F. H. Neville made observations on the f.p. N. S. Kurnakoff and N. S. Konstantinoff's equilibrium diagram, there shown, indicates the existence of two compounds. W. Treitschke, and N. S. Kurnakoff and N. S. Konstantinoff obtained prismatic crystals and plates of **cadmium ditritantimonide**, Cd_3Sb_2 , from alloys with the proper proportions of the two elements. The axial ratios of the rhombic crystals are $a:b:c=0.75909:1:0.96872$; and the crystals were also examined by W. Iskill. The alloy dissociates at about 400° . E. Maey found a break in the sp. vol. curve of the alloys corresponding with the compound. W. Biltz and C. Haase gave 7.03 for the sp. gr. at $25^\circ/4^\circ$; and for the heat of formation ($3\text{Cd}, 2\text{Sb}$)= $c. 4$ Cals. Columnar crystals of **cadmium monantimonide**, CdSb , were obtained by W. Treitschke, and N. S. Kurnakoff and N. C. Konstantinoff from alloys with the correct proportions of the two elements. The m.p. is 455° . W. Biltz and C. Haase gave 6.95 for the sp. gr. at $25^\circ/4^\circ$; and for the heat of formation (Cd, Sb)= $c. 3$ Cals. G. Tammann, and W. Jenge studied the electrode potentials; A. Schulze, and M. Jakob and S. Erk, the heat conductivity; H. Endo, and K. Honda and T. Sone, the magnetic susceptibility.

C. H. Pfaff,⁸ J. F. Simon, A. Partheil and E. Mannheim, and H. Rose said that mercury antimonide cannot be made by passing arsine through a soln. of mercuric chloride. J. G. Wallerius, G. Tammann and J. Hinnüber, and J. Nicklès observed that mercury does not act on antimony at ordinary temp., but if hot mercury be triturated with melted antimony for a short time, *antimony-amalgam* is formed; and a similar product is obtained if the two elements be triturated with a little hydrochloric acid. J. Schumann triturated moistened antimony powder with sodium amalgam. R. Böttger found that when sodium-amalgam is immersed in a sat. soln. of potassium antimonyl tartrate, hydrogen gas is evolved having a peculiar odour—possibly owing to the formation of stibine—and burning with a dazzling white flame; antimony, but not the amalgam, is formed. A. J. J. Vanderveelde obtained the amalgam by the action of sodium-amalgam and antimony; but J. Schumann found that a poor yield of impure antimony-amalgam is produced by the action of a 6 per cent. zinc-amalgam on a conc. soln. of antimony trichloride. J. Schumann also prepared the amalgam by the electrolysis of a soln. of antimony trichloride for two days using a mercury cathode and a platinum anode. G. Tammann and J. Hinnüber used a similar process. G. Vortmann obtained the amalgam by electrolyzing a soln. of mercury and antimony oxides (2:1) in sodium sulphide. J. Regnauld also studied these alloys. Antimony amalgam appears as a steel-grey soft mass with a metallic lustre. J. Schumann found that a 56.6 per cent. amalgam had a sp. gr. 7.17, when the calculated value was 8.9. W. J. Humphreys measured the rate of diffusion of antimony in mercury. W. Ramsay measured the vap. press. of the amalgams and found the calculated mol. wt. of antimony to be 136.5 with 1.117 per cent. soln. of antimony in mercury, and 301.2 with 3.289 per cent. soln.—the theoretical value for Sb is 120.2. The amalgams are stable in air, but with long trituration in air, or shaking in water, black pulverulent antimony separates out. G. Vortmann said that antimony amalgam is soluble in nitric acid; and J. B. Baille and C. Féry, that when mixed with aluminium-amalgam, the antimony separates out, and the aluminium is oxidized. According to A. Partheil and E. Mannheim, when dried stibine is passed through a mixture of dry mercuric chloride and sand, contained in a rotating cylinder at ordinary temp., there is a slow reaction resulting in the formation of **mercuric ditritantimonide**, Hg_3Sb_2 . This compound is a dark grey, heavy powder, which when pure is liable to decompose, but when mixed with sand is stable. Warm nitric acid converts it into mercuric nitrate and antimony tetroxide; and when heated in air, the antimony burns to the trioxide, and mercury sublimes. Ethyl iodide, at about 185° , converts the antimonide into *ethylstibonium iodomercuriate*, $\text{Sb}(\text{C}_2\text{H}_5)_4\text{I.HgI}_2$, in white crystals melting at $93^\circ\text{--}95^\circ$.

C. R. A. Wright⁹ concluded that antimony forms no commercially valuable alloy with aluminium. He found that when antimony is dropped into molten

aluminium it falls to the bottom and melts; no combination takes place until the mixture is stirred, when part solidifies owing to the formation of an alloy with 81·6 per cent. of antimony of high m.p. Considering the m.p. of the component elements, it is remarkable that the alloy should melt over 1000° ; and H. Gautier observed that the m.p. of nearly all these alloys are above the m.p. of either constituent. H. Gautier gave for the f.p. of these alloys:

Al	0	1·13	5·42	8·40	10·28	14·66	18·65	25·0 per cent.
F.p.	632°	630°	855°	945°	1030°	1048°	1035°	1010°
Al	36·42	54·47	60	66	68·52	84·89	91·9	100 per cent.
F.p.	983°	950°	945°	950°	940°	800°	734°	650°

There is a maximum corresponding with 15·0 per cent. of aluminium and another with 68 per cent. The former corresponds with AlSb, and the other with $Al_{10}Sb$. W. Campbell and J. Mathews obtained analogous results but placed the first maximum nearer 18 per cent. of aluminium. D. A. Roche, G. G. Urazoff, and E. van Aubel agree that **aluminium monoantimonide**, AlSb, is formed; but the equilibrium diagram has not yet been definitely established. K. Bornemann based a diagram

FIG. 12.—Freezing-point Curves of Aluminium - Antimony Alloys.

on these observations; the results of G. G. Urazoff are summarized in Fig. 12. According to G. Tamman, the existence of the maximum with 68 per cent. of aluminium is doubtful. He showed that the speed of combination of the two elements is very slow. In preparing the AlSb-alloy, only one-tenth of the mixture had combined in 100 mins. at 715° ; and three-fourths in 30 mins. at 1100° . In cases like this, if two metals enter into combination very slowly, the melting-point curve may show a maximum at a point where no chemical compound exists, and its position will depend on how long the alloy has been heated. C. T. Heycock and F. H. Neville made some X-ray photographs; and E. A. Owen and

G. D. Preston found that the X-radiogram corresponded with face-centred cubic cells of antimony atoms with a side 6·126 Å. intermeshed with an identical lattice of aluminium atoms. L. Pauling discussed the space-lattice. L. Guillet, and W. Campbell and J. Mathews studied the microstructure of these alloys; alloys with 18 per cent. of aluminium are homogeneous; but alloys with more or less aluminium consist of crystals of the monantimonide, decreasing in amount the more the composition of the alloy deviates from the one with 18 per cent. aluminium, and finally disappearing. E. van Aubel said that the monantimonide melts at 1078° – 1080° , and has a sp. gr. 4·2176 at $16^{\circ}/4$, when the value calculated from the mixture rule is 5·2246. Consequently when the compound is formed, there is a large increase in vol. which manifests itself at the moment of solidification.

H. Pécheux gave 2·736 for the sp. gr. at 23° of the $SbAl_{30}$ alloy, 2·700 for $SbAl_{35}$, 2·662 for $SbAl_{38}$, and 2·598 for $SbAl_{40}$. F. Sauerwald studied the sp. vol. D. A. Roche said that the alloy with 5 per cent. aluminium is malleable, and superior in elasticity, tenacity, and hardness to aluminium alone. The hardness and tenacity diminished as the proportion of antimony is increased to 10 per cent. when the alloy crystallizes in brilliant laminae. C. R. A. Wright, and J. W. Richards added that all these alloys disintegrate in a few months. H. Schirmeister studied the tensile strength and elongation.

H. Pécheux found that the alloys are stable in the air at the temp. of fusion, bluish-grey in colour, do not decompose water in the cold, but the alloy $SbAl_{30}$ decomposes water at 100° ; they are attacked by conc., hot sulphuric acid, by cold dil. sulphuric acid, by cold, conc. nitric or hydrochloric acid or aqua regia; and by cold, conc. potassium

FIG. 13.—Magnetic Susceptibility of Al-Sb Alloys.

hydroxide soln. K. Honda studied the magnetic susceptibility, Fig. 13; and R. Kremann and J. Dellacher, the electrolysis of the alloys.

The observations of E. Carstanjen¹⁰ on the thallium-antimony alloys, of M. Chikashige, and R. S. Williams on the f.p. curves, and of R. Kremann and A. Lobinger, and E. Bekier on the chemical properties, have been indicated in connection with the chemical properties of thallium—5. 36, 4. There is evidence on the f.p. curve of the formation of an unstable **thallium tritantimonide**, Tl_3Sb , at 225°—Fig. 4, 5. 36, 4. T. Barth obtained no evidence of the existence of this compound in his study of the X-radiograms of these alloys; but he found that alloys with 30 molar per cent. of antimony have a second type of crystal—presumably thallium antimonide, $TlSb$. The side of the cubic lattice has $a=3.86 \times 10^{-8}$ cm. T. Barth gave 10.66, D. Omodei 10.143 for the sp. gr. of a 20 per cent. antimony alloy at the m.p. 194°, and 9.915 for the sp. gr. of the liquid at the same temp. He also found the cubic expansion coeff. to be 0.000227. G. Winogoroff and G. Petrenko measured the electrode potentials of the alloys. For the alloys of *cerium and antimony*, vide 5. 38, 10; and of *silicon and antimony*, vide 6. 40, 12. For **tin monantimonide**, $SnSb$, and **tin ditritantimonide**, Sn_3Sb_2 , see the chemical properties of tin, 7. 46, 5. R. A. Morgan studied the ternary system: Pb-Cu-Sb; and W. Bonsack, and L. Losana, the systems: Sn-Cu-Sb, and Sn-Cu-Sb-Pb. For

FIG. 14.—Freezing-point Curves of the Ternary System: Pb-As-Sb.

the **lead antimonides**, see the chemical properties of lead—7. 47, 5. R. Kremann and A. Tröster studied the electrolysis of these alloys; Y. Matuyama, the electrical conductivity; E. Kordes, the eutectic; and E. E. Schumacker and G. M. Bouton, the solubility of antimony in lead. R. A. Morgan and co-workers studied the effect of copper, bismuth, and tin on the Pb-Sb alloys. E. Abel and O. Redlich's f.p. curves of the ternary system: Pb-As-Sb, are summarized in Fig. 14. The eutectic line is indicated by E. For **nitrogen antimonide**, vide antimony nitride, 8. 49, 12; for **phosphorus antimonide**, see antimony phosphide, 8. 50, 12; and for **arsenic antimonide**, see antimony arsenide, 9. 51, 10. C. M. Marx,¹¹ and F. Rudberg showed that antimony and bismuth melt and form brittle alloys in all proportions. No *bismuth antimonide* appears to be formed. A. Mazzucchelli and L. Tonini prepared these alloys electrolytically; but A. Mazzucchelli and A. Vercillo could not make them by the action of hydrochloric acid soln. of the trichlorides on bismuth or antimony respectively. The f.p. curves were studied by H. Gautier, M. Cook, C. T. Heycock and F. H. Neville, B. Otani, and K. Hüttner and G. Tammann. The results are shown in Fig. 15. From molten masses rich in antimony, crystals rich in antimony first separate; the main amount of this molten mass solidifies about 50° below the

temp. at which crystallization begins. Molten masses which contain less than 70 per cent. of antimony do not crystallize until the m.p. of bismuth is reached, and finally bismuth itself separates in almost a pure state. When alloys of antimony

FIG. 15.—Freezing-point Curve of Bismuth - Antimony Alloys.

and bismuth are allowed to cool very slowly, the structure of the solid which separates is homogeneous; it is very probable that the two metals are miscible in all proportions. In molten masses containing antimony up to 60 per cent., the temp. at the beginning of the crystallization remains constant for a time. G. Charpy, and W. Campbell studied the structure of these alloys. A. Matthiessen and M. Holzmann found that the Sb:Bi=2:1-alloy has a sp. gr. 7.864 at 9.7°; 1:1, 8.392 at 11.0°; 1:2, 8.886 at 14.0°; 1:4, 9.227 at 12.1°; 1:6, 9.434 at 9.4°. The values calculated from the mixture rule are rather less than this. E. Maey, and F. C. Calvert and R. Johnson studied the sp. gr., and the thermal

electrical conductivities; G. Gehlhoff and F. Naumaier, and A. Schulze the thermal conductivity—Fig. 16; W. Haken, K. Bädeker, Y. Matuyama, and A. Matthiessen, the electrical conductivities—Fig. 17, and the temp. coeff. of the resistance—Fig. 18.

FIG. 16.—Thermal Conductivity.

FIG. 17.—Electrical Conductivity.

FIG. 18.—Temp. Coeff. of Electrical Resistance.

The curve is characteristic of alloys which are solid soln.; J. P. Joule, C. Hutchins, E. Becquerel, A. Matthiessen, W. Rollmann, W. Haken, T. Seebeck, A. Sundell, and A. Battelli, the thermoelectric properties—Fig. 20; N. A. Puschin, and M. Herschkowitsch, the e.m.f.; R. Kremann and A. Tröster, the electrolysis of the alloys; H. Endo, J. Beattie, and K. Honda and T. Sone, the magnetic susceptibility—Fig. 21, the curve is linear until the alloy contains about 90 per cent.

FIG. 19.—Hall's Constant.

FIG. 20.—Thermoelectric Power.

FIG. 21.—Magnetic Susceptibility.

of antimony when the proportionality fails; and A. W. Smith, Hall's constant—Fig. 19, the curve is related with that for the thermoelectric power. N. A. Puschin, and E. Bekier studied the potential of the bismuth-antimony alloys; N. Parravano and E. Viviani, the Bi-Sb-Cu alloys. C. R. A. Wright, and R. Kremann and co-workers studied the ternary Bi-Sb-Zn alloys.

R. S. Williams¹² obtained the curves, Fig. 22, for the f.p. of alloys of chromium and antimony. Two compounds are formed: **chromium diantimonide**, CrSb₂, is stable below its m.p. 675°, and above that temp. it decomposes. It is silver-white

in colour, very brittle, and is slightly acted upon by dil. acids. The other compound, **chromium monantimonide**, CrSb , melts at 1125° ; it is dark-grey, very brittle, and readily attacked by acids. There are two series of mixed crystals. The components of one series are the monantimonide and chromium, and it extends from

FIG. 22.—Freezing-point Curves of the Chromium-Antimony Alloys.

FIG. 23.—Freezing-point Curves of Manganese-Antimony Alloys.

50 to 52.5 at. per cent. of chromium; the other series extends from 95 to 100 at. per cent. of chromium and its components are chromium and antimony. W. F. de Jong and H. W. V. Willems found that the X-radiogram agrees with a hexagonal lattice with $a=4.14$ A., and $c=5.51$ A.; and a sp. gr. of 7.08; I. Oftedal gave $a=4.107$ A., $c=5.468$ A., and $a:c=1.331$. J. J. and F. de Elhuyar, and F. A. Bernoulli prepared a *tungsten-antimony* alloy. A. Colani said that when antimony is heated with uranous chloride, a binary compound of *uranium and antimony* is formed.

L. Troost and P. Hautefeuille obtained an alloy of manganese and antimony by heating manganese carbide with antimony. R. S. Williams found that antimony and manganese form two compounds—**manganese hemiantimonide**, Mn_2Sb , melting at 919° , and **manganese dtritantonide**, Mn_3Sb_2 , melting at 852° , and stable below its m.p., but not above. There are two series of mixed crystals, one of which, having the components antimony and the dtritantonide, extends from 65 to 69 at. per cent. of manganese; and the other series having the components antimony, manganese, and the hemiantimonide, extends from 65 to 69 at. per cent. of manganese. Both antimonides are silver-grey, and the hemiantimonide is less brittle than its components. Both alloys are magnetic—like F. Heusler's non-ferrous magnetic alloys. The hemiantimonide loses its magnetic permeability at 250° – 260° ; and the dtritantonide, at 320° – 330° . E. Wedekind found the alloys to be less magnetic than manganese boride. P. Martin measured the magnetic-optical effect. I. Oftedal found that Mn_3Sb_2 has a lattice of the NiAs-type with $a=4.131$ A., $c=5.744$ A., and $a:c=1:390$. E. Wedekind prepared the hemiantimonide, and also an alloy which he regarded as **manganese monantimonide**, MnSb , by the thermite process, and removing the excess of manganese by dil. hydrochloric acid, and the excess of antimony by heating in a current of chlorine. S. Hilpert and T. Dieckmann also made the monantimonide by heating manganese amalgam with the necessary amount of antimony in an atm. of hydrogen, and distilling off the mercury. W. F. de Jong and H. W. V. Willems found that the X-radiogram of the monantimonide agrees with a hexagonal lattice with $a=4.14$ A., and $c=5.90$ A.; and a sp. gr. 6.71. I. Oftedal gave $a=4.120$ A., $c=5.784$ A., and $a:c=1:1.404$. The monantimonide can dissolve considerable amounts of manganese and of antimony. E. Wedekind found that the black, crystalline powder had a sp. gr. 5.6 at 17° ; it was soluble in aqua regia; and had stronger magnetic qualities than the boride. S. Hilpert and T. Dieckmann said that it is soluble in hot hydrochloric acid and in nitric acid. It burns in air giving non-magnetic products.

