil. aqua regia, and it is insoluble in alkali-lye. At a dull red-heat, there is a slight decomposition, and at a sufficiently high temp. it becomes incandescent, and glows until it is converted into elemental antimony. There is no abrupt change in vol. when heated between 12° and 112° in xylene in a dilatometer. The dihydride reacts vigorously with fused potassium nitrate, while reduced antimony dissolves in the same solvent very slowly.

In 1837, L. Thompson,² and C. H. Pfaff, almost simultaneously discovered gaseous **antimony trihydride**, or **stibine**, SbH_3 . It is formed when dil. hydrochloric or sulphuric acid acts on a suitable antimonial alloy. Thus, L. Thompson, H. Capitaine, J. L. Lassaigue, M. Berthelot and P. Petit, J. P. Cooke, R. H. Brett, H. Halle, K. Olschewsky, H. A. von Vogel, R. Bartels, and A. Stock and W. Doht, used an alloy of zinc and antimony. The proportions Sb : Zn recommended varied from L. Thompson's 1 : 1 to A. Stock and W. Doht's 1 : 4. E. J. Weeks showed that there is no actual best composition since the same amount of stibine can be obtained from alloys varying from 1 : 1 to 1 : 4. J. Schiel, and H. Capitaine used an alloy of potassium and antimony; A. van Bijlert, and T. Poleck and C. Thümmel, an amalgam of sodium and antimony; T. Humpert, an alloy of antimony and magnesium; and H. von der Planitz, an alloy of antimony and lead with conc. hydrochloric acid, or, according to A. Harding, with hydrobromic acid. D. Vitali found that the presence of mercuric chloride seriously interferes with the formation of stibine, in the reaction with zinc, acid, and antimony. H. Caron treated an alloy of antimony with barium, strontium, or calcium with water; H. Moissan said that an alloy of calcium and antimony of a high degree of purity gives hydrogen, not stibine, with dil. acids. The best yield obtained by A. Stock and W. Doht with the zinc-antimony alloy (3 : 1) and dil. sulphuric acid was a mixture of hydrogen with 0.98 vol. per cent. of stibine; the sodium-antimony alloy gave even worse results; a calcium-antimony alloy with dil. hydrochloric acid gave a gas with 9–16 vol. per cent. of stibine; substituting strontium or barium for the calcium did not improve the yield. The very best yield was obtained when an alloy of magnesium with 33 per cent. of antimony was treated with 12 per cent. hydrochloric acid in a vessel cooled by a freezing mixture. The resulting hydrogen contained 14 per cent. of stibine. Alloys of antimony with aluminium, iron, lead, or thallium were found to be unsuitable for the preparation of stibine—aluminium and iron alloys gave a gas with only a little stibine; and lead and thallium alloys, a gas with only a trace of stibine. T. Humpert found that hydrogen iodide acting

on the dry alloy of zinc or sodium and antimony forms no stibine ; nor does hydrogen sulphide acting on the sodium-antimony alloy.

F. Paneth and co-workers, and H. Blumenberg observed that stibine is produced when activated hydrogen is developed electrolytically, using antimony rods as electrodes. Stibine is also formed when soln. containing antimony are treated with nascent hydrogen. For example, soln. of the compounds of antimony with oxygen or chlorine, or potassium antimonyl tartrate, were found by L. Thompson, C. H. Pfaff, H. A. von Vogel, and J. F. Simon to give stibine in the presence of zinc and dil. hydrochloric or sulphuric acid ; Z. Roussin, and K. F. O. Seubert and A. Schmidt used magnesium in place of zinc ; and R. Böttger, aluminium. J. F. Simon found that stibine is formed when kermes is treated with zinc and hydrochloric acid ; and W. Skey, when stibnite is treated in a similar way. A. Dupasquier, and J. Thiele found that no trace of stibine is formed if iron is used in place of zinc, while very little is obtained with tin. According to V. A. Jacquelin, only a very small proportion of the antimony is converted into stibine by these processes—T. Rieckher said 4–8 per cent. T. Humpert found that the gas obtained by adding a soln. of antimony trichloride to a mixture of zinc and dil. sulphuric acid contained 10–12 per cent. by vol. of stibine. F. Jones, and E. J. Weeks and J. G. F. Druce obtained a gas rich in stibine by dropping a soln. of antimony trichloride in conc. hydrochloric acid, diluted with its own vol. of water, into a flask containing zinc and dil. hydrochloric acid. H. Capitaine obtained stibine by treating an alloy of zinc and antimony (2 : 1) with dil. sulphuric acid in which antimony trioxide was suspended ; but J. Schiel said that here the presence of antimony trioxide is not necessary. Sodium amalgam and water can be used as the source of nascent hydrogen. This mixture was found by T. Poleck and C. Thümmel, and O. Brunn to give stibine in the presence of reduced antimony ; by T. Humpert, with antimony trichloride ; and by F. A. Flückiger, with potassium antimonyl tartrate. On the other hand, no stibine was obtained by T. Fleitmann, and H. Hager when an alkaline soln. of an antimony salt was treated with zinc ; or by J. W. Gatehouse, when the soln. was treated with aluminium.

Advantage can be taken of nascent electrolytic hydrogen for the production of stibine. Thus, E. Newbery observed stibine may be associated with the hydrogen liberated from an antimony cathode ; and F. Paneth said that this method of preparing stibine can be usefully adopted in preference to that involving the treatment of a magnesium-antimony alloy with acids. H. J. S. Sands and co-workers found that the most favourable conditions involve a compact antimony electrode in a 4*N*-soln. of sulphuric acid, at a low temp. and with the current density greater than the critical value of 10 milliampères per sq. cm. A yield of about 15 per cent. by vol. may be thus obtained. For a given electrolyte at a given temp., the overvoltage becomes practically independent of current density after a certain critical value has been reached. Below this value no stibine whatever is produced, above it is obtained a yield that is influenced only very slightly by further increase of current density. The curves for acidic and alkaline soln. are quite analogous. In both cases, at a low conc., the overvoltage is high and there is practically no yield of stibine ; with increasing conc. of the acid or alkali, the overvoltage diminishes to a value almost constant at each temp. while the yield slowly increases. This is taken to mean that both acid and alkali act as catalysts, promoting the union between the antimony of the cathode and the hydrogen which is being produced with a large amount of free energy. Such catalysts might be expected to cause the decomposition of the stibine formed, when it has passed from the electrode into the liquid, where it is unstable. In agreement with this, some of the stibine is decomposed in the most conc. acid soln., and in all the alkaline ones. With rise of temp. the overvoltage decreases, the yield of stibine becoming smaller and finally zero. It is probable that these two facts are closely connected, the free energy of the nascent hydrogen gradually becoming too small with rise

of temp. to allow it to form stibine. The yields of stibine obtained by the electrolysis of soln. of sodium carbonate or sulphate using an antimony cathode and its dependence on the temp., voltage, and conc. were studied by E. J. Weeks. H. J. S. Sand and co-workers found that the formation of stibine proceeds somewhat more readily in alkaline than in acid soln., and the conditions favourable to it are similar in the two cases. To obtain appreciable yields of the gas, however, it is necessary to blow a rapid current of hydrogen past the electrode, in order to carry away the nascent gas before it has been decomposed by the alkaline soln. The decomposition product formed, when this is not done, has the properties of metallic antimony. The formation and decomposition of stibine in the corona discharge was observed by C. Montemartini.

O. Brunn recommended drying the gas by passing it over calcium chloride; and he found that it is better to confine the gas over petroleum than over mercury or water. A. Stock and O. Guttman said that the calcium chloride should be free from lime because the gas is decomposed by the hydroxides of the alkalis or alkaline earths, by the alkali carbonates, and by soda-lime. Phosphorus pentoxide can be employed as a desiccating agent. A. Stock and W. Doht obtained stibine free from hydrogen by condensing the dried mixture of hydrogen and stibine in a U-tube surrounded by liquid air. The stibine condenses to a white or colourless crystalline solid, which melts at a higher temp. to a colourless liquid. The liquid vaporizes without leaving a residue at a higher temp.