It loses its magnetic properties at 320°–330°. E. Wedekind found that the magnetic permeability is diminished by the presence of impurities.

An alloy of antimony and iron is the *regulus antimonii martialis* of the alchemists. According to A. F. Gehlen,¹³ iron and antimony readily unite by fusion, producing hard, brittle, white, easily fusible alloys, of lower sp. gr. than the value calculated by the mixture rule. G. Tammann and E. Schaarwächter found that the reaction begins at about 725°. P. Berthier, C. F. Rammelsberg, J. Percy, and C. J. B. Karsten obtained alloys of these two elements. The last-named said that the addition of one per cent. of antimony to a charge of cast-iron, being converted into malleable iron in the charcoal hearth, acts far more injuriously than tin on the metal. J. Percy said that it acts far more injuriously on the magnetic properties of iron than any other metal. An alloy of antimony with twice its weight of iron produces sparks when filed. According to P. Berthier, alloys with more than 70.5 per cent. of antimony lose antimony by volatilization at a white-heat, leaving a residuum of **iron monantimonide**, FeSb. W. F. de Jong and H. W. V. Willems said that iron monantimonide is a definite entity ignored in phase diagrams. X-radiograms of the crystals agree with a hexagonal lattice with $a=4.06$ Å., and $c=5.13$ Å.; and a sp. gr. 8.05. I. Oftedal gave $a=4.064$ Å., $c=5.130$ Å., and $a:c=1:1.262$. P. Christofle also prepared the monantimonide and reported the formation of others: *iron tritantimonide*, Fe₃Sb, as a grey, hard regulus which gives sparks when filed; **iron ditritantimonide**, Fe₂Sb₂, as a black, brittle alloy. N. S. Kurnakoff and N. S. Konstantinoff showed that this compound melts at 1014°, Fig. 22. I. Oftedal found the space-lattice is of the NiAs-type with $a=4.123$ Å., $c=5.168$ Å., and $a:c=1:1.253$. P. Christofle obtained *iron*

Fig. 24.—Freezing-point Curves of Iron-Antimony Alloys.

tetratritantimonide, Fe₃Sb₄, as a crystalline mass; and **iron diantimonide**, FeSb₂, as a hard, grey mass with a crystalline fracture; it gives no sparks when filed. N. S. Kurnakoff and W. S. Konstantinoff obtained the f.p. curve shown in Fig. 24. They found that the f.p. curve has four branches representing four solid phases, there being eutectic points at 628° and 1.5 per cent. iron and 1002° and 49.5 per cent. iron respectively, and a transition point at 732° and 7.0 per cent. iron. The conc. of solid soln. of antimony in iron never exceeds 5 per cent. At 1014° the compound Sb₂Fe₃ separates, and forms solid soln. in iron up to the composition 46.0 per cent. The compound FeSb₂ at its m.p. (732°) decomposes partly, thus: $3\text{FeSb}_2 \rightleftharpoons \text{Fe}_3\text{Sb}_2 + 4\text{Sb}$.

In general, the antimonides of the eighth group are somewhat inert chemically, and have a tendency to form unstable compounds. In the case of the antimonides of iron and nickel, the solid substances which have escaped reaction in the liquid state retain their composition when further cooled rapidly; thus, the diantimonide, when cooled at the rate of 1000–300° in one or two hours, shows a microstructure composed of three elements, and only on heating an alloy of this composition for 30 hrs. at a temp. of 710° could the homogeneous diantimonide be obtained. The raw antimony obtained in the commercial extraction of antimony contains diantimonide in well-formed, rhombic crystals. Compounds such as FeSAs belong to the same type, the arsenic and sulphur being united directly with one another, and the structural formulæ thus obtained are in complete accord with those deduced by other methods. The rhombic prismatic crystals have the axial ratios $a:b:c=0.5490:1:1.1237$; W. Isküll gave $0.5490:1:1.1212$; the (110)-cleavage is incomplete. The hardness is 3. The crystals are isomorphous with löllingite and safflorite. The constitution is possibly $\text{Fe} \begin{smallmatrix} \text{Sb} \\ \text{Sb} \end{smallmatrix}$.

P. Goerens and K. Ellingen found that antimony greatly lowers the solubility of carbon in iron, whilst tin has less effect. In an alloy containing 3.5 per cent. carbon, antimony lowers the initial f.p. of the austenite, and also the eutectic temp., until the latter coincide at 1090° and 5 per cent. antimony. The ternary eutectic, composed of austenite, cementite, and the hemitriantimonide, solidifies at 950° . In an alloy containing 3 per cent. carbon, the austenite curve meets that of the binary eutectic at 1070° and about 14 per cent. antimony. The freezing-point surface is thus made up of three surfaces, corresponding with the separation of austenite (containing some antimony in solid soln.), cementite, and antimonide. The formation of pearlite at 690° is unaffected by the presence of antimony. A. Portevin said that the temp. at which pearlite is formed in alloys of iron and carbon is not appreciably altered by the presence of 1-9 per cent. of antimony. The antimony is retained in solid soln. up to 6.5 per cent.; richer alloys show distinct crystals of an antimonide. E. Maey, and J. Laborde measured the sp. gr.; J. Laborde, and E. van Aubel, the sp. ht. of the alloys; J. Seebeck, and E. Becquerel, the thermoelectric power; and P. Weiss, and L. Cailletet, the magnetic qualities. G. Tammo and K. Dahl studied the brittleness of the FeSb, and Fe₂Sb₃ alloys. G. S. Sérullas reported a **potassium iron antimonide** is formed as a brittle alloy when a mixture of equal parts of iron turnings, powdered antimony, and potassium tartrate is heated in a covered crucible to a high temp.

A. F. Gehlen¹⁴ said that when a powdered mixture of cobalt and antimony (1:2) is heated, the two elements unite with incandescence, forming an iron-grey mass which acquires metallic lustre by press. C. F. Rammelsberg applied the term Spieses to some furnace-products with the composition (Cu,Fe,Co)₅Sb₂. F. Ducelliez observed that cobalt and antimony furnish three classes of alloys which can be made by the direct union of the elements at 500° in a current of hydrogen. (i) Magnetic alloys containing less than 67.04 per cent. antimony. When heated with antimony trichloride at 800° , or when treated with sulphuric acid, these lose their magnetic properties, and leave a residue of the monoantimonide. (ii) Alloys containing 64.04-80.27 per cent. of antimony, which decompose readily on heating, and form the monoantimonide when heated at 1200° in hydrogen.

Substitution of antimony trichloride for hydrogen gives the same compound together with antimony and cobalt chloride. (iii) Alloys containing more than 80.27 per cent. antimony, which, on treatment with nitric acid followed by hydrogen chloride, give the diantimonide. N. S. Kurnakoff and N. I. Podkapajeff, and K. Lewkonja studied the f.p. diagram. K. Lewkonja's curve is shown in Fig. 25. While the two elements are completely miscible in the liquid state, two compounds are formed during the freezing of the alloys. The one, **cobalt monantimonide**, CoSb, melts at 1191° —N. S. Kurnakoff and N. I. Podkapajeff gave 1237° , and F. Ducelliez, about 1200° . Besides being formed by the direct union of the elements, F. Ducelliez

FIG. 25.—Freezing-point Curves of Cobalt-Antimony Alloys.

found that the monantimonide is produced when cobalt at 700° - 1200° is submitted to the action of the vapour of antimony trichloride; at 1200° , the antimony trichloride converts cobalt into a magnetic alloy containing less antimony than the monantimonide, but if the product be treated with sulphuric acid, it loses its magnetic qualities and leaves the monantimonide as a residue. W. F. de Jong and H. W. V. Willems found that the X-radiogram agrees with a hexagonal lattice with $a=3.91$ A., and $c=5.30$; and sp. gr. 8.72. I. Oftedal gave $a=3.866$ A., $c=5.188$ A., and $a:c=1:1.342$. F. Ducelliez observed that

cobalt monantimonide is a crystalline non-magnetic powder of sp. gr. 8.12 at 0°. It undergoes slight oxidation in air, and burns readily in oxygen; hydrogen chloride has little action on it, but hot conc. sulphuric acid dissolves it rapidly. At 700°–1250° it attacks antimony trichloride, forming antimony and cobalt chloride; the composition of the residual substance, however, remains unaltered. K. Lewkonja prepared **cobalt diantimonide**, CoSb_2 , by the direct union of its elements, and F. Ducelliez, by treating alloys with over 80.27 per cent. of antimony as indicated above. The grey crystalline powder has a sp. gr. 7.76 at 0°, and melts about 700°. K. Lewkonja found that the diantimonide melts with decomposition at 879.5°—N. S. Kurnakoff and N. I. Podkopajeff gave 888°. The first eutectic, Fig. 24, is at 1090°, and the last one at 616°. Antimony is soluble to the extent of 12.5 per cent. in cobalt. A. M. Portevin studied the structure of the eutectics. The magnetic transformation temp. from 1134° to 924° for alloys with up to 67 per cent. of antimony represents the temp. at which the alloys lose their magnetic permeability.

According to A. F. Gehlen,¹⁵ if a powdered mixture of nickel and antimony (1:2) be heated, a dark grey metallic powder is formed. The combination is attended by the emission of a red light.

FIG. 26.—Freezing-point Curve of Nickel-Antimony Alloys.

to 92.5 per cent. of nickel, the two series of sat. mixed crystals existing within these limits interact when the temp. falls to 677° with formation of the tetrantimonide: this reaction proceeds in the reverse direction at higher temp. The transition temp.—namely, 90° and 330°—at which the magnetic alloys lose their permeability are shown in the diagram. The subject was studied by W. Guertler and H. Schack.

The evidence for the existence of **nickel pentatetrantimonide**, Ni_4Sb_5 , is not conclusive, on account of experimental difficulties. It decomposes on melting into the monantimonide and a liquid. P. Christoffe reported **nickel ditritantimonide**, Ni_3Sb_2 , to be formed by melting nickel powder with the required proportion of antimony. The violet product does not lose antimony when strongly heated in an indifferent gas, but it loses antimony when heated in air; it is soluble in nitric acid, but insoluble in hydrochloric acid. There is no sign of this product on the f.p. diagram, Fig. 25. N. A. Puschin studied the e.m.f. of these alloys; and also N. S. Kurnakoff and N. S. Podkopajeff, and of K. Losseff. There are three very well-defined nickel antimonides indicated on the thermal diagram, and their existence is confirmed by microscopic observation of polished sections of the alloys. T. Seebeck studied the thermoelectric power of the alloys. Alloys containing 57–92.5 per cent. of nickel contain **nickel tetrantimonide**, Ni_4Sb . It decomposes at 677° into two solid soln. with about 57 and 92.5 per cent. of nickel respectively. The

F. Rössler obtained needle-like crystals when an alloy of the two elements is digested with a mixture of nitric and tartaric acids. According to K. Losseff, the freezing-point curve, Fig. 26, shows two maxima at 1158° and 32.83 per cent. and 1170° and 55 per cent. by weight of nickel respectively, corresponding with the monantimonide and the dipentitantimonide, and there are three eutectic points at 2 to 3, 47.6, and 66.1 per cent. by weight of nickel respectively. From 32.8 to 40 per cent., 55 to 57 per cent. and 92.5 to 100 per cent. of nickel, mixed crystals separate out. In the alloys with from 3 to 32.8 per cent. of nickel, microscopic observation shows a third crystalline form in addition to the monantimonide and the eutectic mixture; there are indications that these crystals represent the pentatetrantimonide, but conclusive evidence on this point could not be obtained. From 57

alloy becomes non-magnetic at 90° . The maximum in the f.p. curve at 1170° represents the m.p. of **nickel pentadiantimonide**, Ni_5Sb_2 . This alloy is a grey colour, and not so hard as the monantimonide, but it behaves towards reagents like that alloy. There is a transition temp. at 580° . The conditions for the formation of **nickel monantimonide**, NiSb , are shown in Fig. 26. This compound was prepared by F. Stromeyer by fusing together eq. proportions of the two elements. Light and heat are emitted during the combination. E. Vigouroux made the monantimonide by the action of antimony trichloride on nickel powder at 800° ; by the action of antimony vapour on pulverized nickel in hydrogen at 1300° ; and by heating a powdered mixture of the two elements in hydrogen at 1200° . It was also made by P. Christofle, and by F. Stromeyer and J. F. L. Hausmann. W. Herz gave 4.91×10^{12} for the vibration frequency of NiSb .

Nickel antimonide is represented in nature by the *antimonial nickel* obtained from Andreasberg by F. Stromeyer and J. F. L. Hausmann; E. J. Chapman called it *hartmannite*, and W. Haidinger, **breithauptite**—after A. Breithaupt. It has also been observed as a furnace-product by J. F. L. Hausmann, F. Sandberger, and A. Brand, although F. Fouqué and A. Michel-Lévy thought that natural breithauptite might be different from the furnace-product. A. Brand, however, showed that the two are identical. The mineral has been also found in Italy, France, and in Connecticut, U.S.A. Analyses were reported by F. Stromeyer, L. N. Vauquelin, P. Berthier, C. F. Rammelsberg, E. Mattiolo, F. Pisani, and A. Brand. Arsenic is sometimes present—*vide* aarite, or arite. The native coppered, or violet-blue crystals are tabular, the artificial crystals are prismatic. The mineral may also occur massive, and in arborescent, and disseminated forms. The crystals belong to the hexagonal system; A. Breithaupt gave for the axial ratio $a : c = 1 : 0.8586$; and K. Busz $1 : 1.2940$. They have been described by A. des Cloizeaux. W. F. de Jong and co-workers' study of the X-radiogram of breithauptite showed that it has the same structure as niccolite, with $a = 3.938$ A. and $c = 5.138$ A. The smallest distance between the Ni-Sb atoms is 2.61 A. I. Oftedal found the X-radiogram corresponded with a space-lattice of the NiAs-type, having $a = 3.907$ A., $c = 5.133$ A., and $a : c = 1 : 1.314$. Twinning has been observed about the $(10\bar{1}1)$ -plane. The basal cleavage is distinct. A. Breithaupt gave 7.541 for the sp. gr.; A. des Cloizeaux, 8.42; and F. Pisani, 7.19. E. Vigouroux gave 7.70 at 0° for the artificial crystals. The hardness of the mineral is 5. K. Losseff gave 1158° for the m.p. E. Vigouroux said that the compound melts at 1100° and begins to decompose at 1400° . J. Joly found that sublimation occurs at 520° in air. A. de Gramont studied the spark spectrum. F. Beijerinck found the mineral is a conductor of electricity; while T. W. Case said that the resistance is greater than a megohm and is not affected appreciably by light. The monantimonide was found by K. Losseff to be easily soluble in nitric acid; but it is not attacked by sulphuric and hydrochloric acids, or by strong bases. E. Vigouroux said that the monantimonide is vigorously acted on by chlorine and by oxygen when heated to dull redness. It is not affected by conc. hydrochloric acid, but is decomposed by warm conc. sulphuric acid and by warm nitric acid. It is scarcely affected even by fused alkalis. E. Vigouroux also discussed the Ni-Sn-Sb alloys.