The composition of stibine was determined—directly and indirectly—by J. L. Lassaigne, F. Jones, T. Poleck and C. Thümmel, R. Bartels, and A. Stock and W. Doht. The results agree with the formula $(\text{SbH}_3)_n$. A. Stock and O. Guttman found the vapour density at 15° , air unity, was 4.360, that is, about 2.95 per cent. higher than the value calculated for SbH_3 . H. Remy discussed the structure of stibine; and H. Henstock, the electronic structure. H. Capitaine, and R. Bartels found the mixed gas obtained by treating an alloy of antimony and zinc with dil. sulphuric acid has no smell. The observations on the smell made by the early workers—L. Thompson, C. H. Pfaff, J. L. Lassaigne, and K. Olschewsky—were probably made with a gas contaminated with arsine or other impurities. A. Stock and W. Doht said that the gas has a faint smell, not unlike that of hydrogen sulphide, but quite different from that of arsine or phosphine. F. Jones said that the gas, freed from arsine, has a distinct, nauseating odour, and an intensely disagreeable taste. Some say that the stibine is as poisonous as arsine, others that it is much less dangerous, and the only poisonous action it exerts is due only to the antimony it contains, for the gas is decomposed by contact with the organism. A. Stock and W. Doht found that gas is a violent poison, being quite as toxic as arsine—*vide infra*, physiological action of antimony.

K. Olschewsky found that when the colourless gas is cooled by liquid ethylene, it forms a snow-white mass, and A. Stock and W. Doht observed that it yields colourless crystals when cooled by liquid air. D. Rabinowitsch gave 54.5 for the mol. vol. B. H. Wilsdon studied the **electronic structure** of stibine. K. Olschewsky gave -91.5° for the **melting point**, but the gas was probably impure, perhaps moist, for A. Stock and W. Doht gave -88° for the m.p. Above this temp., stibine forms a water-white liquid with a **boiling point** of -17° at 760 mm. A. Stock and O. Guttman found the **specific gravity** of the liquid at -25° to be 2.26, and at -50° , 2.34. M. Berthelot and P. Petit found that the **heat of formation** is strongly negative, being -81.8 Cals. per mol.; A. Stock and F. Wrede found this result about two and a half times too small, being -34.27 Cals. per mol. at constant vol., and -33.98 Cals. per mol. at constant press. The subject was studied by R. de Forcrand. H. J. S. Sand and co-workers found the **free energy, F**, of the reaction: $2\text{Sb} + 3\text{H}_2 = 2\text{SbH}_3$ to be $F = 6 \times 96540\pi$, where π denotes the overvoltage, which at 90° was 0.402 in an acidic soln. when stibine at a partial press. of 0.01 atm. was produced. Hence, the free energy is $F = 6 \times 96540 \times 0.402 \times 2.389 \times 10^{-4} = 55.6$ Cals. for 2 mols; at atm. press., the free energy is 62.1 Cals. for 2 mols. A similar value,

62.0 Cals. for 2 mols, is obtained with alkaline soln. At 20°, the results for acidic and alkaline soln. were respectively 74.2 and 77.0 Cals. for 2 mols. From A. Stock and F. Wrede's datum, the internal energy of 2 mols of stibine is 68.5 Cals. Again, $dF/dT=(F-U)/T$, which corresponds with a value almost zero at 100°. J. C. Thomlinson discussed the heat of formation of this family of hydrides.

The decomposition of stibine.—K. Olschewsky found that liquid stibine readily decomposes at very low temp.; and, added A. Stock and O. Guttman, liquid stibine decomposes more readily than the gaseous compound. K. Olschewsky found that the decomposition begins between -65° and -56°. Gaseous stibine explodes at ordinary temp. if there be any local heating of the containing vessel; and if the temp. of the gas at any point exceeds 200°, an explosion occurs. In the evaporation of liquid stibine, an explosion may occur without a rise of temp. The glass containing vessel may be shattered, but the force of the explosion is not great; and the temp. is so low that the hydrogen is not inflamed, and the antimony is not oxidized. R. Böttger found that stibine, presumably slightly diluted with hydrogen, is decomposed by an electric spark, forming a black deposit of antimony; A. Stock and O. Guttman found that stibine alone is instantly exploded by an electric spark; this also occurs if the stibine is diluted with 40 per cent. of hydrogen, but not so with 75 per cent. hydrogen. During the explosion, A. Stock and W. Doht found that the antimony separates as a grey powder, whereas the thermal decomposition of stibine furnishes a lustrous film of antimony. H. Reckleben and J. Scheiber found that the silent electric discharge yields only antimony and hydrogen. H. A. von Vogel studied the spontaneous decomposition of stibine at ordinary temp., and C. H. Pfaff said that the larger the proportion of free hydrogen present, the slower the decomposition. C. Montemartini studied the decomposition and formation of stibine when exposed to the corona electric discharge. K. Olschewsky found that gaseous stibine decomposes at a temp. not far removed from its b.p., -17°; and T. Humpert, and F. Jones said that the gas decomposes at ordinary temp., only if it is not diluted with much hydrogen, but A. Stock and W. Doht did not agree. If air be excluded from stibine confined in a clean glass vessel, free from alkali, it can be kept for some hours without decomposition;

and if air be present decomposition quickly sets in; similar results were obtained with aerated water, but water free from dissolved air has no perceptible effect. J. L. Lassaigue said that the decomposition of stibine is accelerated by the sun's rays, but A. Stock and co-workers could not detect any such effect.

The curves representing the relation between the percentage amount of stibine decomposed and the time vary considerably with the nature of the inner surface of the containing vessel. With a clean, smooth surface, the curve V, Fig. 8, has an S-shape: when the inner surface is etched with hydrofluoric acid, the curve has the appearance shown in III, Fig. 8; and if the inner surface of the containing vessel has a film of arsenic, the result is that indicated by IV, Fig. 8. If the vessel

FIG. 8.—The Progress of the Decomposition of Stibine in Different Containing Vessels.

be filled with stibine, and the gas is warmed, the inner surface acquires a bright film of antimony, and when this vessel is refilled with stibine, the course of the decomposition is represented by curve II, Fig. 8. In another vessel coated with antimony first by warming, and by introducing another charge of stibine and allowing it to decompose slowly for 8 hrs. at ordinary temp., the introduction of another charge of stibine gave the results represented by the hyperbolic curve, I, Fig. 8. The deposited antimony (I) accelerated the decomposition of the stibine quite differently from the acceleration (IV) produced by arsenic. The deposit of anti-

mony loses its activity after it has stood for some time. The progress of the reaction was measured by the change of press. in the containing vessel, and it is supposed that the reaction occurs instantly at the surface of antimony, and the time actually measured is occupied by the diffusion of more stibine from within to the antimony film. This is in agreement with the view of M. Bodenstein. A. Stock and O. Guttmann found that the equation employed for arsine, $kt = \log \{P_0/(3P_0 - 2P)\}$, does not apply, and they obtained better results with $V = 2(x_1 - x_2)/(x_1 + x_2)(t_2 - t_1)$, where V represents its amount of stibine decomposed in unit time—one hour—and calculated as the mean of the amounts present at the beginning and end of the time. In calculating x , an allowance of 15 mm. in 760 mm. must be made at 15° for the deviation of stibine from the normal gas-law. A. Stock, F. Gomolka, and H. Heynemann found that with a given vessel and a mirror deposited at 150° , the initial velocity of reaction is fairly constant, but in successive experiments in the same vessel the initial velocity is constant only after the superposition of three mirrors upon one another, they did not find that the activity of the film of antimony is dependent on the conc. of the stibine from which the film is produced; and they inferred that the measurements are really those of a chemical reaction and not of diffusion phenomena, because the temp. coeff. is 2.050 between 15° and 25° , and 1.909 between 25° and 35° ; the temp. coeff. of chemical reactions lie between 2 and 3 at the ordinary temp. The addition of hydrogen does not affect the rate of decomposition, and under given conditions, the relative velocity of the reaction is nearly proportional to the square root of the conc. of the stibine. In the presence of oxygen, the antimony mirror is poisoned completely for several hours; then it recovers and the reaction proceeds with increased velocity. The mirror is unaffected by oxygen in the complete absence of stibine; hence the poisoning is due to oxidation, not of the mirror itself, but of the hydride or of some compound formed intermediately, by which a layer of oxide is formed and destroys contact between the hydride and the catalyst. The "revivifying" of the mirror may be due to the reduction of this oxide by the stibine; the increased velocity of the reaction is not due to the water so produced, but may be consequent on changes in the surface of the catalyst caused by successive oxidation and reduction. Black antimony is not poisoned by oxygen, and is changed into the ordinary metallic mirror after the decomposition of the stibine has been in progress for a few minutes. A. Stock and M. Bodenstein found that the observed results can be represented by the equation $dx/dt = -kxp$, where x denotes the conc. of the stibine, and k and p are constants dependent on the nature of the reaction substance and the temp.— p was found to vary from 0.5 to 0.6—the results then agree with the assumption that the reaction occurs in two phases: (i) a rapid adsorption of the stibine by the antimony; and (ii) a slowly progressing chemical reaction at the surface. A. Stock, E. Echeandia and P. R. Voigt tested the relation $dx/dt = -kxp$ at different temp., and found that p increases with temp. from 0.4 at 0° to 0.7 at 75° . The relative decomposition velocities at 0° , 25° , 50° , and 75° are 1, 5.8, 23.8, and 86.4; and the temp. coeff. are 2.05 from 0° to 10° ; 1.80 from 30° to 40° ; and 1.66 from 60° to 70° . The reaction was studied by S. Dushman, and M. Trautz.

The decomposition of stibine by heat was noticed by L. Thompson, C. H. Pfaff, and J. L. Lassaigne; and J. F. Simon found that under these conditions stibine is decomposed more readily than arsine. O. Brunn found that stibine mixed with hydrogen begins to decompose at 150° , while A. Stock and W. Doht said that the decomposition takes place rapidly at this temp. Arsine was found by O. Brunn to begin to decompose at about 230° , so that by passing a mixture of stibine and arsine through a tube heated to 200° , the arsine alone escapes decomposition. A. van Bijlert based a method of analysis on this reaction. When a mixture of stibine and hydrogen is passed through a glass tube heated by a gas flame, a mirror of antimony is deposited on the glass before and behind the heated part. A comparison of the properties of the films of antimony and arsine has been given in connection with arsenic.

The chemical properties of stibine.—L. Vallery studied the action of traces of stibine in the combustion of **hydrogen** with palladized asbestos as catalyst. L. Thompson found that when stibine—presumably admixed with hydrogen—is mixed with **oxygen**, it is exploded violently by the electric spark. A. Stock and O. Guttman found that oxygen or **air** decomposes stibine in 24 hrs.: $4\text{SbH}_3 + 3\text{O}_2 = 4\text{Sb} + 6\text{H}_2\text{O}$, a part of the stibine also decomposes spontaneously with the separation of hydrogen. Black antimony is produced; and if the reaction occurs at -90° , yellow antimony is formed. According to H. A. von Vogel, and L. A. Buchner, when stibine, mixed with hydrogen, is set on fire in contact with air, white flakes of antimony trioxide are formed, but no elemental antimony is produced. In the analogous case with arsine, arsenic is formed. L. Thompson said that if a stream of the gas be inflamed, it burns with a bluish-green light producing dense, white clouds of antimony trioxide, and glass or porcelain held in the flame becomes covered with a metallic film, which R. H. Brett found to be darker than those produced with burning arsine. The older observations on the solubility of stibine in **water** were based on those made with hydrogen containing a small proportion of stibine; accordingly, J. F. Simon could say that stibine is not sensibly absorbed by water. F. Jones also working with a mixture of the two gases said that under these conditions water absorbs 4.12 to 5.32 c.c. per litre at 10° – 10.5° . A. Stock and O. Guttman found that at room temp. 100 vols. of water absorb 20 vols. of the gas. H. A. von Vogel, and C. H. Pfaff noticed that the gas in contact with water is decomposed with the precipitation of antimony; and A. Stock and W. Doht found that while air-free water has very little action on stibine, aerated water quickly decomposes the gas; and A. Stock and O. Guttman, and A. Güttich observed that stibine is rapidly decomposed in contact with **hydrogen dioxide**.

According to H. A. von Vogel, and L. A. Buchner, at ordinary temp. **chlorine** acts slowly on stibine, forming antimony trichloride and hydrogen chloride, without the separation of antimony; and J. F. Simon noticed that when the gas is passed through chlorine-water, hydrochloric acid and white flakes of antimony oxychloride are produced. The stibine in question was mixed with a large proportion of hydrogen, and L. Thompson accordingly said that a mixture of the gas with chlorine can be exploded by the electric spark. A. Stock and O. Guttman found that purified stibine decomposes with detonation in contact with chlorine, and similarly also with chlorine-water. A. Stock found that stibine reacts with liquid chlorine to form antimony and antimony pentachloride. J. F. Simon found that an aq. soln. of **bromine** decomposes the stibine (and hydrogen) with the separation of white flecks; while A. Stock and O. Guttman found that stibine alone is instantly attacked without explosion by gaseous and liquid bromine. O. Brunn found that stibine is completely decomposed by **iodine**, and A. Stock and O. Guttman showed that the reaction is slower than with bromine, and that hydrogen iodide and antimony triiodide are formed. With heated iodine, C. Husson observed that an orange or brown substance is formed, and a little antimony. J. F. Simon observed that when an aq. soln. of iodine is treated with stibine, it becomes colourless and deposits white flakes which, if the current of gas be continued, become brown and finally black, being converted into antimony. A. Stock and O. Guttman found that **hydrogen chloride** raises the speed of decomposition of stibine. A. Güttich found that **sodium hypochlorite** soln. slowly oxidize stibine; and that **iodic acid** also oxidizes it: $5\text{SbH}_3 + 8\text{HIO}_3 = 5\text{H}_3\text{SbO}_4 + 4\text{I}_2 + 4\text{H}_2\text{O}$, and also $5\text{SbH}_3 + 6\text{HIO}_3 = 5\text{H}_3\text{SbO}_3 + 3\text{I}_2 + 3\text{H}_2\text{O}$. Stibine does not act on neutral soln. of the **iodates** even if iodine or silver nitrate be used as catalysts.

According to F. Jones, when stibine is passed over **sulphur** it is decomposed: $2\text{SbH}_3 + 6\text{S} = \text{Sb}_2\text{S}_3 + 3\text{H}_2\text{S}$. The reaction occurs at ordinary temp. only in the presence of light, being slow in diffused daylight, rapid in sunlight. The reaction is also brought about by the electric light, light from burning magnesium, and even the light of a good oil-lamp. The same decomposition occurs at 100° , but is rapid

at higher temp. The reaction with paper coated with sulphur, by dipping in a soln. of sulphur in carbon disulphide, is coloured by stibine at a rate proportional to the brightness of the light, and F. Jones based a photometric process on the reaction. The reaction with stibine affords an extremely delicate test for antimony. The development of the orange tint is perceptible in the presence of 0.0001 gm. of antimony. A. Stock and O. Guttmann found that stibine alone reacts with finely-divided sulphur, forming hydrogen and antimony sulphides, and antimony. G. B. Buckton found that triethyl stibine readily reacts with sulphur, forming the sulphide, $(C_2H_5)_3SbS$. A. Stock and O. Guttmann also found that stibine does not react with **hydrogen sulphide**, and the contrary observation by O. Brunn is attributed to the presence of impurities in the gas. J. F. Simon, and F. Jones observed that in light, stibine and hydrogen sulphide react: $2SbH_3 + 3H_2S = Sb_2S_3 + 6H_2$. J. F. Simon found that an aq. soln. of hydrogen sulphide does not react with stibine. When stibine is passed into conc. **sulphuric acid**, T. Humpert, and R. Bartels observed a black metallic separation and the formation of hydrogen sulphide, but not sulphur dioxide—R. Bartels supposed the black substance to be antimony, and T. Humpert, antimony hydride. O. Brunn also found stibine is decomposed by dil. sulphuric acid. F. Jones also found that stibine reacts slowly with **selenium** in sunlight, and at 100° , but not in darkness; while **tellurium** reacts with stibine in sunlight; very slowly at 100° ; and not at all in darkness.