An alloy of platinum and antimony was made by A. F. Gehlen¹⁶ by heating a powdered mixture (1 : 2) of the two elements; the combination is attended by vivid incandescence, and when the temp. is further raised, it furnishes a steel-grey, brittle, fine-grained alloy; and R. W. Fox found that at a still higher temp., the antimony is almost wholly expelled, leaving malleable platinum. The alloys were also made by J. Murray, W. Lewis, P. Christofle, H. Landolt, and F. Rössler. Those rich in antimony are inclined to liquation; and F. Rössler found that the presence of platinum makes the crystals of antimony smaller. C. Barus found the sp. electrical resistance of an alloy of sp. gr. 20.75 at 0° to be 29.5 ohms, with the temp. coeff. 0.00111 between 0° and 100° , and 0.00109 between 0° and 357° . The alloys readily fuse before the blowpipe, and K. Friedrich and A. Leroux represented their

observations on the f.p. of the alloys by Fig. 27. The f.p. of antimony is not appreciably lowered by the addition of platinum. The f.p. curve rises to a maximum at 1226° and 44.7 per cent. Pt, corresponding with **platinum diantimonide**, PtSb_2 . A second compound, **platinum monantimonide**, probably PtSb , is formed at 1045° . The curve then falls to a eutectic point at 685° and 77 per cent. Pt, and rises to the

FIG. 27.—Freezing-point Curve of Platinum-Antimony Alloys.

f.p. of platinum. Two reactions take place in the solid state, the monantimonide being transformed into one richer in antimony, and a third compound, **platinum dipentitantimonide**, Pt_5Sb_2 , being formed from alloys rich in platinum at 644° , the eutectic structure disappearing when the alloys are maintained for some hours at this temp. The diantimonide was made by F. Rössler by melting a mixture of antimony and platinum (40 : 1) under glass, and digesting the regulus for a long time with a mixture of nitric and tartaric acids; J. F. Simon reported it to be formed by the action of stibine on a soln. of platinic chloride; according to P. Christofle, the admixed platinous chloride and antimony can be removed by soln. of potassium cyanide, and potassium sulphide. R. Bartels found very little diantimonide is formed in this reaction, but he obtained it from an acid soln. of $\text{Na}_2\text{Pt}(\text{SO}_4)_2$. The cubic or octahedral crystals are hard, and brittle. The m.p. is 631° . P. Christofle said that the antimony can be all removed by chlorine at a red-heat. H. Landolt said that boiling aqua regia does not remove all the antimony from the platinum antimony alloys. The alloy is insoluble in nitric and hydrochloric acids, and is soluble in aqua regia. J. Murray made alloys of Pt-Sb-Sr; Pt-Sb-Be; Pt-Sb-Al; and Pt-Sb-Si.

N. W. Fischer¹⁷ found that when a mixture of antimony and palladium is heated, the two elements unite with the evolution of light and heat, and the formation of a brittle alloy. F. Rössler also prepared some of these alloys. W. Sander prepared alloys by heating mixtures of the two elements in nitrogen in porcelain tubes; and he measured the f.p. of the alloys. His results are summarized in Fig. 28. He found that undercooling could occur to the extent of 40° - 50° . The f.p. curve has two maxima at 805° and 1220° , corresponding respectively with **palladium monantimonide**, PdSb , and **palladium tritantimonide**, Pd_3Sb .

FIG. 28.—Freezing-point Curves of the Palladium-Antimony Alloys.

There are also breaks in the curves at 680° and 839° due to **palladium diantimonide**, PdSb_2 , and **palladium tripentitantimonide**, Pd_5Sb_3 , respectively. Palladium retains antimony in solid soln. up to 15 per cent., and the tritantimonide also forms solid soln. between 68.5 and 72.5 per cent. Pd, and the tripentitantimonide forms solid soln. between 57.5 and 61.5 per cent. Pd. Between 57.5 and 65 per cent. a thermal arrest occurs at 524° - 532° , and is accompanied by a change from a polyhedral to a lamellar structure. The change is attributed to a transformation of the tripentitantimonide. The triantimonide, which also undergoes a transformation at 1070° , is less readily attacked by aqua regia than the palladium solid soln. The alloys are brittle up to 85 per cent. Pd, the maximum brittleness occurring at the composition of the triantimonide.

§ 10. Antimonious Oxide, or Antimony Trioxide

It is not known if the *stibia femina*—female antimony—referred to by Pliny, in his *Historia naturalis* (**33**, 33), written in the first century of our era, was antimony oxide, or antimony sulphide. The *vitrium antimonii*, or the *Spiessglanzglas* of Basil Valentine¹ in the seventeenth century, was a mixture of oxide and sulphide obtained by incompletely roasting the sulphide ore. This subject was also discussed by A. Libavius, and N. Lemery. It was also mentioned in the first century by Dioscorides, in his *De materia medica*, and by Pliny, in the work just cited; it is also mentioned in the twelfth-century Latin translation of Geber—*De investigatione magisterii*. In the seventeenth century, Basil Valentine described the preparation of *flores antimonii* which is the calx of antimony now known as antimony trioxide. Some antimony oxide of commerce is a potassium antimonate. Basil Valentine also described another preparation obtained by igniting a number of times a mixture of antimony and nitre, and treating the product with an acid—sulphuric or acetic. The preparation—antimony pentoxide—was called *antimonium diaphoreticum ablutum*, or *calx antimonii clota*, and it acquired some fame, amongst the Iatro-chemists, for its medicinal properties. It was also called *materia perlata Kerkringii*—after T. Kerkring, who edited Basil Valentine's work; and *fondant de Rotrou*—after a medical practitioner at St. Cyr. A. Libavius, and O. Croll called it *antimonium diaphoreticum*; M. Ettmüller gave a clear history of this subject in 1693. O. Croll obtained diaphoretic antimony by repeatedly evaporating antimony trichloride with nitric acid; and he called it *bezoar*; R. J. Glauber, *bezoardecium minerale*. At the beginning of the nineteenth

century, L. J. Thénard² supposed that antimony formed half a dozen different oxides. J. L. Proust limited the number to two—the ordinary trioxide, and one with a higher proportion of oxygen which J. J. Berzelius referred to as antimonious and antimonie oxides. Only three oxides are now recognized—**antimony trioxide**, or *antimonious oxide*, Sb_2O_3 ; *antimony tetroxide*, Sb_2O_4 ; and *antimony pentoxide*, or *antimonie oxide*, Sb_2O_5 .

J. J. Berzelius³ said that *antimony suboxide*, or **antimony hemioxide**, Sb_2O , is formed as a thin, grey film when antimony is exposed to moist air; and as a bluish-grey flocculent powder when powdered antimony is immersed in water, and connected by a platinum wire so that the antimony forms the anode in the electrolysis of the water. The suboxide is resolved into antimonie oxide and antimony, when treated with hydrochloric acid. J. L. Proust supposed that the alleged suboxide is itself a mixture of oxide and metal. F. Jones obtained a black substance, with nearly this composition, by the action of stibine on alkali-lye. A. Ludwig reported the suboxide to be formed by cooling molten antimony in the presence of water at about 6000 atm. R. F. Marchand reported another suboxide—**antimony ditritoxide**, Sb_3O_2 , to be deposited on the platinum anode when a conc. soln. of potassium antimonyl tartrate is electrolyzed. R. Böttger obtained a somewhat similar product. The individuality of these two oxides has not been established.

A native form of antimony trioxide, occurring in *rhombic crystals*, was found by J. A. Mongez⁴ in the Mine des Chalanches, *Allemont*, and the mineral was also described by R. J. Haüy as *chaux d'antimoine native*. A deposit of the mineral at Pribram was described by B. Rössler, and B. Hacquet and called *antimonium spatosum album splendens*; A. G. Werner and C. A. S. Hoffmann named it *Weissspiessglanzerz*. M. H. Klaproth's analysis showed that the mineral is antimony trioxide. R. Kirwan called the mineral *white antimonial ore*; C. C. von Leonhard, *Antimonblüthe*; A. Breithaupt, *Antimonspath*; F. S. Beudant, *exitèle*—from ἐξίτηλος, vaporizable; E. J. Chapman, *exitélite*; and W. Haidinger, **valentinite**—after Basil Valentine. Another form of antimony trioxide occurring in *cubic crystals* at Haraclas, Algeria, was called by H. de Sénarmont,⁵ *antimoine oxydé octaédrique*, and by J. D. Dana, **sénarmontite**—after H. de Sénarmont. It was also found by G. A. Kenngott at Perneck, Hungary. F. Wöhler, and P. Groth emphasized the dimorphism of antimony trioxide, and the isodimorphism of arsenic and antimony trioxides—*vide arsenic trioxide*, 9. 52. 11.

Antimony trioxide, calx antimonii, can be prepared by burning antimony in an inclined crucible exposed to air, and passing the products of combustion through wide glass or earthenware tubes, in which the *flores antimonii* are deposited. The antimony can be heated to redness in a wide crucible, inclined and loosely covered. The oxide collects in the cooler parts of the crucible in the form of brilliant needles. H. Debray⁶ obtained the oxide in this way. H. Rose found that the trioxide prepared by combustion contains some tetroxide, and this makes it fuse with difficulty. H. V. Regnault also made the trioxide by passing steam over red-hot antimony. R. Brandes, and J. Preuss obtained the trioxide by boiling pulverized antimony with moderately conc. nitric acid until it is converted into a white powder which is a mixture of a basic nitrate, antimony trioxide, and antimony. Some higher oxides are also present. The nitric acid is removed by repeated boiling with water. R. Brandes found that when one part of powdered antimony is digested with two parts of aqua regia, and four parts of water, 96.6 per cent. of antimony trioxide is obtained. J. Preuss projected a mixture of 74 parts of antimony; 39, of nitric; and 34, of potassium hydrosulphate in small portions at a time into a red-hot crucible; the mass is kept red-hot in a covered crucible for some time; and, when cold, boiled first with water, then with sulphuric acid, and finally with water. Any arsenic oxide present is washed out by the water, but iron oxide is not removed by the washing. S. Berberich found that antimony trioxide is formed at the antimony electrode during the electrolysis of sulphuric and hydrochloric acid, or potash-lye, and this the more the greater the conc. of the electrolyte.

Antimony trioxide is produced by roasting the trisulphide—*vide supra*, the

history and the extraction of antimony. J. J. Berzelius showed that the product of roasting the sulphide is largely the tetroxide, and if the product is fused with one-sixteenth to one-twentieth of its weight of the trisulphide, antimony trioxide is formed. If but a small excess of the trisulphide is present, transparent and colourless *Spiessglanzglas* is formed as an oxysulphide; if too little sulphide be produced, some tetroxide remains undecomposed and the *Spiessglanzglas* will be opaque. E. G. Hornung obtained antimony trioxide by treating the trisulphide with conc. sulphuric acid; washing the product with water; and then treating the residue with a soln. of sodium carbonate. M. Durand employed a somewhat similar process. S. Metz treated the trisulphide with alkali sulphate and sulphuric acid, and digested the resulting complex salt with water. W. Lindner boiled the trisulphide with a soln. of ferric chloride and dil. hydrochloric acid, diluted the liquid with water, washed the precipitate with water and then with a soln. of sodium carbonate. A. Germet made the trioxide for use as a paint by blowing air into the molten metal, and collecting the fumes in suitable chambers.

According to H. Rose, antimonious salt soln. give white, voluminous precipitates when treated with alkali-lye or aq. ammonia—in the case of the alkali-lye, the precipitate is soluble in excess, but not so with the aq. ammonia. Similarly with soln. of alkali carbonates, and, according to C. Arnold, the precipitates are not soluble in an excess. The precipitates are thoroughly washed and dried. G. von Knorre, A. Guntz, and E. Mitscherlich obtained the trioxide in this manner. H. Debray prepared the oxide by decomposing the oxychloride with water at 150°; and A. Guntz, by treating the oxychloride with sodium carbonate. According to J. H. Long, an aq. soln. of potassium antimonyl tartrate is decomposed by the salts of many of the feeble acids—boric, acetic, thiosulphuric, phosphoric, sulphurous, or tungstic—with the separation of the hydrated trioxide. G. von Knorre showed that the trioxide is formed by reducing antimony pentoxide, with sulphur dioxide, etc. H. Baubigny found that the tetroxide, at a high temp. passes into the trioxide. W. Spring obtained a **colloidal solution** of antimony trioxide; and V. Kohlschütter and J. L. Tüscher obtained highly dispersed, or colloidal antimony trioxide by vaporization in the electric arc. R. W. Gray and co-workers studied the formation of the dispersed oxide—smoke. S. Wosnessensky discussed the coagulation of the antimony trioxide sol.

Rhombic antimony trioxide—valentinite—is the commoner form. The rhombic crystals appear when the trioxide is slowly cooled. J. Weber also obtained valentinite mixed with a little sénarmontite by cooling molten valentinite or sénarmontite. Rhombic crystals are formed when the trioxide is sublimed. According to R. Brauns, molten sénarmontite or valentinite, on cooling, furnishes crystals of valentinite as well as of amorphous trioxide; and when the trioxide is sublimed, both sénarmontite and valentinite may be found beside one another. According to A. Terreil, E. Mitscherlich, and F. Wöhler, valentinite is formed at a higher temp. than sénarmontite. C. W. C. Fuchs, and J. Weber showed that the rhombic crystals are formed when the trioxide is obtained by the action of steam on red-hot antimony; and, according to C. W. C. Fuchs, when prepared by the action of a hot soln. of alkali carbonate on a soln. of antimony trichloride in hydrochloric acid. Thus, E. Mitscherlich obtained the rhombic crystals by pouring a boiling hydrochloric acid soln. of the trichloride into a boiling soln. of alkali carbonate. H. Debray said that valentinite appears when the trioxide is formed by wet processes at a temp. above 100°. The crystals may also appear in the flues of furnaces in which antimony trisulphide has been roasted; thus, A. Arzruni found valentinite as well as sénarmontite in the flues of an antimony furnace at Schlaining, Hungary.

Octahedral crystals of antimony trioxide—sénarmontite—were obtained by E. Mitscherlich, and F. Wöhler by heating antimony for a long time exposed to air. A. Terreil obtained sénarmontite by subliming antimony trioxide at as low a temp. as possible—say dull redness—in an inert gas. He also observed that

when antimony is heated in a porcelain tube in a stream of dry air, the sublimate has crystals of valentinite nearest the antimony, then follow a mixture of crystals of valentinite and s enarmontite, and finally of s enarmontite alone. If antimony be laid on a piece of charcoal and heated in the blowpipe flame until it oxidizes to a white substance, the fine powder, when examined under a microscope, will show both a mass of needle-like latticed crystals, and a mass of perfect cubic and octahedral crystals. A. Schrauf also said that when the molten trioxide is cooled, crystals of valentinite are first formed, and at a lower temp. s enarmontite appears. The crystals of both forms of the trioxide may be found in the flues of furnaces roasting antimony trisulphide—*vide supra*. H. Fischer, and G. A. Kenngott made analogous observations. H. Debray, and A. Terreil found that s enarmontite appears when the trioxide is formed by wet processes at a temp. below 100°. L. Pasteur obtained the octahedral crystals by digesting the oxychloride for many days with an excess of a soln. of sodium carbonate; and E. Mitscherlich, by treating a soln. of potassium antimonyl tartrate with aq. ammonia, or a soln. of an alkali hydroxide or carbonate; and by treating a hydrochloric acid soln. of antimony trichloride with alkali carbonate.

The natural forms of antimony trioxide are produced by the oxidation of antimonial ores. J. R. Blum observed pseudomorphs of valentinite after antimony, and stibnite; and H. Laspeyres, pseudomorphs after allemontite. T. Carnelley and J. Walker found the precipitated trioxide is anhydrous after drying in air for five months. Analyses of antimony trioxide, made by J. J. Berzelius, J. Davy, T. Thomson, and J. L. Proust, are in agreement with the formula Sb_2O_3 . S enarmontite was analyzed by L. E. Rivot; and analyses of valentinite were reported by M. H. Klaproth, L. J. Spencer, G. Suckow, F. Sandberger, and A. Schuller. Both minerals have the same composition. V. Meyer and H. Mensching found that at 1560°, the vapour density 19.60–19.98 is in agreement with 19.90, the calculated value for $(Sb_2O_3)_2$ or Sb_4O_6 . H. Biltz showed that dissociation occurs at a higher temp. R. M. Bozorth found that the unit mol in the solid trioxide is Sb_4O_6 . The degree of purity of commercial white antimony oxide is 96–98 per cent. Sb_2O_3 . The chief impurities are antimony tetroxide and sulphide; and the sulphides and oxides of iron, lead, copper, arsenic, nickel, cobalt, and bismuth.

The physical properties of antimony trioxide.—The colour of antimony trioxide is snow-white, but as a mineral it may appear peach-blossom red, ash-grey, or brown. Valentinite may occur in lamellar, columnar, or granular masses, or in prismatic crystals, which may appear in fan-shaped or stellar groups, in bundles, and as aggregates of thin plates; while s enarmontite may occur in granular masses, and incrustations, as well as in octahedral crystals—the *antimoine oxyd e octa edrique* of H. de S enarmont. W. Phillips, and F. Mohs made observations on the rhombic or prismatic crystals of valentinite; and H. Laspeyres gave for the axial ratios $a : b : c = 0.3910 : 1 : 0.3364$; L. J. Spencer, $0.3938 : 1 : 0.4344$; A. Brezina, $0.3925 : 1 : 0.4205$; and F. Millosevich, $0.39122 : 1 : —$. Observations were also made by A. Brezina, E. S. Dana, W. Haidinger, G. Cesaro, A. des Cloizeaux, A. Pelloux, J. N oggerath, D. Lovisato, P. Groth, etc. The cleavage on the (010)- and the (110)-face of valentinite is perfect; s enarmontite shows traces of octahedral cleavage. The octahedral crystals of s enarmontite were shown by A. des Cloizeaux to be **optically anomalous** like boracite; and this property was investigated by P. Groth, E. Mallard, E. Bertrand, A. Grosse-Bohle, J. Weber, R. Brauns, and R. Prendel. E. Mallard attributed the effect to the crystal being compounded of triclinic individuals, and A. Grosse-Bohle, of monoclinic individuals. R. Brauns thought that the existence of twinned groupings is very unlikely; the crystals become isotropic when warmed, and the isotropism remains when the crystals are cooled; the anomalous state can be produced by press.; and the sublimed crystals are isotropic. A. Pelloux gave for the **optic axial angle** of valentinite, $2E = c. 60^\circ$. A. des Cloizeaux found that the optic axes parallel to c converge slightly when the crystals are heated to 75° , while those perpendicular to c open slightly.