A. Stock and O. Guttmann found that **nitrogen** is without action on stibine; similarly, with **ammonia**, as was also observed by J. F. Simon; and R. Bartels added that purified ammonia does not react with stibine in darkness, but the impure gas reacts with stibine in light. The presence of ammonia, however, was found by A. Stock and O. Guttmann to accelerate the decomposition of stibine, and when a mixture of the two gases is heated, an explosion occurs. The action of **nitrous oxide** is like that of oxygen; similarly also with **nitric oxide**. At ordinary temp. the reactions with nitric oxide are represented by the equations, $6NO + 2SbH_3 = 3N_2O + 3H_2O + 2Sb$; $3NO + 2SbH_3 = 3N + 3H_2O + 2Sb$; and $3NO + 5SbH_3 = 3NH_3 + 3H_2O + 5Sb$. A. Güttich found stibine is readily oxidized by a 20 per cent. soln. of **nitrous acid**, and by a 30 per cent. soln. of **nitric acid**. C. F. Ansell found that hot nitric acid oxidizes stibine, admixed with hydrogen, forming antimony pentoxide; conc. nitric acid was found by A. Stock and O. Guttmann to act explosively on stibine. R. Mahr observed no reaction between **phosphorus trichloride** and stibine, but **phosphorus pentachloride** is slowly reduced to the trichloride. A. Stock and O. Guttmann showed that **phosphorus triiodide** reacts with stibine producing the diiodide; and the **phosphorus diiodide** reacts: $3P_2I_4 + 4SbH_3 = 4PH_3 + 4SbI_3 + 2P$; and the **antimony triiodide** then reacts: $SbH_3 + SbI_3 = 2Sb + 3HI$. R. Bartels found that **arsenic tribromide**, dissolved in carbon disulphide, gives a brown precipitate of arsenic and antimony; while R. Mahr observed that with **antimony trichloride**, a precipitate of antimony formed. R. Bartels found that an aq. soln. of **arsenic trioxide** is gradually blackened by stibine without forming a precipitate. The black soln. does not change in an atm. of carbon dioxide, but the colour gradually disappears on standing in air, and rapidly when warmed with nitric acid. When heated with hydrochloric acid, a brown precipitate is formed. A soln. of **bismuth nitrate** in nitric acid gives with stibine a metallic mirror on the walls of the containing vessel; a piece of filter-paper soaked in a soln. of bismuth nitrate is browned by stibine, the brown colour disappears on exposure to air. A soln. of **bismuth chloride** gives with stibine a steel-grey precipitate and a metallic mirror; a **bismuth acetate** soln. gives a black, pulverulent precipitate; **bismuth hydroxide** is blackened by stibine. No complex compound is formed between stibine and **boron tribromide**; arsine does form a complex.

According to A. Stock and O. Guttmann, **carbon dioxide** is without action on stibine, but when a mixture of the gases is sparked for some time the reaction can be

symbolized: $2\text{SbH}_3 + 3\text{CO}_2 = 2\text{Sb} + 3\text{H}_2\text{O} + 3\text{CO}$. A. Stock and O. Guttman said that **carbon disulphide** is the best solvent for stibine, since one vol. of the liquid dissolves 250 vols. of stibine at 0° —it is said that no chemical compound is formed because when the soln. boiled, stibine is given off and carbon disulphide remains. J. Schiel showed that when stibine is passed through carbon disulphide, and then through a glowing porcelain tube, antimony trisulphide is deposited along with sulphur and a trace of carbon, while the escaping gas contains hydrogen, methane, hydrogen sulphide, and some undecomposed carbon disulphide. A. W. Hofmann found that triethylstibine is without action on carbon disulphide even at 100° ; F. Jones showed that **mercaptan** decomposes stibine with the separation of a black powder. One vol. of **alcohol** dissolves 15 vols. of stibine; and stibine is freely soluble in **ether**, **benzene**, and **petroleum ether**. Stibine has no action on soln. of **sodium acetate**, or of **ammonium oxalate**.

According to G. Dragendorff, stibine is decomposed when passed over solid **potassium hydroxide**, and the alkali acquires a metallic film which separates in black flecks when the product is treated with water; the colourless filtrate contains antimony. The film also becomes colourless on exposure to air—presumably the film is an alloy of potassium and antimony which in both cases passes into the alkali antimonate. A. Stock and O. Guttman said that stibine is rapidly decomposed by aq. soln. of potassium or **sodium hydroxide**; a similar result was observed by O. Brunn, G. Dragendorff, and R. Bartels. A. Güttich represented the reaction: $\text{SbH}_3 + 3\text{KOH} = \text{K}_3\text{Sb} + 3\text{H}_2\text{O}$. According to F. Jones, when stibine is passed through soln. of sodium or potassium hydroxide, the liquid is tinged yellowish-brown, then deep brown, and finally a black powder separates out. This brown soln. is extremely oxidizable; the simple shaking of an open flask containing it causes the colour to disappear almost instantly; it forms indeed a delicate test for the presence of oxygen. The soln. rapidly decolorizes one of potassium permanganate. The composition of the black precipitate which separates out from such alkaline soln. has been assumed to be an antimonide of sodium or potassium, but F. Jones found its composition to be H_3SbO , or Sb_2O . W. Meissner found that alcoholic potassium or sodium hydroxide is coloured brownish-yellow by stibine, and then dark brown with the separation of dark brown flecks; arsine does not act on the alcoholic soln. I. Guareschi found that stibine is absorbed by **soda-lime**. R. Bartels found that soln. of **potassium and sodium chlorides** have no perceptible influence on stibine—*vide infra*, the desiccation of stibine.

A. Lionet found that when stibine and hydrogen are passed over **copper**, the whole of the antimony is retained; and a similar result was obtained with **cuprous oxide** and with **cupric oxide**. R. Bartels found that moist cupric hydroxide is blackened by stibine, and that a soln. of **cupric sulphate** is very slowly attacked by stibine, depositing, according to J. F. Simon, a few black flecks of copper antimonide, or, according to R. Bartels, a mixture of copper and antimony. By using a small proportion of soln., and a large proportion of gas, the deposit can be augmented. A. Güttich also studied this reaction. R. Bartels found that a soln. of **cupric chloride** gives a similar deposit, and leaves behind a soln. of cuprous chloride. A soln. of **cuprous chloride** in hydrochloric acid gives a reddish deposit which appears to be similar to that obtained with cupric salt soln. J. Riban obtained a black precipitate. In contrast with arsine, E. Dowzard found that stibine is absorbed by a 15 per cent. soln. of cuprous chloride in hydrochloric acid. R. Bartels found that moist **silver oxide** is blackened by stibine. J. F. Simon said that a dil. aq. soln. of **silver nitrate** precipitates all the antimony as silver antimonide, and if arsine be also present, the soln. will contain arsenic trioxide. The reaction was examined by C. H. Pfaff, J. L. Lassaigne, H. Halle, A. W. Hofmann, T. Humpert, A. Houzeau, F. Jones, and R. Bartels. The clear liquid has an acidic reaction, and contains very little antimony; the black precipitate was considered by T. Poleck and C. Thümmel, and R. Bartels to be a mixture of silver and antimony trioxide; by J. L. Lassaigne, and F. Jones as a silver antimonide alone or mixed