A. Grosse-Bohle found the **corrosion figures** of s enarmontite, with warm hydrochloric acid, are triangular with the apices towards the corners of the octahedra. R. M. Bozorth examined the **X-radiogram** of the octahedral crystals of antimony trioxide, and found the corresponding space-lattice is of the diamond type with a mol of Sb_4O_6 in place of one carbon atom. The case is analogous to that of arsenic trioxide (*q.v.*). The unit cube, with 8 mols of Sb_4O_6 , has a side 11.14 A.; and the shortest distance between the antimony and oxygen atoms in the same group is 2.22 A., and in a neighbouring group 2.61 A.—*vide* Fig. 13, 9. 52. 11. The **X-radiogram** was also studied by A. Simon, and U. Dehlinger and co-workers.

The **specific gravity** of antimony trioxide was found by C. J. B. Karsten to be 6.6952. For s enarmontite, A. Terreil gave 5.20; H. de S enarmont, 5.22–5.30; and for the artificial crystals, A. Terreil gave 5.11; and L. Playfair and J. P. Joule, 5.251. For valentinite, A. Breithaupt gave 5.558–5.577; F. Mohs, 5.566; D. Lovisato, 5.807; A. Terreil, 5.70; L. J. Spencer, 5.76; and for the artificial crystals, P. F. G. Boullay gave 5.778; and A. Terreil, 5.72. The best representative values are 5.25 for s enarmontite and 5.72 for valentinite. A. Simon found that the sp. gr. of the trioxide sublimed in vacuo at 1000° is 5.19; while the value calculated from the X-radiogram is 5.49. For the **vapour density**, *vide supra*. The **hardness** of s enarmontite is 2–2.5; and of valentinite, 2–3. The cubical coeff. of **thermal expansion** of s enarmontite was found by H. Fizeau to be 0.00002501 at 40° ; and the linear coeff. 0.00001963. H. V. Regnault found the **specific heat** of artificial crystals of s enarmontite, between 15° and 99° , to be 0.09009; and C. F. Neumann, 0.0927 between 17° and 19° . F. Winkler gave 25.9 for the mol. ht. of the solid, and 20 for the mol. ht. of the gas. Hot antimony trioxide is yellow, and when cold, white. H. Debray's work would make the **transition temp.** run over 100° , but this datum has not been established. E. Quercigh gave 656° for the **melting point** of the trioxide. The molten oxide is yellow or grey, and it freezes to a white mass resembling asbestos. The trioxide volatilizes when heated out of contact with air, without passing into the tetroxide, and forms a sublimate with needle-like crystals. A. A. Read found that the trioxide volatilizes freely at 1750° . M. R. Mott calculated 1570° for the **boiling point**. A. Simon and E. Thaler gave for the **dissociation pressure**: 26.4 mm. at 2127° ; 73 mm. at 2227° ; and 184 mm. at 2327° —*vide* Fig. 31. F. Winkler gave 0.09 atm. for the partial press. of the oxygen at 820° ; and 44.850 Cals. for the **heat of vaporization** of a mol of the trioxide. A. Ditte and R. Metzner gave for the **heat of formation**, $(2\text{Sb}, 3\text{O})=167.4$ Cals.; A. Simon and E. Thaler, 167.4 Cals.; W. Biltz, 167.4 Cals.; W. G. Mixer, 163.0 Cals.; and J. Thomsen, for the rhombic form, 166.9 Cals. From the heat of soln. of the trioxides in hydrofluoric acid, A. Guntz obtained 1.2 Cals. for the **heat of transformation** of the rhombic into the cubic form. From the e.m.f. of cells with antimony oxide and perchloric acid and the hydrogen electrode, R. Schuhmann calculated the **free energy** of the formation of antimony trioxide from its elements at 25° to be $-148,600$ cal. C. Hensgen observed that the trioxide obtained by the hydrolysis of antimony sulphate is **photo-sensitive**; and C. Renz made a similar observation, for, when exposed to sunlight in the presence of glycerol, benzaldehyde or tartaric acid in alcoholic soln., it becomes grey and ultimately black owing to the formation of a suboxide of the metal. H. S. Patterson and R. Whytlaw studied the photophoresis of particles of the trioxide suspended in air. A. des Cloizeaux gave for the **index of refraction** of s enarmontite 2.073 for red-light, and 2.087 for sodium-light. A. de Gramont examined the **spark spectrum** of s enarmontite. W. Heintze observed a maximum **photoelectric effect** at $\lambda=313\mu\mu$; and found the trioxide is opaque to waves shorter than $313\mu\mu$. F. Beijerinck found both forms of the trioxide to be **non-conductors of electricity**; while T. W. Case said that the resistance is not appreciably affected by light. R. W. Gray, J. B. Speakman and E. Thomsen measured the tendency of the oxide dispersed in air to condense in string-like aggregates under the influence of an electrostatic field.

The chemical properties of antimony trioxide.—According to A. Terreil,⁷ valentinite is more easily attacked than sénarmontite, since the former is coloured brownish-red by ammonium sulphide and then dissolved, while the latter is not attacked; and the rhombic form dissolves more easily in acids and in alkali-lye. Antimony trioxide is amphoteric; it reacts with acids, forming salts in which antimony, or the univalent radicle *antimonyl*, SbO , acts as cation; while with bases, antimony trioxide acts as an acidic anhydride, forming a series of salts, **antimonites**. W. Metzener studied the amphoteric qualities of antimony trioxide. According to J. von Liebig, the trioxide is reduced by **hydrogen** at a red-heat. V. Ipatieff found that when the trioxide is heated with hydrogen under press., stibine and antimony are formed. J. J. Berzelius found that when heated in **air**, the finely divided trioxide burns like tinder, forming the tetroxide. According to T. Carnelley and J. Walker, the trioxide is stable in air until a temp. approaching 360° is attained; between 360° and 400° , oxygen is rapidly absorbed, forming a product Sb_5O_8 , which gains only 0.11 per cent. as the temp. rises from 415° to 440° ; there is a rapid absorption of oxygen between 440° and 500° , and the product Sb_4O_7 is comparatively stable between 500° and 565° . There is again a rapid absorption of oxygen between 565° and 585° , forming the tetroxide which is stable as the temp. rises 590° to over 775° . H. Baubigny found that the tetroxide at still higher temp. passes into the trioxide. For the hydrates of antimony trioxide, *vide infra*, antimonious acids. J. J. Berzelius said that the trioxide is but slightly soluble in **water**, and H. Capitaine observed that it also dissolves sparingly in hot water without separating as the liquid cools. According to H. Schulze, 100 parts of water at 15° dissolve 0.0016 part of the trioxide; and at 100° , 0.01 part. P. Edgerton, in opposition to J. B. Tingle, found that antimony trioxide is not oxidized when aqueous-alcoholic soln. are boiled. L. J. Thénard found that **hydrogen dioxide** has no action on antimony trioxide.

When antimony trioxide is heated in a current of **chlorine**, R. Weber found that antimony tri- and pentachlorides are formed as well as the tetroxide, which at a higher temp. is decomposed. K. H. Butler and D. McIntosh observed that the trioxide is insoluble in liquid chlorine; and C. Willgerodt found the trioxide is a good *Ueberträger*, or catalyst, in chlorinating organic compounds. R. F. Weinland and P. Gruhl could not obtain compounds with the metal iodides analogous to those obtained with arsenic trioxide, but a soln. of antimony trioxide in fused potassium iodide gave crystals of **potassium oxyiodoantimonite**, $\text{K}_2\text{O} \cdot 2\text{KI} \cdot 8\text{Sb}_2\text{O}_3$. The trioxide is soluble in **hydrochloric acid**—*vide* antimony oxychloride. R. Schuhmann found that soln. containing 0.2310, 0.4970, 0.8610, and 1.1330 mols of **perchloric acid** per litre dissolve respectively the eq. of 0.000236, 0.000317, 0.000575, and 0.000752 gram-atoms of antimony per litre at 25° . According to J. L. Proust, when the trioxide is melted with a little **sulphur** it forms *Spiessglanzglas*—*vide* the oxysulphides—while with an excess of sulphur it forms the trisulphide: $2\text{Sb}_2\text{O}_3 + 9\text{S} = 2\text{Sb}_2\text{S}_3 + 3\text{SO}_2$. E. Mitscherlich obtained sodium sulphantimonate and antimonate by boiling the trioxide with sulphur and soda-lye. O. Schumann found that in the cold, antimony trioxide is coloured yellow by **hydrogen sulphide**, but when heated, an oxysulphide is formed. J. J. Berzelius found that **ammonium sulphide** first produces an orange oxysulphide, then brownish-red trisulphide, and finally dissolves that sulphide; A. Terreil, as indicated above, found that the rhombic trioxide is more quickly attacked than the cubic trioxide. With **sulphur dioxide**, a sulphite is produced. J. Milbauer and J. Tucek found that when sulphur dioxide is passed over heated antimony oxide, sulphate and sulphur are formed. As shown by A. Terreil, dil. **sulphuric acid** does not dissolve the trioxide, but the conc. acid forms a soln. of antimony sulphate (*q.v.*). G. Oddo and E. Serra observed that **sulphur monochloride** converts the trioxide into the trichloride; and H. Prinz represented the reaction at 120° in a sealed tube: $6\text{S}_2\text{Cl}_2 + 2\text{Sb}_2\text{O}_3 = 4\text{SbCl}_3 + 3\text{SO}_2 + 9\text{S}$. F. Faktor obtained antimony trisulphide by the action of the trioxide on fused **sodium thiosulphate**; and M. Meyer observed that the reaction

between a soln. of antimony trioxide in alkali-lye and sodium thiosulphate may be used as a clock reaction, in that the conc. of the soln. may be regulated so that the orange sulphide appears after definite intervals of time.

G. Gore said that the trioxide is insoluble in liquid **ammonia**. E. R. Schneider, and R. H. Brett found the trioxide to be soluble in a cold soln. of **ammonium chloride** or **ammonium nitrate**. J. J. Berzelius prepared what he regarded as **antimony aminotrioxide**, $Sb_2O_3 \cdot nNH_3$, by the action of aq. ammonia on antimony chloride at ordinary temp.; the white powder is slightly soluble in water. F. Ephraim found that when the trioxide is heated with **sodamide**, antimony and sodium antimonite are formed. According to J. J. Berzelius, **nitric acid** dissolves a little antimony trioxide and converts it into the pentoxide (*q.v.*). A. Terreil said the trioxide is insoluble in dil. nitric acid; and E. M. Péligot, that, with the conc. acid, a mixture of tetra- and penta-oxides is formed. Fuming nitric acid dissolves more trioxide. Fused **alkali nitrates** transform the trioxide into an alkali antimonate. E. Berger and L. Debnas found that the presence of the trioxide facilitates the combustion of **carbon** in air. W. Bulgrin studied the complex salts.

T. Köhler found that the trioxide dissolves in a soln. of **phosphoric acid**, forming a phosphate. A. Michaelis represented the reaction with **phosphorus trichloride** at 160° in a sealed tube: $5Sb_2O_3 + 6PCl_3 = 3P_2O_5 + 6SbCl_3 + 4Sb$, and the antimony reduces a little of the trichloride to red phosphorus. For the action of phosphorus halides on the trioxide, see N. N. Sen's observations with arsenic trioxide. J. L. Proust observed no reaction between **antimony** and antimony trioxide; E. R. Schneider said that 100 parts of boiling **antimony trichloride** dissolve 6.7 parts of the trioxide; for the reaction between **antimony trisulphide** and trioxide, *vide infra*, the oxysulphides. W. R. Schoeller observed that antimony trioxide is reduced to antimony when heated to incipient fusion, or to 965° , in an atm. of an inert gas.

L. Möser and W. Eidmann found that **boron nitride** reduces the trioxide to antimony; the trioxide dissolves in fused **borax**. J. J. Berzelius found that the trioxide is readily reduced by **carbon** at a red-heat; and J. F. Gmelin, by **carbon monoxide** at a red-heat—*vide antimony*. W. Fränkel and co-workers studied the reduction of the trioxide by carbon monoxide at 400° , 500° , 600° , and 900° . J. von Liebig found that fused **potassium cyanide** reduces the trioxide, forming antimony and potassium cyanate; and, added F. Nelissen, some sodium formate is also produced. Dittler and Co., and T. Köhler found the trioxide to be slightly soluble in **alcohol**, and in **glycerol** in the presence of alkalis. H. Gordon studied this subject; and H. Meerwein, the formation of alkoxides $H[Sb(OR)_4]$. H. Schulze observed that the trioxide prepared in the wet-way dissolves more easily in a soln. of **tartaric acid** than if it had been made by a sublimation process. A. Naumann, and W. Eidmann reported that the trioxide does not dissolve in **acetone**. Antimony trioxide dissolves in **acetic, benzoic, or pyrotartaric acid**. C. N. Waite, and M. Kretschmar found the trioxide to be soluble in **lactic acid**; W. Vogel, in a soln. of **grape sugar** containing a little lime water; G. G. Henderson and D. Prentice, a soln. of **potassium citrate, malate, mucate, lactate, and tartrate**. Observations were also made by E. Jordis, and A. Rosenheim. A. C. Vournasos found that at 400° , antimony oxide is reduced by **sodium formate** without the production of stibine. H. Causse studied compounds with the **catechols**. L. Lévy observed that **phenols** and **alkaloids** give coloured reactions with antimony trioxide. L. Kahlenberg and W. J. Trautmann observed a very slow reaction with **silicon** at high temp. G. Rauter found that when heated with **silicon tetrachloride** in a sealed tube at 360° – 370° , antimony trioxide forms antimony trichloride and silica. K. Fawa examined the effect of the trioxide on **glass**. O. Ruff and K. Albert observed that **trichlorosilane** reacts with antimony trioxide in the presence of sodium hydroxide or hydrocarbonate: $Sb_2O_3 + 9NaOH + 3SiHCl_3 = 9NaCl + 3Si(OH)_4 + 2Sb$.

J. J. Berzelius found that at a gentle heat **potassium** reduces antimony tri-

oxide to antimony—light and heat are developed during the reaction. L. Guillet observed that **magnesium**, and **aluminium** also reduce the trioxide to the metal. A series of antimonites is produced by the action of aq. soln. of the **alkali or alkaline earth hydroxides** on antimony trioxide. The composition of the products depends on the temp. and conc. of the soln.—*vide infra*, the antimonites. R. Bunsen found that an ammoniacal soln. of **silver oxide** is reduced by antimony trioxide.

§ 11. The Antimonious Acids, and the Antimonites

The compounds of antimony trioxide with the bases are called **antimonites**; the antimonites can be regarded as salts of ortho-, pyro-, and meta-antimonious acids,

or of the more complex, hypothetical acids, HSb_3O_5 , $\text{H}_2\text{Sb}_4\text{O}_7$, $\text{H}_4\text{Sb}_6\text{O}_{11}$, $\text{H}_2\text{Sb}_6\text{O}_{10}$, and $\text{H}_2\text{Sb}_{16}\text{O}_{25}$. These salts were specially investigated by H. Rose,¹ E. Frémy, etc. E. Mitscherlich found that the precipitate obtained by the action of cold soln. of sodium carbonate on antimony trichloride usually changes in the cold, and always on boiling, into a white powder consisting of small octahedra of the trioxide. F. W. Clarke and H. Stallo prepared **orthoantimonious acid**, H_3SbO_3 , by decomposing barium antimonyl tartrate with the calculated quantity of sulphuric acid; warming the soln. of antimonyl tartrate; and drying the white precipitate at 100° . C. Lea and J. K. Wood showed that the composition of the product obtained by this process does not correspond with orthantimonious acid. They also found that conc. sulphuric, hydrochloric, or nitric acid, or alkali-lye precipitates orthantimonious acid from soln. of potassium antimonyl tartrate. A. Guntz said that antimony trioxide and not the hydrate is precipitated by acids from soln. of potassium antimonyl tartrate. In opposition to F. W. Clarke and H. Stallo, A. Guntz found that the precipitate obtained by the addition of an acid to potassium antimonyl tartrate, even after washing until the filtrate gave no acidic reaction, still retained as much as 5 per cent. of tartaric acid. R. Lorenz found antimony acquires a grey film of hydroxide when made the anode in the electrolysis of soln. of alkali chlorides, sulphates, or nitrates. T. Carnelley and J. Walker made a similar observation with respect to alkali-lye, and aq. ammonia. The white powder was stated by F. W. Clarke and H. Stallo to be stable in air, even at 150° , but to pass into the trioxide at a higher temp. H. Remy discussed the structure of antimonious acid. A. Simon and H. Pöhlmann studied the dehydration and rehydration of the **hydrogels** of antimony trioxide at 18° , and the results are summarized in Fig. 29. There is no evidence of the formation of a definite hydrate. T. Carnelley and J. Walker found that precipitated antimony trioxide is always anhydrous after being kept in air a few months. L. Schaffner heated to boiling a soln. of recently precipitated antimony sulphide in potash-lye, and added a soln. of copper sulphate until the liquid gives a white precipitate without a tinge of orange. The filtered liquid was then treated with acetic acid so long as a precipitate was formed. The washed and dried precipitate was supposed to be **pyroantimonious acid**, $\text{H}_4\text{Sb}_2\text{O}_5$, or $\text{Sb}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$; but C. Sereno showed that the product is really orthoantimonious acid, H_3SbO_4 , formed at the expense of a portion of the oxygen of the cupric salt—a cuprous salt is present among the products of the reaction. According to J. H. Long and H. E. Sauer, **metantimonious acid**, HSbO_2 , is produced when potassium antimonyl tartrate is decomposed by an alkali carbonate, phosphate, tungstate, or acetate. C. Lea and J. K. Wood found that the composition of the product depends on the mode of preparation, being at ordinary temp. $\text{Sb}_2\text{O}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$.