with silver. D. Vitali found the action of stibine on an aq. soln. of silver nitrate to be in all respects like that of arsine: $\text{SbH}_3 + 6\text{AgNO}_3 + 3\text{H}_2\text{O} = \text{H}_3\text{SbO}_3 + 6\text{Ag} + 6\text{HNO}_3$, except that antimonious acid, being insoluble, separates with the silver from which it can be extracted by hydrochloric acid. H. Reckleben agrees with J. L. Lassaigne's conclusion that the first action of stibine is: $\text{SbH}_3 + 3\text{AgNO}_3 = \text{Ag}_3\text{Sb} + 3\text{HNO}_3$, while the excess of silver nitrate causes the further reaction: $\text{Ag}_3\text{Sb} + 3\text{AgNO}_3 + 3\text{H}_2\text{O} = 6\text{Ag} + \text{H}_3\text{SbO}_3 + 3\text{HNO}_3$. The final precipitate, therefore, consists of silver, antimony hydroxide, and a little metallic antimony—some antimony at the same time passes into soln. A. Güttich agrees with this view of the reaction. W. J. Russell, and E. Schobig found that silver nitrate reduced by the hydrogen usually accompanying the stibine is negligibly small. According to T. Poleck and C. Thümmel, with conc. soln. of silver nitrate, say a gram of the salt in 0.7 gm. of water, the soln. is coloured yellow; if the stibine is very much diluted with hydrogen, a green coloration first appears, and grey silver is deposited. The yellow colour could not be isolated, and it is thought to be $\text{SbAg}_3 \cdot 3\text{AgNO}_3$, being formed by the reaction: $\text{SbH}_3 + 6\text{AgNO}_3 = \text{SbAg}_3 \cdot 3\text{AgNO}_3 + 3\text{HNO}_3$, and it is hydrolyzed by water: $\text{SbAg}_3 \cdot 3\text{AgNO}_3 + 3\text{H}_2\text{O} = \text{H}_3\text{SbO}_3 + 6\text{Ag} + 3\text{HNO}_3$. R. Bartels thought the yellow coloration to be due to the formation of $\text{SbH}_3 \cdot \text{AgNO}_3$, which reduces the remaining silver nitrate: $\text{SbH}_3 \cdot \text{AgNO}_3 + 5\text{AgNO}_3 + 3\text{H}_2\text{O} = \text{H}_3\text{SbO}_3 + 6\text{Ag} + 6\text{HNO}_3$. If stibine acts on a piece of filter-paper with a spot wetted with a conc. soln. of silver nitrate, the periphery is coloured dark brown or black, and the interior is either coloured grey, or not coloured at all; if the spot be wetted with a 1 : 2-soln. of silver nitrate and water, the interior will be coloured brownish-red; and if with a dil. soln., black. According to R. Bartels, moist **gold hydroxide** is blackened by stibine. V. A. Jacquelin found a soln. of **gold chloride** is decomposed by stibine; R. Bartels said the precipitate which first forms is black, the colour then changes to brown, and it then consists of gold mixed with a little antimony; antimonious acid passes into soln. The composition of the black body has not yet been determined.

R. Bartels found that aq. soln. of the **alkaline earth hydroxides** are coloured brown by stibine; and similarly with an alcoholic soln. of barium hydroxide—*vide infra*, the desiccation of stibine. He also found that the soln. of the **alkaline earth chlorides** have no perceptible action on stibine; similarly also with soln. of **magnesium chloride**, and of **zinc chloride**. J. F. Simon observed no effect with aq. soln. of **zinc sulphate**. R. Bartels observed that moist **zinc hydroxide** is but slightly affected by stibine, but after an hour's action, it acquires a yellowish-green colour; moist **cadmium hydroxide** is blackened; a black precipitate mixed with white or brass-coloured particles is slowly formed with neutral and ammoniacal soln. of **cadmium sulphate**—the precipitate with neutral soln. has very little cadmium, while that with ammoniacal soln. has 53.08 per cent. of antimony and 38.46 per cent. of cadmium. R. Bartels found that moist **mercuric oxide** is blackened by stibine. According to J. F. Simon, when stibine, admixed with hydrogen, is slowly passed into a soln. of **mercuric chloride**, the whole of the antimony collects in the precipitate, which is first white, then grey, and finally black. According to R. Bartels, the white precipitate is a mixture of mercurous chloride and antimony oxychloride, the filtrate contains antimonious acid; he represented the reaction: $6\text{HgCl}_2 + \text{SbH}_3 = 6\text{HgCl} + \text{SbCl}_3 + 3\text{HCl}$; the trichloride is then hydrolyzed by water. The grey and black colorations are due to the reduction of the mercurous chloride to mercury. A. Güttich also studied this reaction. Filter-paper soaked with a soln. of mercuric chloride was found, by M. Mayençon and M. Bergeret, to be coloured greyish-brown by stibine; F. A. Flückiger obtained this result only when the stibine is present in not too small a proportion. D. Vitali made some observations on the formation of antimonial mercury compound by stibine and mercuric chloride. R. Bartels found that soln. of **mercuric sulphate** and of **mercuric nitrate** behave in a manner analogous to that of mercuric chloride; and P. Lemoult found that a soln. of **potassium tetrodomecuriate**—Nessler's

reagent—is slowly coloured brown as in the analogous cases with phosphine and arsine. R. Bartels found that soln. of **mercurous salts** immediately give a black precipitation when treated with stibine; the black precipitate is a mixture of antimony trioxide and mercury.

R. Bartels found that a soln. of **potash-alum** has no perceptible action on stibine. R. Mahn observed no reaction between soln. of **stannic chloride** and stibine; and R. Bartels, none with soln. of **stannous chloride**; while **lead hydroxide** suspended in water is immediately blackened. E. Doward said that a soln. of **lead acetate** does not absorb stibine, while R. Bartels, and J. F. Simon observed no reaction between stibine and soln. of **lead salts**. R. Bartels found that a soln. of **chrome-alum**, or of **potassium dichromate**, is rapidly blackened by stibine; and E. Varenne and E. Herbé, that a mixture of potassium dichromate and sulphuric acid oxidizes stibine completely. R. Bartels said that a dil. soln. of **ammonium molybdate** is coloured blue by stibine; and that a soln. of **sodium tungstate** is indifferent towards stibine. Moist **manganese hydroxide** is blackened by stibine if air be excluded, while a soln. of **manganese sulphate** has no action on the gas. F. Jones found that stibine reacts with a neutral soln. of **potassium permanganate** giving a precipitate of manganese oxide while antimonious acid passes into soln.: $2\text{KMnO}_4 + \text{SbH}_3 = \text{Mn}_2\text{O}_3 + \text{K}_2\text{HSbO}_4 + \text{H}_2\text{O}$; E. Schobig said that in neutral and acidic soln., antimony trioxide and pentoxide are formed; and R. Bartels added that with dil. neutral soln., the change is not very marked; the violet soln. becomes brownish-red. J. F. Simon found that a soln. of **ferrous chloride**, and R. Bartels that **ferrous hydroxide**, is indifferent towards stibine; while soln. of **ferric chloride**, and of **potassium ferricyanide**, are slowly reduced. A soln. of **cobaltous chloride** is indifferent towards stibine; while **cobaltous hydroxide** is blackened if air be excluded; and a soln. of **cobalt hydroxypentamminochloride** gives white flecks, and finally a black precipitate which oxidizes in air, forming a pale blue mass. Moist **nickelous hydroxide** is blackened by stibine when air is excluded; and a soln. of **nickelous chloride** is indifferent towards the gas. Moist **platinum oxide** is blackened by stibine; a soln. of **platinum tetrachloride** decomposes stibine completely, producing, according to J. F. Simon, platinum antimonide; according to P. Christoffe, a mixture of the antimonide, platinous chloride, and antimony; and, according to R. Bartels, a mixture of platinum and antimony trioxide.

§ 9. The Antimonides

P. Lebeau¹ found that an alloy of lithium and antimony is formed with violence when the two elements are fused together; he obtained **lithium tritanti- monide**, Li_3Sb , by electrolyzing a fused mixture of equal parts of lithium and potassium chlorides with a current of 15 amps. using an antimony cathode; it is also formed when a small fragment of antimony is heated with lithium in a sealed tube containing liquid ammonia; the reaction is completed when the blue colour of the lithium ammonium disappears; or finely powdered antimony may be suspended in liquid ammonia at -80° , and lithium added in successive small portions until a permanent blue coloration is obtained. Lithium antimonide, thus prepared, is a brownish-grey powder in a very fine state of division, having a density 3.2 at 17° . It fuses a little above 950° , and is therefore less fusible than either of its components. It reacts readily with chlorine, bromine, iodine, sulphur, selenium, or tellurium, and burns in oxygen with a violet flame. When heated with arsenic, it yields lithium arsenide. It is more easily decomposed by carbon than the corresponding arsenide. It decomposes hydrogen chloride, bromide, and iodide, the oxides of nitrogen, and sulphur dioxide with incandescence. At a red-heat, ammonia is decomposed, hydrogen being evolved. The antimonide dissolves in liquid ammonia, forming a reddish-brown liquid which contains **lithium amminotritantimonide**, $\text{Li}_3\text{Sb} \cdot \text{NH}_3$. With water, the antimonide reacts at the ordinary temp., pure hydrogen being evolved, and antimony being formed as a black, flocculent mass; with aq. acids, a little hydrogen antimonide is also formed. The chlorides, sulphides, and oxides of the metals are reduced by the antimonide.

J. L. Gay Lussac and L. J. Thénard obtained an alloy of sodium and antimony by fusing mixtures of the two elements; E. Wiederhold, by heating a mixture of antimony trioxide and sodium in a covered crucible; and G. S. Sérullas, by heating

a mixture of sodium tartrate, sodium carbonate, and charcoal for some hours. H. Caron also made a sodium antimonide. E. B. Peck showed that the electrolytic properties of soln. of antimony and sodium in liquid ammonia indicate that a series of compounds is formed, that antimony forms the anion, and that more than one atom of antimony is associated with each negative charge. C. H. Mathewson found the two metals unite quietly at the m.p. of sodium, but at higher temp. the reaction is violent. The f.p. curve, Fig. 9, has two maxima, at 856° and 75 at. per cent. of sodium, and 465° with 50 at. per cent. of sodium, corresponding respectively with the trita- and mono-antimonides. The two eutectics are at 435° and 55.5 at. per cent. of sodium, and 400° and 39.4 at. per cent. of sodium. E. Kordes studied the eutectic mixtures. J. A. Joannis obtained **sodium tritantimonide**, Na_3Sb , by the action of an excess of a soln. of sodium in liquid ammonia

FIG. 9.—Freezing-point Curves of the Sodium-Antimony Alloys.

potential of the compound monoantimonide.

J. L. Gay Lussac and L. J. Thénard found that antimony alloys with potassium, and the reaction is accompanied by incandescence. E. Wiederhold, indeed, found that when warmed, the two elements unite with explosive violence, and he obtained alloys by heating a mixture of antimony trioxide and potassium in a covered porcelain crucible; G. S. Sérullas, by heating a mixture of antimony, potassium carbonate, and carbon; L. N. Vauquelin, by heating a mixture of antimony or roasted antimony sulphide with potassium tartrate for 2 hrs. in a covered crucible at a red-heat; by heating potassium antimonyl tartrate which has been roasted in air until it appears incandescent, or the unroasted tartrate with one-tenth its weight of potassium nitrate; and C. Löwig and E. Schweizer, by slowly heating a mixture of antimony and potassium tartrate in a covered crucible. The greyish-

FIG. 10.—Freezing-point Curves of the Potassium-Antimony Alloys.

white, soft, brittle, fine-grained, fusible alloys are best preserved in stoppered bottles under the form of naphtha. The alloys oxidize rapidly in air, and when in powder disengage so much heat that paper is ignited; under water, the alloys give off much hydrogen, and if arsenic be present, arsine. The alloys rich in potassium assume the spheroidal state when placed on the surface of mercury moistened with water. N. Parravano found the m.p. diagram of the alloys to be simple. The formation of the alloys is accompanied by the evolution of much heat, and with the high potassium alloys, the union occurs with almost explosive violence. There are three eutectics at 485° , 400° , and 63° . No solid soln. are formed. The eutectic $\text{K}_3\text{Sb}-\text{KSb}$ at 485° solidifies with supercooling in the presence of the tritantimonide, but not in the presence of the monoantimonide. T. Seebeck studied the thermo-

on antimony; and P. Lebeau, by the method employed for the corresponding arsenide. The conditions of equilibrium, studied by C. H. Mathewson, are shown in Fig. 9. The deep blue compound has the m.p. 856° . It is decomposed by water giving off hydrogen, and inflames when heated in air. C. H. Mathewson also obtained **sodium antimonide**, NaSb , Fig. 9. The colour is like that of antimony; its hardness is like that of gypsum; and it is softer and less easily oxidized than the tritantimonide. R. Kremann and E. Preszfreund found that the e.m.f. curve of the sodium-antimony alloys showed a break corresponding with the tritantimonide; but the could not be distinguished from that of the

could not be distinguished from that of the

could not be distinguished from that of the

electric properties of the potassium-antimony alloys. One of the two maxima corresponds with **potassium tritimonide**, K_3Sb , which is yellowish-green and iridescent; melts at 812° , undergoes rapid change in air, and usually ignites spontaneously when broken in air. The other maximum corresponds with **potassium monantimonide**, KSb , which forms long, slender prisms of the colour of antimony; m.p. 605° ; oxidizes in air less readily than the tritimonide, and does not ignite spontaneously when struck with a hammer. G. Bredig and F. Haber made colloidal sodium and potassium antimonides by the submerged arc process.