The individuality of none of the antimonious acids, or hydrates of antimonious acids has been definitely established. C. Lea and J. K. Wood concluded: when hydrated antimonious oxide is liberated, as by the action of a mineral acid on a soln. of tartar emetic, the finely-divided precipitate tends to adsorb some of the added acid or some of the liberated tartaric acid, forming an adsorption product in equilibrium with the soln. On removing the supernatant liquid by decantation and replacing it with fresh water, the equilibrium conditions are disturbed, and some of the adsorbed acid is removed; this operation is repeated at each decantation, until eventually it becomes impossible to detect the acid in the soln. by the ordinary methods. Although antimony trioxide is amphoteric, so long as an appreciable quantity of an acid is present the behaviour of the hydrated oxide in an acidic capacity is impossible. As the acid is removed, however, the hydrated oxide begins to act as an acid in addition to behaving as a base; interaction between

FIG. 29.—Vapour Pressure of Hydrated Antimony Trioxide at 18° .

molecules acting in these two capacities will lead to the formation of a condensation product of a salt-like nature. If the solid is left in contact with water for a considerable period, the last traces of adsorbed acid are slowly removed and the process of condensation continues until an almost anhydrous product is eventually obtained. Hydrated antimonious oxide is more feeble as an acid than as a base. When, therefore, the substance is precipitated by an alkaline reagent, there is little tendency for the formation of adsorption compounds with the alkali employed; on filtering and washing the product, therefore, condensation can proceed unchecked and the almost anhydrous oxide is obtained more readily than when an acid precipitant is employed. When a soln. of antimony trichloride is titrated with sodium hydroxide, the precipitate begins to separate before the neutral point is reached and may at this stage be regarded as a hydrated basic chloride. As the addition of the alkali is slowly continued, the chlorine is gradually removed, the removal of the last traces of halogen by the practically neutral soln. taking place slowly; the small amount of acid retained by the precipitate makes no appreciable difference to the titration, but retards the process of condensation. If a slight excess of alkali is added, the whole of the halogen is eliminated, condensation can then proceed unhindered, and the nearly anhydrous oxide results. A. Simon and H. Pöhlmann studied the adsorption of potassium hydroxide by the trioxide prepared in different ways, and attributed the different results solely to differences in the grain-size of the trioxides. They also studied the peptization of the colloid by acids. While phosphoric acid peptizes the colloidal trioxide, an excess of that acid coagulates it. They also prepared **alcogels** of hydrated antimony trioxide; and **acetonegels** in which the water of the hydrate is completely replaced by acetone.

E. Mitscherlich² obtained **sodium metantimonite**, NaSbO_2 , by melting antimony trioxide with an excess of sodium carbonate; an eq. amount of carbon dioxide is expelled; and the antimonite isolated by washing away the soluble salts. A. Terreil found that the *trihydrate*, $\text{NaSbO}_2 \cdot 3\text{H}_2\text{O}$, crystallized from a soln. of antimony trioxide in soda-lye; and it was obtained by H. Cormimbœuf by saturating with antimony trioxide a boiling soln. of sodium hydroxide in twice its weight of water; pouring the liquid into a large proportion of boiling water; and on cooling the filtered liquid, quadratic plates of the metantimonite were deposited. H. Cormimbœuf said that the crystals are clear, colourless, octahedra with square bases. The trihydrate was found by A. Terreil to have a sp. gr. 2.864, and when heated, the salt loses its water of crystallization and becomes opaque. H. Cormimbœuf said that the salt is decomposed by moist air, forming antimony trioxide and sodium carbonate; with hot or cold water the salt is hydrolyzed and rhombic antimony trioxide is formed. According to H. Rose, E. Frémy, and E. Mitscherlich, the alkaline soln. of antimony trioxide is oxidized by exposure to air, and the antimonites are oxidized when fused with alkali hydroxide in air. If an excess of alkali-lye is present, the clear soln. does not become turbid by dilution or by boiling. H. Hager said that the antimonites are oxidized by hydrogen dioxide and by the halogens. A. Terreil said that hydrogen sulphide transforms the antimonite into a sulphantimonite; and R. Weinland and A. Gutmann, that sodium thiosulphate is reduced to sulphite, and unlike the corresponding case with arsenites, only antimonates and sulphantimonates are formed; no oxysulphantimonate could be detected. O. Brunck found that sodium hyposulphite in alkaline soln. reduces the trioxide to antimony; likewise also in neutral or feebly acidic soln. if a large excess of reducing agent is employed. A. C. Vournasos found that sodium antimonite mixed with sodium formate is reduced to antimony at 800° , and a little stibine is formed. A. Terreil obtained a precipitate soluble in nitric acid when a copper salt is treated with an antimonite. According to M. C. Harding, an alkaline soln. of cupric sulphate precipitates copper antimonite. According to A. Terreil, silver nitrate gives a white precipitate with alkali antimonites; but H. Rose found that in alkaline soln. silver nitrate gives a black precipitate which R. Bunsen regarded as a suboxide, but which was shown by W. Piltitz to be a

mixture of silver oxide, silver, and antimony: $6\text{NaSbO}_2 + \text{Ag}_2\text{O} = 4\text{NaSbO}_3 + 2\text{Sb} + 2\text{Ag} + \text{Na}_2\text{O}$; and also $\text{NaSbO}_2 + \text{Ag}_2\text{O} = \text{NaSbO}_3 + 2\text{Ag}$. H. Rose said that gold chloride gives a black precipitate with antimonites, and M. C. Harding added that if the gold chloride be in excess, aurous oxide is formed, and if the antimonite be in excess, an aurous antimonite is produced. A. Terreil found that an ammoniacal soln. of barium chloride gives a precipitate with antimonites; and mercurous salts also give a precipitate with the antimonites. M. C. Harding found that a soln. of antimony trioxide in alkali-lye in excess gives with mercuric chloride a precipitate of mercuric oxide with no free mercury, but with the antimonite in excess free mercury is formed on standing or on warming. The alkaline soln. of antimonite reduces stannous chloride. A. Terreil found that lead salts give a precipitate with a soln. of an antimonite; similarly also with ferric salts. M. C. Harding found that an alkaline soln. of an antimonite gives a precipitate with ferric chloride which slowly dissolves, forming a red soln. An alkaline soln. of an antimonite is oxidized by potassium dichromate or permanganate to antimonate; and J. Quincke obtained a similar result with potassium ferricyanide. M. C. Harding found that a soln. of platonic chloride gives a brown liquid from which a black precipitate settles—the precipitate contains platinous oxide, and antimony trioxide.

H. Cormimbœuf obtained **sodium triantimonite**, NaSb_3O_5 , by keeping an excess of antimony trioxide in contact with 33 per cent. soda-lye at 100° for a long time. A. Terreil obtained the *monohydrate*, $\text{NaSb}_3\text{O}_5 \cdot \text{H}_2\text{O}$, from a soln. of antimony trioxide in conc. soda-lye. The rhombic crystals are almost insoluble in water, and have a sp. gr. 5.05. H. Cormimbœuf found that when a soln. of sodium hydroxide with twice its weight of water is boiled with an excess of antimony trioxide, the warm liquid deposits rhombic plates of **sodium tetrantimonite**, $\text{Na}_2\text{Sb}_4\text{O}_7$.

A number of observers have recorded the formation of **potassium antimonite** without stating definitely the composition of the product. Thus, J. J. Berzelius obtained a grey powder by digesting antimonyl chloride with potash-lye; the powder dissolves in boiling potash-lye, and separates out in crystals on cooling; R. Brandes, and H. Rose and F. Varrentrapp obtained a similar result with a soln. of antimony trioxide in potash-lye. J. von Liebig fused antimony trioxide with potassium carbonate and found that carbon dioxide is driven off; if the trioxide is in excess, the product is more fusible than if the carbonate be in excess, and in the latter case some free antimony is formed as well as antimonate. H. Cormimbœuf found that when a soln. of two parts of potassium hydroxide in an equal weight of water holding in suspension one part of precipitated antimony trioxide, is boiled for a few minutes, prismatic crystals of **potassium triantimonite**, KSb_3O_5 , are formed. They are decomposed by water, and by the carbon dioxide of the atm. Rectangular lamellæ of the *hydrate*, $\text{KSb}_3\text{O}_5 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, are formed by saturating a boiling soln. of equal parts of water and potassium hydroxide with antimony trioxide, and allowing the liquid to cool. H. Cormimbœuf said that when water is added gradually to the anhydrous or hydrated triantimonite, the salt is decomposed with separation of prismatic antimony trioxide, but as soon as the water, by decomposition of the salt, has become charged with the 5 per cent. of potassium hydroxide, octahedral antimony trioxide is formed, and when the proportion of hydroxide in soln. reaches 20.9 per cent., decomposition ceases. The octahedral trioxide obstinately retains 0.6–0.2 per cent. of alkali. It is noteworthy that sodium hydroxide yields three antimonites, all of which yield antimony oxide in the crystalline form of valentinite when they are decomposed by water, whereas potassium hydroxide yields only one antimonite, but this, when treated with water, yields antimony oxide crystallized in the forms of both valentinite and sénarmontite. H. Cormimbœuf obtained small crystals of **potassium hexadecantimonite**, $\text{K}_2\text{Sb}_{16}\text{O}_{25} \cdot 7\text{H}_2\text{O}$, by passing carbon dioxide into the mother-liquor from the preceding salt, until a turbidity appears. This salt is stable in contact with cold water, but is decomposed by boiling water.

G. Tammann³ heated mixtures of copper oxide and antimony trioxide, and observed that a reduction of the former occurs at 420°, presumably, $4\text{CuO} + \text{Sb}_2\text{O}_3 = 2\text{Cu}_2\text{O} + \text{Sb}_2\text{O}_5 - 10.6$ cals. It is probable that some antimonite is formed at the same time. The subject was discussed by D. Balareff. According to M. C. Harding, **copper metantimonite**, $\text{Cu}(\text{SbO}_2)_2$, is obtained by adding a dil. soln. of copper sulphate to an excess of a sat. soln. of antimony trioxide in potash-lye; or by adding copper sulphate to a soln. of potassium antimonyl-tartrate in 8 per cent. aq. potassium hydroxide; it is a green, crystalline powder, is soluble in hydrochloric, tartaric, or citric acid, and when heated in an open crucible at first evolves antimony oxide and then explodes, leaving a residue of antimony trioxide and copper oxide; when heated in a closed vessel, the residue contains metallic copper. The mineral **thrombolite** was found by A. Breithaupt in the limestone of Rezbanya, Hungary. The first incomplete analysis indicated that it is a phosphate, but A. Schrauf showed that its composition can be represented by $10\text{CuO} \cdot 3\text{Sb}_2\text{O}_3 \cdot 19\text{H}_2\text{O}$. A. Breithaupt gave 3.381–3.401 for the sp. gr., and A. Schrauf gave 3.668. It may be a mixture, and not a definite individual—*vide* cuprous antimonate. I. Domekyo described a copper antimonite resembling the mineral stetefeldite—*vide infra*—occurring in the Potochi copper mine of Peru. As indicated above, **silver antimonite** is not formed by the action of silver nitrate on a soln. of alkali antimonite. M. C. Harding treated gold chloride with an excess of an alkaline soln. of an antimonite and obtained a precipitate which may be a **gold antimonite**, $\text{Au}_2\text{O} \cdot \text{Sb}_2\text{O}_3$, or AuSbO_2 —*vide supra*.

The antimonites of *barium*, *strontium*, and *calcium* have not been examined. G. Tammann⁴ found that when a mixture of equimolar parts of calcium oxide and antimony trioxide is heated, an acceleration is indicated on the heating curve at about 570°, and the residue remaining after extractions with ammoniacal acetic acid, and with dil. tartaric acid, seems to contain a mixture of two calcium antimonites. The reaction was discussed by D. Balareff. A. Terreil found that barium chloride gives a precipitate with a soln. of alkali antimonite only when aq. ammonia is present. A hyacinth-yellow or honey-yellow mineral obtained by A. Damour from St. Marcel, Piedmont, was called *roméine*—after J. B. L. Romé de l'Isle—a term subsequently altered to **romeite**. A. Damour's analysis corresponds with $3\text{RO} \cdot \text{Sb}_2\text{O}_3 \cdot \text{Sb}_2\text{O}_5$, where $\text{R} = \text{Ca}, \text{Mn},$ and Fe —*vide infra*, calcium hypoantimonate. P. Groth regarded the idealized mineral as **calcium metantimonite**, $\text{Ca}(\text{SbO}_2)_2$. W. T. Schaller found that A. Damour's analysis was probably in error, that the formula corresponds with **calcium hexantimonate**, $\text{Ca}_5\text{Sb}_6\text{O}_{20}$ —or $(\text{Ca}, \text{Na}_2, \text{Fe}, \text{Mn})_5\text{Sb}_6\text{O}_{20}$ —in which the mineral is considered to be the salt of a partially dehydrated hexantimonous acid, $\text{H}_{12}\text{Sb}_6\text{O}_{21}$ less H_2O . A. Damour's tetragonal crystals have the axial ratio $a:c=1:1.0257$. The double refraction is strong; and E. Bertrand discussed the optical anomaly. W. T. Schaller reported the index of refraction to be 1.83–1.87. The crystals were also examined by A. Pelloux, E. Hussak, W. T. Schaller, and E. R. Schröder. The crystals are really octahedra belonging to the cubic system; and they possess an imperfect octahedral cleavage. W. T. Schaller added that the mineral is probably dimorphous with the high temp. form cubic. The sp. gr. is 4.713; W. T. Schaller gave 5.074; and E. Hussak, 5.1. The hardness is 5.5. Romeite is insoluble in acids. It fuses to a black slag. W. T. Schaller supposes that the Swedish and Brazilian atopites are romeite. The *antimonites of beryllium*, *magnesium*, *zinc*, and *cadmium* have not been prepared in the wet way. G. Tammann observed that with mixtures of magnesia and antimony trioxide, **magnesium metantimonite**, $\text{Mg}(\text{SbO}_2)_2$, is formed at 500°; and with zinc oxide and antimony trioxide, **zinc metantimonite**, $\text{Zn}(\text{SbO}_2)_2$, is formed at 485°. The reactions were discussed by D. Balareff. The *mercurous* and *mercuric antimonites* have not been prepared. A. Terreil obtained a precipitate with a mercurous salt and alkali antimonite; and M. C. Harding, one with mercuric chloride. No *tin antimonite* has been prepared—*vide supra*. A. Terreil, and A. Streng obtained a precipitate with

a lead salt and alkali antimonite. G. Tammann found that when a mixture of lead oxide and antimony trioxide is heated **lead metantimonite**, $\text{Pb}(\text{SbO}_2)_2$, is formed at 400° ; with mixtures of calcium dioxide and antimony trioxide, a reduction of the former occurs at 300° . The reaction was discussed by D. Balareff. The mineral *lewisite*—after R. J. Lewis—was found at Ouro Preto, Brazil, and described by E. Hussak and G. T. Prior.⁵ The analysis approximates $5\text{CaO}\cdot 2\text{TiO}_2\cdot 3\text{Sb}_2\text{O}_3$, or $3\text{Ca}(\text{SbO}_2)_2\cdot 2\text{CaTiO}_3$, **calcium dititanatohexametantimonite**. It crystallizes in minute octahedra belonging to the cubic system. The sp. gr. is 4.9, the hardness 5.5. The mineral **mauzeliite**—named after R. Mauzelius—was obtained by H. Sjögren from Jakobsberg, Sweden. It is a light yellow **calcium lead orthotitanatotetrantimonite**, $4(\text{Ca},\text{Pb})\text{O}\cdot \text{TiO}_2\cdot 2\text{Sb}_2\text{O}_3$, or $2(\text{Ca},\text{Pb})(\text{SbO}_2)_2\cdot \text{Ca}_2\text{TiO}_4$. The octahedral crystals belong to the cubic system and have a sp. gr. 5.11, and hardness 5–6—*vide* derbylite.