The alloys of antimony and copper have been discussed in connection with the latter element—**3**. 21, 6; A. A. Baikoff's ² diagram of the f.p. curves there indicated shows the existence of two compounds—the hemi- and trita-antimonides. The equilibrium diagram was studied by N. S. Kurnakoff and K. F. Beloglazoff, and K. Honda and T. Ishigaki. A. Mazzucchelli and L. Tonini prepared those alloys electrolytically; H. Weiss studied the rate of formation of homogeneous alloys from the heterogeneous alloy; and M. Chikashige studied the colour of the alloys. A silver-white mineral occurring massive near Mytilene, Asia Minor, was named *horsfordite*—after E. N. Horsford—and described by A. Laist and T. H. Norton. The analysis corresponds with **copper hexitantimonide**, Cu_3Sb —or possibly Cu_5Sb . The sp. gr. is 8.12—the value calculated from the mixture rule is 8.19. The hardness is 4–5. G. Drath and F. Sauerwald studied the surface tension of the alloys; A. Mallock, the hardness; and A. Bienias and F. Sauerwald, the viscosity. The mineral tarnishes easily in air. A. Brand described octahedral crystals containing the hexitantimonide apparently in isomorphous association with lead nickel sulphantimonide and copper lead sulphantimonide. The conditions of stability of **copper tritimonide**, Cu_3Sb , are indicated in A. A. Baikoff's diagram. S. Stevanovic found octahedral crystals in a lead furnace associated with lead, iron, nickel, and cobalt; and some rhombic crystals associated with antimonial lead. Copper tritimonide is pale grey with a feeble greenish tinge. It is dimorphous. W. M. Jones and E. J. Evans studied the X-radiogram. When the compound at 600° is quenched in water, β - Cu_3Sb is obtained in a stable form at ordinary temp.; it melts at 687° , and at 407° it passes into α - Cu_3Sb with the development of 2.5 Cals. The sp. gr. of the α -form is 8.48. β - Cu_3Sb forms solid soln. with antimony and copper, but α - Cu_3Sb does not form solid soln. Of all the alloys of copper, this was found to be the hardest. E. Sauerwald found that the degree of dissociation at 900° is 50 per cent.; at 1000° , 46 per cent.; at 1100° , 41 per cent.; and at 1200° , 37 per cent. It is oxidized by water more rapidly than the hemiantimonide. P. Braesco studied the transformation point of the tritimonide. F. Sauerwald said that at 900° , the tritimonide is 50 per cent. dissociated; at 1000° , 46 per cent.; at 1100° , 41 per cent.; and 1200° , 37 per cent. The conditions of formation of **copper hemiantimonide**, Cu_2Sb , are indicated in A. A. Baikoff's diagram. The compound was prepared by P. Christoffe, G. Kamensky, and E. J. Ball. A. Mazzucchelli and A. Vercillo made it by the action of a hydrochloric acid soln. of antimony trichloride on copper. The hard, violet or purple alloy is the *regula veneris* of the alchemists. P. Christoffe gave 7.463 for the sp. gr.; G. Kamensky, 8.339; and W. Biltz and C. Haase gave 8.75 at $25^\circ/4$. It has a fine-grained crystalline fracture. A. A. Baikoff found that the compound melts at 587° with decomposition into the tritimonide, etc. W. Biltz and C. Haase give for the heat of formation $(3Cu,Sb)=2.3$ Cals. G. Kamensky measured the e.m.f. of the alloy. F. Sauerwald said that the degrees of dissociation of **copper dipentitantimonide**, Cu_5Sb_2 , at 900° , 1000° , 1100° , and 1200° are respectively 53, 51, 46, and 36 per cent. H. Reimann gave 682° for the m.p.

E. J. Ball prepared a white alloy of copper and antimony with a conchoidal fracture. It was considered to be **copper tetrantimonide**, Cu_4Sb . The sp. gr. was 8.871. G. Kamensky found that it conducted electricity worse than antimony. E. Elsässer obtained **copper ditritantimonide**, Cu_3Sb_2 , by melting the two elements under borax.

The fine-grained, brittle, violet alloy has a sp. gr. 8.00-8.05; P. Christofle gave 7.387. E. Elsässer found the alloy conducted the electric current without decomposition. R. Christofle, and F. C. Calvert and R. Johnson found **copper monantimonide**, CuSb , collected on the surface of the alloy in needle-like crystals of sp. gr. 7.119 according to the former, and 7.99 according to the latter. P. Christofle found **copper diantimonide**, CuSb_2 , collected in rhombohedral crystals in druses in molten alloys. The sp. gr. is 6.825.

The alloys of silver and antimony were discussed in connection with the chemical properties of silver, **3**, 22, 7. They were prepared by P. Berthier,³ P. Christofle, C. R. A. Wright, and P. A. von Bonsdorff. H. Weiss studied the rate of formation of the homogeneous alloy from the heterogeneous state. H. Gautier, C. T. Heycock and F. H. Neville, and G. I. Petrenko studied the f.p. curve; W. Campbell, and G. Charpy, the microstructure; E. Maey, the sp. gr.; H. Weiss, the rate of diffusion or cementation of the two elements; A. M. Portevin, the structure of the eutectics; G. Sachs and F. Saefel, the hardness; and also the mechanical properties of these alloys; E. Elsässer, and M. Hansen and G. Sachs, the electrical conductivity; N. A. Puschin, the electrochemical behaviour; R. Kremann and K. Bayer, the electrolysis of the alloys; E. van Aubel, and W. Haken, the thermoelectric force; G. Tammann, the potential; H. Rose, the action of ammonium chloride. G. I. Petrenko's f.p. curves there shown indicate the existence of only one compound, **silver tritantimonide**, Ag_3Sb . It was obtained by P. Christofle by melting together the calculated quantities of the two elements. P. A. von Bonsdorff said that this compound is produced when pyrargyrite is heated to redness in a current of hydrogen. N. W. Fischer prepared the tritantimonide when antimony is placed in a soln. of silver nitrate, and, as shown by T. Poleck and C. Thümmel, the antimonide is soon converted into a mixture of antimony trioxide and silver. J. F. Simon, and A. W. Hofmann said that the tritantimonide is precipitated when stibine is passed into a soln. of silver nitrate, but, added F. Jones, the precipitate is always mixed with some metallic silver; and, according to H. Reckleben, with a little antimony and antimonious acid. E. J. Weeks also obtained the tritantimonide by the action of stibine on a cold dil. soln. of silver nitrate; E. J. Weeks and W. V. Lloyd used a similar process and found that the product is not oxidized by the nitric acid formed if the action be conducted in an atm. of hydrogen. E. J. Weeks said that the properties of silver antimonide are remarkable by the fact that it is totally insoluble in both hot and cold, conc. and dil., sulphuric and hydrochloric acids. It is, however, soluble in boiling dil. nitric acid, giving off nitrous fumes, but is insoluble in the cold dil. acid.

The compound is represented in nature by a mineral called by B. G. Sage, and J. B. L. Romé de l'Isle, *mine d'argent blanche antimoniale*; by T. Bergman, as *argentum nativum antimonio adunatum*; by C. J. Selb, *Spiesglanzsilber*; and by L. A. Emmerling, *Spiesglassilber*. A. Breithaupt used a similar term. Terms corresponding with *antimonial silver* were used by J. F. L. Hausmann, R. J. Haüy, and C. C. von Leonhard. J. D. Dana gave *stöchiolith* as an old name for the mineral. F. S. Beudant called it *discrase*—from $\delta\nu\sigma\kappa\rho\acute{\alpha}\iota\varsigma$, a bad alloy—and E. F. Glocker *dyskrasit*, that is, **dyscrasite**. The mineral occurs near Wolfach, Baden; Andreasberg, Harz; Casalla, Spain; Allemont and Isère, France; and in Norway, Chili, Bolivia, Mexico, Canada, New South Wales, etc. H. Wurtz called a variety from Thunder Bay, Lake Superior, Ontario, *animikite*—from an Indian word for thunder; and J. D. Dana, a variety from Chanarcillo, Chili, *chanarcillite*. Analysis were reported by C. J. Selb, M. H. Klaproth, C. F. Rammeisberg, T. Petersen, R. A. Abich, R. J. Haüy, I. Domeyko, and H. Wurtz. Some of the analyses agree with the tritantimonide, others with *silver hexitantimonide*, Ag_6Sb ; and T. Petersen called the former *stibiotriargentite*; and the latter, *stibiohexargentite*; and he suggested that the observed results represent variable mixtures of these two minerals. Some analyses correspond with $\text{Ag}_2\text{S}\cdot\text{Ag}_4(\text{Sb},\text{As})$; and the analysis of chanercillite, with $\text{Ag}_4(\text{Sb},\text{As})_3$. T. Liebisch

found a specimen from Andreasberg with the composition Ag_3Sb . G. Rose, and C. F. Rammelsberg assumed that the similarity of the crystalline form of the different varieties of the antimonial silver showed that they are isomorphous mixtures. G. A. Kenngott, and P. Groth argued that the similarity in the crystalline form of stromeyerite, chalcocite, etc., shows that dyscrasite is a mechanical mixture of *silver hemiantimonide*, Ag_2Sb , with other elements; and P. Groth later regarded dyscrasite as a mechanical mixture of the tritantimonide with silver or antimony. C. W. C. Fuchs discussed the synthesis of dyscrasite.