T. Thomson⁶ obtained a brownish-yellow precipitate and a green soln. by adding potassium chromate to a soln. of antimony trichloride. The observations of M. C. Harding, and F. Kessler show that the antimony trioxide is oxidized. O. W. Gibbs⁷ obtained **alkali antimonitomolybdates** by dissolving freshly precipitated antimony trioxide, or antimonyl chloride in a boiling soln. of alkali molybdate. There is a partial reduction of the molybdate during the action; and the conc. of the soln. is attended by decomposition with the separation of antimony trioxide. If ammonium molybdate be employed, pale greenish-yellow crystals of **ammonium antimonitomolybdate**, $6(\text{NH}_4)_2\text{O}\cdot 3\text{Sb}_2\text{O}_3\cdot 17\text{MoO}_3\cdot 21\text{H}_2\text{O}$, are formed. They are insoluble in cold water. O. W. Gibbs reported **platinum antimonitomolybdate** to be formed like the corresponding arsenite. Alkali and ammonium tungstates, under similar conditions, give **alkali and ammonium antimonitotungstates** as yellow oils. When treated with a barium salt, crystals of barium antimonitotungstate, $2\text{BaO}\cdot 3\text{Sb}_2\text{O}_3\cdot 11\text{WO}_3\cdot 18\text{H}_2\text{O}$, are formed. The salt under hot water melts to a yellow oil which with a large proportion of water dissolves to a yellow, acidic liquid which gives pale yellow flocculent precipitates with *mercurous nitrate*, *silver nitrate*, or *thallous nitrate*. O. W. Gibbs reported **platinum antimonitotungstate** to be formed like the corresponding arsenite. O. W. Gibbs obtained **antimonitophosphatotungstates** by the action of metal salts on a soln. obtained by the action of phosphates on antimonitotungstates, or of phosphatotungstates on hydrated antimony oxide. Pale yellow crystals of **potassium antimonitophosphatotungstate**, $12\text{K}_2\text{O}\cdot 5\text{Sb}_2\text{O}_3\cdot 6\text{P}_2\text{O}_5\cdot 22\text{WO}_3\cdot 48\text{H}_3\text{O}$, were obtained by mixing sodium antimonitophosphatotungstate with potassium phosphate. The salt is insoluble in hot or cold water.

J. J. Berzelius⁸ obtained **ferrous antimonite** by the action of a ferrous salt on an alkali antimonite. For the action of ferric salts on soln. of alkali antimonites, *vide supra*. J. J. Berzelius obtained a violet precipitate of **cobalt antimonite** from a soln. of a cobalt salt and an alkali antimonite. The precipitate is slightly soluble in water, and when heated gives off water, becoming dark green; at a higher temp., it emits a glimmering light and afterwards appears white. G. Tammann observed the formation of **nickel metantimonite**, $\text{Ni}(\text{SbO}_2)_2$, when mixtures of antimony trioxide and nickel oxide are heated to 600° . The reaction was discussed by D. Balareff.

§ 12. Antimony Tetroxide, and the Hypoantimonates

As indicated in connection with the history of antimony trioxide, at the beginning of the nineteenth century, quite a number of antimony oxides were supposed to exist. J. J. Berzelius¹ recognized the suboxide, Sb₂O; the trioxide, or antimonious oxide, Sb₂O₃; the tetroxide, Sb₂O₄; and the pentoxide or antimonic oxide, Sb₂O₅. The oxide between antimonious and antimonic oxide was called *hypoantimonic oxide*, and later **antimony tetroxide**, Sb₂O₄, or *antimony dioxide*, SbO₂. Analyses were made by J. J. Berzelius, T. Thomson, L. J. Thénard, J. L. Proust, W. P. Dexter, C. F. Rammelsberg, and E. Bechi. Antimony tetroxide can be regarded as a definite oxide which furnishes the hydrate, **hypoantimonic acid**, H₂Sb₂O₅, and the corresponding salts, **hypoantimonates**. The oxide may also be regarded as *antimony metantimonate*, (SbO)SbO₃, a salt of metantimonic acid, HSbO₃, and the acid as a derivative of orthantimonic acid, H₂(SbO)SbO₄. P. Groth represented it as *antimony orthantimonate*, SbSbO₄, that is, Sb≡O₃≡Sb=O. E. Mitscherlich, and E. Frémy regarded it as a mixed antimonite and antimonate, HSbO₂.HSbO₃; or as a mixed oxide, Sb₂O₃.Sb₂O₅, *antimonious antimonate*, O=Sb—O—Sb≡O₂. If the tetroxide be a definite individual, like the tri- and penta-oxides, antimony would appear to be quadrivalent in the tetroxide, O=Sb=O₂=Sb=O, or O=Sb—O—Sb≡O₂; trivalent in the trioxide, O=Sb—O—Sb=O; and quinquevalent in the pentoxide, O₂≡Sb—O—Sb≡O₂. The brown liquid obtained by mixing equimolar proportions of antimony tri- and penta-chlorides is supposed to contain antimony tetrachloride, and, like other tetrachlorides, C. Setterberg, R. F. Weinland and H. Schmid, and F. Ephraim and S. Weinberg said that it forms a series of salts—e.g. Cs₂SbCl₆, Rb₂SbCl₆, etc.—isomorphous with K₂PtCl₆, (NH₄)₂PtCl₆, K₂SnCl₆, and (NH₄)₂SnCl₆. H. Biltz found that the valency diminishes with rising temp.; thus antimony pentoxide

passes into the tetroxide at 450°; the tetroxide into the trioxide at 1060°; and the trioxide into antimony, etc., at 2490°.

J. J. Berzelius obtained antimony tetroxide by heating antimony or antimony trioxide or pentoxide in air for a long time. J. von Szilagyí recommended this process. From the observations of T. Carnelley and J. Walker, the tetroxide is the stable oxide between 585° and 775°—*vide supra*, antimony trioxide—and H. Biltz said that the tetroxide passes into the trioxide at temp. exceeding 1060°. J. J. Berzelius, J. von Szilagyí, and W. P. Dexter obtained it by treating antimony with nitric acid, and calcining the residue at a red-heat until it has a constant weight. R. Bunsen treated antimony trisulphide in a similar way, and also by heating a mixture of the sulphide with 30–40 times its weight of mercuric oxide. H. Capitaine roasted the sulphide on a gradually rising temp., without fusion, until sulphur dioxide is no longer evolved; but the sulphur cannot be all expelled by this procedure. J. von Liebig melted antimony with potassium sulphate and obtained a mixture of potassium sulphantimonite, and hypoantimonate; and M. Websky obtained a similar product by fusing antimony or its sulphate with potassium hydrosulphate. A. Simon observed that in the transformation of antimony pentoxide into the trioxide, at 430°, there is formed **antimony hexatridecoid**, Sb_6O_{13} ; at 700°, this forms antimony tetroxide; and this at 910°, yields the trioxide. No other intermediate oxides were observed. A. Simon and E. Thaler represented this compound by $\text{Sb}_2\text{O}_3 \cdot 2\text{Sb}_2\text{O}_5$, or $2\text{Sb}_2\text{O}_4 \cdot \text{Sb}_2\text{O}_5$, or $(\text{SbO}_3)_2 = \text{Sb}-\text{O}-\text{Sb}=(\text{SbO}_3)_2$; or as the anhydride of a *hydropyroantimonic acid*, SbHSb_2O_7 , being equivalent to $2\text{SbH} \cdot \text{Sb}_2\text{O}_7$ less $\text{H}_2\text{O} = \text{Sb}_2\text{Sb}_4\text{O}_{13}$. The formation of this compound is shown on the heating curve, Fig. 30. The vap. press. is 21·7 mm. at 630°; 59·4 mm. at 670°; and 23·2 mm. at 730°—*vide* Fig. 31. The heat of formation is represented by $2\text{Sb}_6\text{O}_{13} = 6\text{Sb}_2\text{O}_4 + \text{O}_2 - 39 \cdot 274$ Cals.; and $3\text{Sb}_2\text{O}_5 = \text{Sb}_6\text{O}_{13} + \text{O}_2 - 25 \cdot 47$ Cals. U. Dehlinger and R. Glocker, and A. Simon studied the X-radiogram. A. Simon found the sp. gr. after 3 hrs.' calcination to be 5·70; and after 6 months at 690°, 6·22.

The early mineralogists, D. L. G. Karsten,² L. A. Emmerling, A. G. Werner, and C. A. S. Hoffmann, described *ε Spiessglanzocker* which J. F. L. Hausmann regarded as a *Spiessglanzoxydul*. C. C. von Leonhard called it *Antimonocker*; A. Breithaupt, *Gelbantimonerz*; F. S. Beudant, *stibiconise*—from *στίβι*, antimony; and *κόμης*, powder; and G. L. Brush, *stibiconite*. J. R. Blum and W. Delffs described a hydrated tetroxide which they called *stiblich*—from *στίβι*, antimony; and *λίθος*, stone—in allusion to its hardness. P. A. Dufrenoy had previously described an *antimony ochre* from Cervantes, Galicia, as *un acide antimonieux anhydre*, with the formula Sb_2O_4 . E. Bechi also described some small needle-like crystals of the same composition occurring at Pereta, Tuscany. E. S. Dana, and G. A. Kenngott showed that both minerals are the same species, and J. D. Dana called them **cervantite**. Subsequent writers—J. D. Dana, M. Bauer, F. Klockmann, P. Groth, G. Tschermak, and F. Zirkel—confined the term *cervantite* to the anhydrous mineral, and *stibiconite* or *antimony ochre* to the monohydrate. These minerals occur in several localities where they have been produced by the weathering of stibnite or other antimony minerals.

Artificial antimony tetroxide is a white powder; *cervantite* occurs massive, as an incrustation, or in powder as well as in acicular crystals belonging to the rhombic system. The colour of the mineral is white with a yellow or red tinge, and sulphur-yellow. U. Dehlinger and R. Glocker³ found that the X-radiogram corresponds with a lattice like that of the trioxide; but rather more compact. A. Simon discussed this subject. C. J. B. Karsten gave 6·7 for the sp. gr., but this is too high; F. Winkler gave 6·641 for the sp. gr. of the tetroxide which had been

FIG. 30.—The Action of Heat on Antimony Pentoxide.

heated at 740°–830° for 21 hrs. ; and 6.643 when heated for 42 hrs. L. Playfair and J. P. Joule gave 4.07 for the sp. gr. ; and P. A. Dufrenoy, 4.08. A. Simon found the sp. gr. at 25°/4° of the tetroxide calcined at 840° for

Time .	1	2	48	60	72	96	100	150 hrs.
Sp. gr.	5.99	6.21	6.65	6.71	6.73	7.26	7.50	7.50

The hardness of cervantite is 4–5. H. V. Regnault gave 0.0951 for the sp. ht. ; and F. Winkler gave 28 for the mol. ht. R. Bunsen said that the tetroxide is reduced to the trioxide, and volatilized at a temp. a little higher than that at which it is formed ; A. Guntz also observed a loss when the tetroxide is calcined at dull redness. O. Brunck showed that the tetroxide is not reduced when ignited in a crucible provided reducing gases from the flame are excluded. In an uncovered crucible neither reduction nor loss of weight occurs, but with a covered crucible reduction occurs even when the flame surrounds only the lower half of the crucible. J. J. Berzelius said that the white tetroxide becomes yellow when hot, and the white colour returns on cooling ; the tetroxide emits a vivid light in the oxidizing blowpipe flame without fusing, and in the reducing flame it is slowly dissipated. W. P. Dexter said that the tetroxide is not decomposed when heated many hours at a bright red-heat ; T. Carnelley and J. Walker observed no decomposition at 775° ; H. Biltz said that decomposition occurs towards 1060° ; and H. Baubigny, below the m.p. of gold (1068°). A. A. Read found that at 1750°, the tetroxide volatilizes freely, and that which had not volatilized was the trioxide showing that the trioxide was volatilizing. H. Halle studied this subject. H. W. Foote and E. K. Smith could not measure the dissociation press. accurately because an appreciable loss of weight occurred at about 950°. This is taken to mean that at that temp. the dissociation press. is nearly equal to the partial press. of the oxygen in atm. air. A. Simon and E. Thaler gave 19.42 mm. at 930° ; 137.8 mm. at 1080° ; and 224.9 mm. at 1110°—*vide* Fig. 30. F. Winkler calculated the vap. press. of the oxygen to be 1.2×10^{-11} atm. at 820° ; and for the heat of formation, $2\text{Sb}_2\text{O}_3(\text{solid}) + \text{O}_2 = 2\text{Sb}_2\text{O}_4 + 89,700$ cal. W. G. Mixer gave $(2\text{Sb}_2\text{O}_2) = 209.8$ Cals. and $(\text{Sb}_2\text{O}_3, \text{O}) = 46.8$ Cals. ; W. Biltz gave $(2\text{Sb}_2\text{O}_2) = 192.65$, and $(\text{Sb}_2\text{O}_3, \text{O}) = 25.25$ Cals. ; while A. Simon and E. Thaler gave $(2\text{Sb}_2\text{O}_2) = 195.29$ Cals., and $(\text{Sb}_2\text{O}_3, \text{O}) = 27.89$ Cals. T. W. Case said that the tetroxide is a non-conductor and its resistance is not appreciably affected by light.

H. Rose found that antimony tetroxide is sparingly soluble in water ; and it reddens moist litmus-paper rather less intensely than the pentoxide. The tetroxide also forms a hydrate—*vide infra*. R. Weber found that the heated oxide is decomposed by chlorine. H. Rose said that the tetroxide is but sparingly soluble in acids ; even boiling hydrochloric acid attacks it very slowly ; and R. Bunsen said that it liberates iodine from a mixture of potassium iodide and hydrochloric acid ; J. von Szilagyí represented the reaction : $\text{Sb}_2\text{O}_4 + 6\text{HCl} + 2\text{HI} = 2\text{SbCl}_3 + 4\text{H}_2\text{O} + \text{I}_2$, and said that metastannic acid does not liberate iodine under these conditions. H. Capitaine found that when the tetroxide is heated with potassium iodide, iodine is evolved, and potassium antimonite is formed. J. L. Proust observed that when the tetroxide is heated with sulphur, Spiessglanzglas is formed : $\text{Sb}_2\text{O}_4 + 5\text{S} = \text{Sb}_2\text{S}_3 + 2\text{SO}_2$; and J. J. Berzelius, that alkali hydrosulphides do not attack the tetroxide in the cold, but when heated, the oxide dissolves with the evolution of hydrogen sulphide. J. J. Berzelius found the tetroxide to be slightly soluble in sulphuric acid. The oxide is reduced when heated with carbon ; and also, according to J. von Liebig, when treated with fused potassium cyanide. H. Rose said that potassium antimonyl tartrate is not produced when the tetroxide is boiled with a soln. of potassium hydrotartrate ; E. Mitscherlich found that some potassium antimonyl tartrate is formed with the separation of antimony pentoxide. J. L. Proust found the tetroxide is reduced to the trioxide when heated with antimony : $2\text{Sb} + 3\text{Sb}_2\text{O}_4 = 4\text{Sb}_2\text{O}_3$; and J. J. Berzelius showed that when the tetroxide is fused with antimony trisulphide, Spiessglanzglas is formed : $9\text{Sb}_2\text{O}_4 + \text{Sb}_2\text{S}_3$

$=10\text{Sb}_2\text{O}_3+3\text{SO}_2$. W. R. Schoeller studied the reaction. J. L. Gay Lussac and L. J. Thénard found that when heated with potassium or sodium, the tetroxide is reduced, with incandescence, to antimony. R. Bunsen showed that the oxide blackens ammoniacal silver nitrate.

J. J. Berzelius⁴ obtained **monohydrated antimony tetroxide**, $\text{Sb}_2\text{O}_4\cdot\text{H}_2\text{O}$, or **hypoantimonic acid**, $\text{H}_2\text{Sb}_2\text{O}_5$, by precipitation with strong acids from a soln. an alkali hypoantimonate. As indicated above, this same compound occurs in nature as the mineral **stibiconite**. Analyses were reported by J. R. Blum and W. Delffs, J. R. Santos, C. F. Rammelsberg, C. Schnabel, and S. P. Sharples. The mineral occurs in pale yellow compact masses; in powder, or in crusts. H. C. Lewis obtained artificial crystals of sp. gr. 4.9; J. R. Blum and W. Delffs gave 5.28 for the sp. gr.; A. Frenzel, 5.08; F. P. Dunnington, 5.58. The hardness is 4.5–5.0.

A number of other minerals containing antimony oxide has been reported. O. Volger⁵ found white antimony ochre to be a common product of the alteration of stibnite. E. Cumenge analyzed a variety from Constantine, Algeria, and the results corresponded with $\text{Sb}_2\text{O}_5\cdot 4\text{H}_2\text{O}$. G. A. Kenngott called the mineral *cumengite*, and J. D. Dana, *volgerite*. A mineral obtained from Sierra del Cadi, Spain, was analyzed by H. Ducloux, and called *rivotite*—after L. E. Rivot. The analysis approximates to $\text{Sb}_2\text{O}_5\cdot 4(\text{Cu}, \text{Ag}_2)\text{CO}_3$. The sp. gr. is 3.55–3.62; and the hardness 3.5–4.0. It is considered to be a mixture of antimony ochre, and silver copper carbonate. The so-called *partzite*—named after A. F. W. Partz—was obtained by A. Arrens from the Blind Spring Mountains, California. The sp. gr. is 3.8; and the hardness, 3–4. J. M. Blake regarded *partzite* as a hydrated antimony oxide mixed with different metal oxides—*e.g.* Cu_2O , Ag_2O , FeO , and PbO . E. Riote described a mineral from Nevada, U.S.A., which he called *stetefeldite*—after C. Stetefeldt. It is a variety of *partzite*. The sp. gr. is 4.12–4.24, and the hardness 3.5–4.5. E. Goldsmith applied the term *stibioferrite* to an amorphous incrustation on the antimonial ores of Santa Clara Co., California. It is a hydrated antimony oxide mixed with 31.85 per cent. of ferric oxide, and 8.84 per cent. of silica. The sp. gr. is 3.598, and the hardness 4.

J. J. Berzelius⁶ prepared what he regarded as **potassium hypoantimonate**, $\text{K}_2\text{Sb}_2\text{O}_5$, by fusing antimony tetroxide with an excess of potassium hydroxide or carbonate; removing the excess of alkali with cold water; and dissolving the residue in boiling water. The aq. soln. does not crystallize on evaporation, but dries to a yellow mass, freely soluble in water. When the aq. soln. is treated with carbon dioxide, a white powder is deposited, and it has the composition of **potassium bishypoantimonate**, $\text{K}_2\text{Sb}_4\text{O}_9$. J. von Liebig reported potassium hypoantimonate to be present in the product obtained by fusing potassium sulphate with antimony; and M. Websky fused antimony or antimony trisulphide with potassium hydrosulphate at a red-heat; the cold mass dissolves in water, and was said to contain hypoantimonate because it reduced gold chloride: $3\text{Sb}_2\text{O}_4+2\text{AuCl}_3+3\text{H}_2\text{O}=3\text{Sb}_2\text{O}_5+2\text{Au}+6\text{HCl}$. Sulphuric acid precipitates hydrated antimony tetroxide from the aq. soln. These observations do not discredit E. Frémy's opinion that the alleged hypoantimonites are mixtures of antimonites and antimonates. J. J. Berzelius obtained **sodium hypoantimonate** in a similar way, but E. Mitscherlich melted antimony tetroxide with sodium carbonate, and extracted the cold mass with water. He found that the main product was sodium hypoantimonate which dissolved, and a little sodium metantimonate most of which remained as a residue. J. J. Berzelius said that **barium hypoantimonate**—presumably BaSb_2O_5 —is produced by slowly adding a boiling dil. soln. of potassium hypoantimonate to one of barium chloride. Small, flat, needle-like crystals were deposited; the crystals were permanent in air; sparingly soluble in water; and gave up baryta to acids. He made **calcium hypoantimonate**, CaSb_2O_5 , in a similar way. The white crystalline powder was insoluble in water. The mineral *romeite*—*vide supra*—can be regarded as calcium hypoantimonate.

I. Domeyko⁷ also described what he called *antimonie de mercure* obtained from the Chilian mines. This red or scarlet powder was called by J. D. Dana *ammiolite*—from ἀμμιον, vermilion—is of doubtful composition. It may be *copper hypoantimoniate* or antimonate mixed with cinnabar; or *mercury hypoantimoniate* or antimonate mixed with copper oxide. L. E. Rivot, and F. Field analyzed Chilian red earths which may be related to ammiolite.

A dark grey mineral from Huitzucco, Mexico, was analyzed by J. R. Santos, and named, by J. W. Mallet, *barcenite*—after M. Barcena. J. W. Mallet supposed it to be a mixture of mercuric sulphide and a calcium antimonate and antimony trioxide, $(\text{Sb}_2\text{O}_3, 4\text{RO})(\text{Sb}_2\text{O}_3)_5$; while P. Groth supposed it to be a mixture of mercury and calcium antimonate with antimonic acid. Its sp. gr. is 5.34 at 20°, and its hardness 5.5.

§ 13. Antimony Pentoxide and the Antimonic Acids

The history of antimony pentoxide, and *antimonium diaphoreticum*, dating from the end of the sixteenth century, has been discussed in connection with antimony trioxide. J. J. Berzelius¹ prepared **antimony pentoxide**, or *antimonic oxide*, Sb_2O_5 , by heating antimony, or one of its lower oxides, with nitric acid or aqua regia. In the latter case, the soln. is evaporated to dryness, mixed with conc. nitric acid, again evaporated to dryness, and then heated sufficiently to drive off the nitric acid, but not to redness. J. Bourson found that antimony precipitated by zinc is more easily oxidized by nitric acid than ordinary antimony. H. Rose said that complete oxidation to the pentoxide is attained only by repeatedly evaporating the product with conc. nitric acid, although C. P. Conrad reported that the complete oxidation of antimony cannot be effected with nitric acid, and O. Bosek, too, was unable to complete the oxidation by means of nitric acid, or by a mixture of hydrochloric acid and potassium chlorate. O. Bosek also found that bromine does its work slowly. The temp. to which the product is heated is of importance. H. Biltz said that the pentoxide passes into the tetroxide at 450° —*vide infra*. The same remarks apply when the pentoxide is obtained by heating one of its hydrates—say that produced by the hydrolysis of antimony pentachloride (H. Rose). J. S. F. Pagenstecher has described the preparation of the diaphoretic antimony. L. Zambelli and E. Luzzatto transformed antimony trisulphide into the hydrated pentoxide by treatment with hydrogen dioxide. J. J. Berzelius heated a mixture of antimony and mercuric oxide whereby the mercury antimonate first produced is transformed into the pentoxide. S. Berberich observed the formation of antimony pentoxide in the electrolysis of sulphuric, nitric, hydrochloric, or acetic acid, or potash-lye using an antimony electrode. An alkali antimonate was obtained by J. Clark by the action of an alkaline soln. of hydrogen dioxide on antimony—*vide infra*, sodium antimonates—and by W. Hampe, by the action of sodium dioxide on antimony. J. J. Berzelius also produced the alkali antimonate by projecting a mixture of alkali nitrate with antimony, antimony oxide or sulphide, or potassium antimonyl tartrate in small portions at a time into a red-hot crucible; when the deflagration has ceased, the temp. is raised; the cold powdered mass is extracted with water, and the filtrate which contains potassium antimonate treated with an excess of nitric acid gives a precipitate of hydrated antimony pentoxide, which is to be washed with water and dried. When the residue is boiled with dil. nitric acid, and washed with water, the hydrated pentoxide results. J. W. Slater oxidized antimony to antimonate by the action of potassium permanganate; and M. C. Harding oxidized antimony trioxide or the antimonites by potassium permanganate, dichromate, or ferricyanide. E. Frémy found that the antimonites are slowly converted into antimonates when heated in air. E. Berglund converted the alkali sulphantimonites into antimonates by boiling the aq. soln. with copper oxide—cuprous sulphide is formed; and C. Serono boiled copper oxide with a soln. of antimony trisulphide in alkali-lye—complete oxidation to the antimonate occurred; H. Rose added that oxidation is complete only if sulphur be

present. T. Rieckher, and M. Duyk used copper hydroxide as the desulphurizing and oxidizing agent.

Antimony pentoxide is a pale yellow powder which becomes deeper in tint as the temp. is raised. A. Simon, and U. Dehlinger and R. Glocker studied the X-radiogram, and found that it corresponds with a cubic lattice. P. F. G. Boullay gave 6.525 for the sp. gr., but this number is far too high since L. Playfair and J. P. Joule obtained 3.78 for the sp. gr. at 3.9°. A. Simon gave for the sp. gr. of the pentoxide calcined at 840°, 5.41; and for $\text{Sb}_2\text{O}_4\cdot_{98}\cdot 0.4\text{H}_2\text{O}$, calcined one hour at this temp. 3.799; for $\text{Sb}_2\text{O}_4\cdot_{95}\cdot 0.14\text{H}_2\text{O}$, calcined 3 hrs., 4.147; $\text{Sb}_2\text{O}_4\cdot_{95}\cdot 0.2\text{H}_2\text{O}$, calcined 4 hrs., 4.309; and $\text{Sb}_2\text{O}_4\cdot_{98}\cdot 0.5\text{H}_2\text{O}$, calcined many weeks, 5.116. D. Balareff, and C. del Fresno studied the mol. vol. H. Biltz showed that the pentoxide changes into the tetroxide at about 450°; A. A. Read, and J. J. Berzelius examined the action of heat on this oxide. A. Geuther said that the decomposition occurs at 300°, but H. Daubrawa found this temp. too low. H. Baubigny reported that the oxide is stable at 357°, but slowly decomposes at 440°; the decomposition is slow even at dull redness, but is rapid at 750°–800° when $2\text{Sb}_2\text{O}_5 = 2\text{Sb}_2\text{O}_4 + \text{O}_2$. E. Weidenbach observed the same reaction occurs at 1000° and 1100°. A. Simon said that when the pentoxide is heated, there is a transformation at 430° corresponding with the formation of an *antimony hexatridecaoxide*, Sb_6O_{13} , which, at 700°, decomposes into the tetroxide, and at 910°, into the trioxide—*vide supra*, Fig. 30. A. Simon and E. Thaler gave for the vap. press :

p . . .	70°	90°	130°	190°	350°	400°
	0.1	0.4	1.1	6.3	29.6	224 mm.

The results are plotted in Fig. 31. W. G. Mixer gave for the heat of formation $(2\text{Sb}_2\text{O}) = 229.36$ Cals., $(\text{Sb}_2\text{O}_3, 2\text{O}) = 66.6$ Cals., and $(\text{Sb}_2\text{O}_4, \text{O}) = 19.8$ Cals.; W. Biltz gave respectively, 205.65, 38.25, and 13 Cals.; and A. Simon and E. Thaler, 210.325, 42.925, and 15.035 Cals. S. Glixelli studied the electro-osmosis of the pentoxide.

FIG. 31.—Dissociation Pressure Curves of the Antimony Oxides.

The composition of antimony pentoxide was established by the analyses of J. J. Berzelius, J. L. Proust, L. J. Thénard, and T. Thomson. J. J. Berzelius said that antimony pentoxide has no taste; and H. Rose added that it reddens moist

litmus-paper; and that it is sparingly soluble in **water**—*vide infra*. R. Weber found that at a high temp. **chlorine** converts the pentoxide (trioxide) into antimony trichloride; and H. Rose observed that **hydrochloric acid** dissolves it in the cold with difficulty without the evolution of chlorine; the action is faster when the temp. is raised; presumably the soln. contains antimony pentachloride. According to E. Stelling, antimony pentoxide is readily dissolved by conc. hydrochloric acid in the presence of sulphurous acid. R. Bunsen observed that the pentoxide oxidizes **hydriodic acid**—*i.e.* a soln. of potassium iodide in an acid—liberating iodine, and, added J. Klein, if starch-paste be present, one part of the pentoxide in 633,000 parts of liquid can be detected. A. Kolb and R. Formhals discussed the mechanism of the reversible reaction: $\text{Sb}_2\text{O}_5 + 4\text{HI} \rightleftharpoons \text{Sb}_2\text{O}_3 + 2\text{H}_2\text{O} + 2\text{I}_2$. The reaction has been utilized by H. Giraud, F. A. Gooch and H. W. Gruener, F. E. Herroun, G. von Knorre, M. Rohmer, and A. Weller. The reaction with **potassium iodide** was symbolized by C. F. Schönbein: $3\text{Sb}_2\text{O}_5 + 4\text{KI} = 4\text{KSbO}_3 + \text{Sb}_2\text{O}_3 + 2\text{I}_2$; and H. Schulze found that with an **alkali chloride** in the presence of oxygen, chlorine is evolved. C. F. Rammelsberg observed that when the pentoxide is heated with a small proportion of **sulphur** it is reduced to the trioxide: $\text{Sb}_2\text{O}_5 + \text{S} = \text{SO}_2 + \text{Sb}_2\text{O}_3$; and with a large proportion of sulphur, antimony trisulphide is formed: $2\text{Sb}_2\text{O}_5 + 11\text{S} = 2\text{Sb}_2\text{S}_3 + 5\text{SO}_2$. O. Schumann obtained an oxysulphide, Sb_4OS_5 , by heating the pentoxide in a current of **hydrogen sulphide**; while H. Rose found that an aq. soln. of hydrogen sulphide slowly transforms the pentoxide into orange-red penta-

sulphide, while a soln. of **ammonium sulphide** slowly dissolves the pentoxide. J. J. Berzelius said that the pentoxide dissolves in a warm soln. of **alkali hydro-sulphide**, and that from the soln. acids precipitate the pentasulphide. H. Rose found that the pentoxide is but sparingly soluble in dil. and conc. **sulphuric acid**. H. Prinz represented the reaction with **sulphur monochloride** when heated in a sealed tube: $6\text{S}_2\text{Cl}_2 + 2\text{Sb}_2\text{O}_5 = 4\text{SbCl}_3 + 5\text{SO}_2 + 7\text{S}$.

G. Gore found hydrated antimony pentoxide to be sparingly soluble in liquid **ammonia**. According to H. Rose, antimony pentoxide is insoluble in aq. ammonia; and A. Rosenheim and F. Jacobsohn found that it is not attacked by liquid ammonia. V. Thomas found that when **nitrogen peroxide** is passed into a soln. of antimony tribromide in chloroform, or antimony triiodide in ether, there is precipitated white, crystalline, **antimony nitropentoxide**, $2\text{Sb}_2\text{O}_5 \cdot \text{N}_2\text{O}_5$, which is not decomposed by water. L. Rosenstein said that red **phosphorus** does not reduce antimony salts. A. Michaelis represented the reaction with **phosphorus trichloride** at 160° in a sealed tube: $\text{Sb}_2\text{O}_5 + 2\text{PCl}_3 = 2\text{SbCl}_3 + \text{P}_2\text{O}_5$. For the action of **phosphorus halides**, *vide* N. N. Sen's observations with arsenic trioxide. J. J. Berzelius observed that when heated with **antimony** or with **antimony trisulphide**, the pentoxide is reduced to the trioxide; he also found that the pentoxide is reduced to a lower oxide which glows brightly when heated on **carbon** before the blowpipe; H. Rose added that reduction to antimony occurs in the presence of sodium carbonate. The pentoxide is reduced when heated with **potassium cyanide**, or **sodium formate**. W. Müller said that the pentoxide is not reduced by **carbon disulphide**. H. Rose found that the pentoxide is insoluble in **alcohol**; and J. J. Berzelius, that it is sparingly soluble in **tartaric acid**. W. Bulgrin studied the complex salts of quinquevalent antimony. G. Rauter observed that when the pentoxide is heated with **silicon tetrachloride** in a sealed tube, at 260° – 270° , antimony trichloride and silica are formed and chlorine is set free.

Aq. soln. of **alkali hydroxides** slowly dissolve antimony pentoxide; soln. of **alkali carbonates** react even more slowly. When the pentoxide is fused with alkali hydroxides or carbonates, antimonates are produced—*vide infra*. According to C. F. Rammelsberg, **copper, silver, and lead sulphides** reduce the pentoxide to the trioxide with the elimination of sulphur dioxide. R. Bunsen found that antimony pentoxide is darkened by an ammoniacal soln. of **silver nitrate**; G. Tammann studied the reduction of silver nitrate in light, and H. Schiff, by a soln. of **stannous chloride**. M. Mengin obtained antimony by treating the pentoxide with a mixture of tin and hydrochloric acid.