The mineral occurs massive, granular, and foliated; as well as in silver-white or tin-white crystals, sometimes tarnished yellow or black. J. B. L. Romé de l'Isle, and R. J. Haüy supposed the crystals of dyscrasite to be hexagonal, but J. F. L. Hausmann, C. C. von Leonhard, A. Breithaupt, F. Mohs, and F. Sandberger showed that they belong to the rhombic system; and J. F. L. Hausmann found the axial ratios to be $a:b:c=0.5775:1:0.6718$. G. Smith made some observations on the crystals. The twinning about the (110)-plane produces stellate and pseudo-hexagonal forms. The (001)- and (011)-cleavages are distinct; and the (110)-cleavage, imperfect. The crystals were studied by T. Liebisch. C. F. Rammelsberg gave 9-611-10-027 for the sp. gr.; T. Petersen, 9-611-9-960; and H. Wurtz, 9-45. E. Maey studied the sp. vol. of the alloys. The hardness is between 3 and 4. L. Jordan and co-workers studied the hardness, elongation, and tensile strength of the silver-antimony alloys. M. de Hemptinne found a maximum in the thermal expansion curves of the alloys corresponding with 73 per cent. Ag when $\alpha=0.042459$. A. Sella found the sp. ht. to be 0.0558; and J. Joly said that dyscrasite sublimates at 520° . G. I. Petrenko found a break in the f.p. curve at 559° - 560° corresponds with the tritantimonide which dissociates into a solid soln. and a molten liquid by a reversible reaction. Some observations on this subject were made by C. T. Heycock and F. H. Neville. A. de Gramont examined the spark spectrum. H. E. McKinstry observed no change when the mineral is exposed to the light of an electric arc. C. A. Kraus, and E. Elsässer studied the electrical conductivity; W. Haken, the thermoelectric properties; and N. A. Puschin, the electrochemical behaviour. F. Sandberger found dyscrasite altered to pyrrargyrite, and native silver; and T. Liebisch found the mineral becomes richer in silver by weathering. Dyscrasite is not attacked by alkali-lye; but it is soluble in nitric acid, and it leaves antimony trioxide as a residue. T. Poleck and C. Thümmel found that a current of stibine passed into a conc. soln. of silver nitrate forms a yellow soln. with an acidic reaction: $\text{SbH}_3+6\text{AgNO}_3=3\text{HNO}_3+\text{Ag}_3\text{Sb}.3\text{AgNO}_3$; the alleged **silver trinitratoantimonide**, $\text{Ag}_3\text{Sb}.3\text{AgNO}_3$, was not isolated because it is decomposed by water with the separation of silver tritantimonide.

As indicated in connection with the chemical properties of gold—**3. 23, 6**—the two elements form alloys. The alloys were prepared by C. Hatchett.⁴ H. Weiss studied the formation of homogeneous alloys from the heterogeneous state. C. T. Heycock and F. H. Neville, and R. Vogel studied the f.p. of these alloys, and W. C. Roberts-Austen and F. Osmond, and L. Nowack, the structure. The equilibrium diagram, worked out by R. Vogel, shows the existence of an unstable **gold diantimonide**, AuSb_2 , which is brittle and hard and which dissociates at about 460° . P. Christoffe obtained what he regarded as **gold monantimonide**, AuSb , by fusing a mixture of the two elements in the correct proportions. The sp. gr. is 11.13. Nitric acid oxidizes the alloy superficially; hydrochloric acid has no action; and aqua regia dissolves it easily. There is no satisfactory evidence that the monantimonide is a chemical individual; similar remarks apply to the gold tritantimonide, Au_3Sb , obtained by F. Rössler in grey crystals, when the alloy is digested with a mixture of nitric and tartaric acids. The crystals soon turn red or bronze-colour. C. Hatchett made the ternary alloys Au-Cu-Sb. G. Tammann studied the potential of these alloys.

H. Caron⁵ prepared alloys of *calcium and antimony* as indicated below.

J. D. Reidel obtained an antimonide by fusing an intimate mixture of sand, calcium, and antimony. L. Donsky examined the f.p. of alloys with up to 9 per cent. of calcium, and the results are illustrated by Fig. 11. The f.p. of antimony is lowered to the eutectic at 585° by the addition of 22 per cent. of calcium. Alloys containing a small proportion of calcium are less brittle than antimony; the 9 per cent. calcium alloy is brittle and porous; and alloys with up to 6 per cent. of calcium are not

FIG. 11.—Freezing-point Curve of Calcium-Antimony Alloys.

acted on by hot water. O. Ruff and H. Hartmann studied the velocity of absorption of nitrogen by the alloy at 400° - 520° . H. Caron prepared alloys of *strontium and antimony*; and of *barium and antimony* by treating the alkaline earth chloride with a sodium-antimony alloy containing less than 33 per cent. of sodium. The alloys oxidize rapidly in air, and if more than 5 per cent. of the alkaline earth metal be present, they are decomposed by water, forming antimony and stibine. S. Parkinson⁶ made magnesium-antimony alloys. J. D. Reidel obtained an antimonide by fusing an intimate mixture of sand, magnesium, and antimony. R. Kremann and co-workers studied the electrode potentials of these alloys. The alloys were

indicated in connection with the chemical properties of magnesium—4. 29. 5. G. Grube's diagram, there indicated, shows that only one compound is formed, namely, **magnesium ditritantimonide**, Mg_3Sb_2 . This substance appears in steel-grey needles, easy to pulverize. It melts at 961° ; and decomposes on exposure to air, forming a greyish-black powder. E. Becquerel studied the thermo-electric power of the alloys; and E. Kordes, the eutectic mixtures. The alloys of zinc and antimony were discussed in connection with the chemical properties of zinc—4. 30, 6—and the f.p. curve of S. F. Schemtschuschny⁷ is there shown. J. P. Cooke obtained large crystals of **zinc ditritantimonide**, Zn_3Sb_2 , by slowly cooling an alloy of the correct proportions of the two elements. S. F. Schemtschuschny, T. Takei, and K. Mönkmeyer also obtained this compound. C. T. Heycock and F. H. Neville, and T. Takei made observations on the f.p. of these alloys. J. P. Cooke gave 6.48 for the sp. gr.; and C. F. Rammelsberg, 6.327. F. Sauerwald studied the sp. vol. S. F. Schemtschuschny gave 565° for the m.p. M. Kawakami gave for maximum heat of admixture at 700° , 681 cal. with 46.77 at. per cent. Sb. E. Elsässer examined the electrical conductivity—*vide* the general properties of these alloys. F. Sauerwald found that at 700° , 38 per cent. of the ditritantimonide is dissociated, and at 800° , 35 per cent. Rhombic crystals of **zinc monoantimonide**, $ZnSb$, were reported by J. P. Cooke, T. Takei, and K. Mönkmeyer to be formed by cooling an alloy of the two elements in the correct proportions. J. P. Cooke gave for the axial ratios $a:b:c=0.9597:1:0.7610$. C. F. Rammelsberg gave 6.384 for the sp. gr., and K. Mönkmeyer, 6.41. The last-named gave 544° for the m.p., and S. F. Schemtschuschny showed that the alloy dissociates at 539° . T. Takei also found **zinc tetratritantimonide**, Zn_4Sb_3 , in alloys with between 35 and 45 per cent. of zinc. A. V. Saposhnikoff measured the hardness of these alloys; G. Tammann and K. Dahl, the brittleness; A. Eucken and G. Gehlhoff, the thermal and electrical conductivities; K. Herrmann, the photoelectric effects; G. Tammann, the potential. R. Kremann and J. Gmachl-Pammer examined the e.m.f. of the cadmium-antimony alloys; W. Jenge, the electrode potentials; F. Fischer and G. Pfeiderer, the thermo-electric power; H. Endo, and K. Honda and T. Sone, the magnetic susceptibility; A. Schleicher, the ternary system Cu-Cd-Sb. W. Heike found that silver mixed with zinc monantimonide made the crystals good radio-detectors. A. Battelli, E. Becquerel, and J. Beattie studied the thermoelectric properties. The alloys of cadmium and antimony were discussed in connection with the chemical properties of the former element—4. 30, 6. The alloys were made by B. Wood. C. T. Heycock and