The hydrates of antimony pentoxide.—J. J. Berzelius² obtained hydrated antimony pentoxide, as indicated above, by treating alkali antimonate with dil. nitric acid. L. Heffter said that the alkali is very tenaciously retained by the hydrate and is not removed by washing with dil. acid. H. Rose obtained the hydrate by the hydrolysis of antimony pentachloride; when the hydrochloric acid has been washed away, the hydrate diffuses through the wash-water in so finely-divided a state that it passes through the filter-paper, and the liquid is opalescent. The hydrate is also produced when antimony is treated with aqua regia—*vide supra*, preparation of antimony pentoxide. Analyses of the air-dried product by C. P. Conrad, H. Daubrawa, E. Frémy, A. Geuther, L. Heffter, J. B. Senderens, and C. Serono, give results ranging from 15.77 to 20.02 per cent. of water, corresponding with the tetrahydrate. Analyses by C. P. Conrad, H. Daubrawa, A. Geuther, and J. B. Senderens of the product dried over conc. sulphuric acid show 12.87–14.53 per cent. of water in agreement with the *trihydrate*, $\text{Sb}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$. J. B. Senderens regarded the trihydrate as *orthoantimonic acid*, H_3SbO_4 , and obtained it by drying the hexahydrate for 3 weeks over conc. sulphuric acid. F. Raschig, and others question the existence of the ortho-acid; H. Remy discussed its structure. According to J. B. Senderens, when antimony trichloride is treated with conc. nitric acid, a vigorous action occurs, and a clear red liquid is obtained which, on dilution, yields a white deposit, and which has the composition

of the *hexahydrate*, $\text{Sb}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, when exposed to air for 3 months at ordinary temp. 100 c.c. of water dissolve 2.2 grms. of Sb_2O_5 , but the soln. gradually becomes turbid, and a precipitate of the *tetrahydrate*, $\text{Sb}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, appears which increases until the conc. of the soln. is 0.3 grm. of the pentoxide per 100 c.c. This hydrate is less readily dehydrated by heat than in the case with hydrates prepared in other ways. These results were confirmed by the work of H. Baubigny. E. Frémy represented the tetrahydrate as dihydrated pyroantimonic acid, $\text{H}_4\text{Sb}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$ —*vide infra*. The dehydration curves of the hydrate obtained by the hydrolysis of the pentachloride were found by A. Simon and E. Thaler to be of the continuous type characteristic of hydrated metal oxides of the hydrogel type. At lower temp., the hydrogel holds its water more tenaciously the greater the dispersity—*i.e.* the lower the temp. of preparation; as the temp. rises, the differences become smaller; at 200° , the composition of all the gels approximates *tritapentahydrate*, $3\text{Sb}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, and the curve has a point of inflexion, indicating that hydrated antimony pentoxide begins to crystallize, and a similar result occurs when the hydrate is kept for some time—*ageing*. This hypothesis is confirmed by X-radiograms. The crystallization of the hydrogel is favoured by heating it with water under press. The product then gives a definite indication of the existence of the $3\text{Sb}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$ -hydrate, and also less clear indications of a dihydrate and a hemihydrate. In the absence of the treatment with water under press., which aids in the breaking down of the gel structure, the indications of the hydrates on the vap. press. curves is masked by capillary effects. Analyses by C. P. Conrad, H. Daubrawa, and A. Geuther of the product dried at 100° show 9.698–11.44 per cent. of water corresponding with the *dihydrate*, $\text{Sb}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$. J. B. Senderens regarded the dihydrates as *pyroantimonic acid*, $\text{H}_4\text{Sb}_2\text{O}_7$, and obtained it by heating the trihydrate to 200° . Analyses by J. J. Berzelius, H. Daubrawa, and A. Geuther of the product dried between 175° and 200° , show 5.09–6.20 per cent. of moisture corresponding with the *monohydrate*, $\text{Sb}_2\text{O}_5 \cdot \text{H}_2\text{O}$. J. B. Senderens regarded the monohydrate as *metantimonic acid*, HSbO_3 , and obtained it by heating the trihydrate to 300° . According to E. Goldsmith, the massive mineral *stibianite* from Victoria, Australia, has an analysis corresponding with $\text{Sb}_2\text{O}_5 \cdot \text{H}_2\text{O}$. The hardness is 5, and the sp. gr. 3.67. According to C. P. Conrad, the product dried at 300° has the composition of the *hemihydrate*, $\text{Sb}_2\text{O}_5 \cdot \frac{1}{2}\text{H}_2\text{O}$, and only at dull redness is all the water expelled, and at the same time the pentoxide begins to decompose into the tetroxide. J. B. Senderens said that the hydrated pentoxide becomes anhydrous at 400° . A. Naumann said metantimonic acid is insoluble in acetone.

If the red liquid obtained by J. B. Senderens by the action of conc. nitric acid on antimony trichloride be heated, and the white precipitate which forms be washed with dil. nitric acid, then with water, and dried in air, the *hemienneahydrate*, $\text{Sb}_2\text{O}_5 \cdot 4\frac{1}{2}\text{H}_2\text{O}$, is formed. Again, if the same red liquid be evaporated to dryness on a sand-bath until acid fumes are no longer evolved, the white residue has the composition of the *pentahydrate*, $\text{Sb}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$. E. Frémy found that the tetrahydrates obtained by the hydrolysis of antimony pentachloride, and by the action of acids on soln. of the antimonites, have different properties. The former was supposed to be $\text{H}_4\text{Sb}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$, and the latter, $2\text{H}_3\text{SbO}_4 \cdot \text{H}_2\text{O}$. The former was said to dissolve in much water, and to be precipitated by acids from the aq. soln. The precipitate dissolved in conc. ammonia whereas that obtained from the latter acid was not so dissolved. F. F. Beilstein and O. von Bläse, and C. P. Conrad showed that there is no real difference between the two products. J. B. Senderens, and A. E. Delacroix agreed that a soluble and an insoluble form of antimonic acid exists, and they called them ortho- and pyro-acids; but they differed as to which was which. The conductivity observations of E. S. Tomula show that the soluble acid is orthoantimonic acid, whether prepared by J. B. Senderens' or A. E. Delacroix's method. The eq. conductivities of the potassium salts of both acids were nearly the same, and in agreement with those of the dihydroantimonates. A conc. soln. of antimonic acid is not a true soln. but a

supersaturated, colloidal pseudo-solution from which the acid soon separates in an insoluble form.

A. E. Delacroix reported what he first called *pyroantimonic acid*, and later **tetrantimonic acid**, because it forms salts of the type $K_2O.4Sb_2O_5$, or $K_2Sb_8O_{21}$. The acid is prepared by adding antimony pentachloride to 20–25 times its weight of cold water, the excess of chlorine being removed by drawing air through the liquid, and, after remaining for an hour or so, the precipitated hydroxide is transferred to a filter; it is extremely difficult to remove the last traces of hydrogen chloride. By freezing the aq. soln., the acid is obtained in thin scales which are optically active. The ultimate composition is $Sb_2O_5.4H_2O$; when dried over sulphuric acid, $Sb_2O_5.3H_2O$; and when dried at 100° , $Sb_2O_5.2H_2O$. When left in contact with cold water, the hydroxide slowly dissolves, yielding a soln. of pyroantimonic acid. At 15° , the soln. contains 5.88 grms. of Sb_2O_5 per litre; at 25° , 8.55 grms.; at 60° , 21.30 grms. When treated with mineral acids, a precipitate is obtained, but organic acids have no action. The hydroxides yield white precipitates soluble in water, but insoluble in an excess of alkali. When titrated with alkali, using methyl-orange as indicator, neutralization is reached when the ratio of alkali to Sb_2O_5 is 0.25 : 1. With phenolphthalein, the ratio is 0.5 : 1. It was not possible to isolate the salt $K_2O.4Sb_2O_5$, but $Na_2O.4Sb_2O_5$ was obtained, and the salt $K_2O.2Sb_2O_5$ is produced when the acid is treated with a slight excess of potassium hydroxide or acetate. The observations of G. Jander show that the so-called tetrantimonic acid is a hydrosol of small stability.

A. E. Delacroix could not make **ammonium tetrantimonate**, $(NH_4)_2Sb_4O_{11}$, by neutralizing the free acid, but it is produced when the acid is treated with ammonium acetate. A. E. Delacroix prepared **sodium tetrantimonate**, $2Na_2O.4Sb_2O_5.18H_2O$, by neutralizing the free acid with sodium hydroxide, and freezing the soln. The salt is decomposed into the triantimonate by water. A crystalline powder, with the composition $Na_2O.4Sb_2O_5.20H_2O$, was obtained by freezing a soln. of a mol of antimony pentoxide and 3 mols of sodium chloride; or a soln. of a mol of antimony pentoxide and half a mol of sodium hydroxide. By neutralizing a soln. of the free acid with potash-lye, using phenolphthalein as indicator, and treating the liquid with alcohol, and by freezing a soln. obtained by neutralizing tetrantimonic acid with potash-lye, **potassium tetrantimonate**, $2H_2O.4Sb_2O_5.18H_2O$, was obtained; **copper tetrantimonate**, $2CuO.4Sb_2O_5.18H_2O$, was produced in a similar way. A. E. Delacroix also obtained evidence of the formation of **barium tetrantimonate**, $BaO.4Sb_2O_5.15H_2O$, by freezing a soln. of a mol of antimony pentoxide and 2 mols of barium chloride; and of $BaO.2Sb_2O_5.5H_2O$, from a soln. of tetrantimonic acid and baryta-water. The chemical individuality of these products has not been established.

A. E. Delacroix also made what he first called *orthoantimonic acid*, and later **triantimonic acid**, because it forms salts of the type $R_2O.3Sb_2O_5$, or RSb_3O_8 . The acid was made by heating tetrantimonic acid for some minutes at 100° ; the same transformation occurs slowly at ordinary temp., and the soln. so obtained are feebly opalescent. By freezing its soln., triantimonic acid was obtained in crystals with the ultimate composition $Sb_2O_5.3H_2O$, or $Sb_2O_5.2H_2O$, when dried over conc. sulphuric acid. The potassium salt KSb_3O_8 is indicated when the acid is titrated with the alkali, using methyl-orange as indicator. Triantimonic acid forms salts of the type $R_2O.3Sb_2O_5$, $2R_2O.3Sb_2O_5$, and $3R_2O.3Sb_2O_5$, and other more complex derivatives. The alkali salts are alone soluble in water, and those containing one eq. of base are soluble in alcohol. G. Jander showed that the alleged triantimonic acid is a hydrosol of small stability.

A. E. Delacroix obtained an aq soln. of **lithium triantimonate** by neutralizing free triantimonic acid with lithium hydroxide, using phenolphthalein as indicator; if the hot soln. be neutralized, the liquid deposits the metantimonate after standing some hours. The lithium salt resembles that of potassium. By a similar process, using sodium hydroxide, a soln. of **sodium triantimonate**, $2Na_2O.3Sb_2O_5.10H_2O$, was produced; and if the free acid be treated with an excess of sodium chloride, sulphate, or nitrate, the crystalline powder which is precipitated has the composition $Na_2O.3Sb_2O_5.11H_2O$. It is also obtained by freezing the soln. obtained by half neutralizing the free acid with sodium hydroxide. Where potassium hydroxide is employed in neutralizing the free acid—with phenolphthalein as indicator—the soln. contains **potassium triantimonate**, $K_2O.3Sb_2O_5.nH_2O$ —

A. E. Delacroix gave the formula $K_2O \cdot 2Sb_2O_5 \cdot nH_2O$. If a soln. of the free acid be treated with an excess of potassium hydroxide, and then with alcohol, an amorphous precipitate of potassium triantimonate, $2K_2O \cdot 3Sb_2O_5 \cdot 10H_2O$, is produced. A. E. Delacroix obtained from the triantimonic acid **barium triantimonate**, $BaO \cdot 3Sb_2O_5 \cdot 5H_2O$; as well as the salts $4BaO \cdot 5Sb_2O_5 \cdot nH_2O$; $9BaO \cdot 10Sb_2O_5 \cdot 18H_2O$; and $BaO \cdot Sb_2O_5 \cdot 2H_2O$; **copper triantimonate**, $2CuO \cdot 3Sb_2O_5 \cdot 10H_2O$, was obtained from copper acetate and triantimonic acid. Likewise also **copper hexantimonate**, $CuO \cdot 6Sb_2O_5 \cdot 16H_2O$. Analogous evidence of the existence of **strontium and calcium triantimonates** was obtained. The chemical individualities of the triantimonates was not established.

G. Jander and A. Simon prepared hydrates of antimony pentoxide by these methods: (i) the hydrolysis of the pentachloride at $0^\circ-1^\circ$; (ii) hydrolysis at 100° ; and (iii) oxidation of the trichloride by conc. nitric acid and hydrolysis of the product at 60° . The products were dried on porous plates in the air, and were found to contain (i) 30.57, (ii) 9.97, (iii) 7.91 mols of water to one mol of the pentoxide. After drying over sulphuric acid, the water contents were (i) 3.68, (ii) 2.17, (iii) 0.60 mols per mol Sb_2O_5 . Drying at 105° reduced the molecules of water per mol of the pentoxide to (i) 2.43, (ii) 1.02, (iii) 0.45. The behaviour of the three hydrates towards alkalis and phosphoric acid was investigated, and their vapour tension isotherms were measured. No definite hydrates were formed, but gels were present, the behaviour of which depend on grain size, which varies with the method of

FIG. 32.—Speeds of Dehydration of the Hydrates of Antimony Pentoxide.

FIG. 33.—Adsorption of Alkali by the Hydrates of Antimony Pentoxide.

preparation. Alcolgels of the pentoxide were also prepared, and these were dealcoholated by placing them over glycerol; the curves of dealcoholation were similar to those of dehydration. The pentoxide was also able to take up benzene when kept in an atm. of the latter. The speeds of dehydration of the acids prepared at 0° , 60° , and 100° , in vacuo over conc. sulphuric acid at room-temp., are indicated by the curves shown in Fig. 32; and the adsorption of alkali from soln. of lithium sulphate of different conc., in Fig. 33. G. Jander showed that the

FIG. 34.—Hydration and Dehydration of Antimony Pentoxide.

hydrates of antimony pentoxide show a marked selective adsorption towards dil. alkalis, forming what appear to be alkali antimonates. Conc. soln. of the alkalis dissolve the hydrates of antimony pentoxide, and the evaporation of the soln. at low temp. furnishes crystals of various alkali antimonates, but the nature of the salt depends on the conc. of the mother-liquor. The compound $1.71K_2O \cdot Sb_2O_5 \cdot 8H_2O$ was obtained in this way. Analogous results were obtained for the adsorption of phosphoric acid by hydrated antimony pentoxide. In no case is there any evidence of the formation of definite hydrates. The vap. press. curves support this conclusion. The results for the hydration and dehydration of the acid prepared at 0° are given in Fig. 34, and they are analogous with those obtained with other colloids—e.g. silica acid, stannic acid, etc. The results depend on the grain-size and mode

of preparation of the hydrates. A. Lottermoser found that the electrical conductivity of a mixture of antimony pentoxide rises to a maximum, corresponding with the clarification of the soln., and then slowly falls. It is thought that the clear soln. represents a soln. of $\text{Sb}(\text{OH})_5$, and that subsequently dehydration occurs, and a colloid is formed.

The hydrates of antimony pentoxide, or the antimonic acids, are therefore **hydrogels** of antimony pentoxide; this agrees with the observed properties of the hydrates—peptization with alkalis and water; flocculation with acids. H. Lachs and F. Lachmann studied the coagulation of colloidal antimonic acid. The soluble antimonic acid of J. B. Senderens, for instance, is the **hydrosol** of antimony pentoxide. G. Jander and A. Simon also prepared **alcogels** of antimony pentoxide which were dealcoholated by placing them over glycerol. The dealcoholation and dehydration curves were similar. S. Glixelli and M. Deniszczukowna prepared antimonic acid by the hydrolysis of a conc., aq. soln. of antimony pentachloride at 0° for 12–14 hrs., and subsequently removing the hydrochloric acid with iced water. A soln. containing 150 grms. per litre is slightly opalescent, and stable at 0° . It is coagulated by cations in the usual way. The mol. wt. determined by the f.p. method is influenced by the conc. of the soln. Measurements of the conc. of the H^+ -ion show the number of ions associated with the colloidal anion in each micelle, and the electrical conductivity is attributed to the decomposition of these micelles, and their subsequent ionization on dilution. For conc. soln., the conductivity decreases with time; but for dil. soln., it rises to a maximum and then falls. The soln. are not susceptible of ultra-filtration, but they can be made so by prolonged heating. Stable colloidal soln. are then obtained which give a mol. wt. of the order of 10,000. The mol. conductivities are small and increase with time, especially in dil. soln. where the micelles are split up into molecules. H. Lachs and F. Lachmann studied the coagulating effect of soln. of electrolytes on hydrosols of antimonic acid.

P. F. G. Boullay gave 6.6 for the sp. gr. of the tetrahydrate. H. Rose said that the hydrates of antimony pentoxide have a metallic taste; that they strongly redden moist litmus-paper; and that they slowly dissolve in cold hydrochloric acid, and rapidly when heated, with the evolution of chlorine and the formation of antimony trichloride. The soln. initially turbid becomes clear on standing. The hydrate is gradually transformed by hydrogen sulphide into antimony pentasulphide; H. Capitaine observed that hydrogen sulphide colours the soln. yellow, and the addition of an acid gives a precipitate of antimony pentasulphide. H. Rose found that a soln. of ammonium sulphide gradually dissolves the hydrate; while the hydrate is insoluble in sulphuric acid, and also in aq. ammonia. E. Frémy reported that one hydrate prepared as indicated above dissolves slowly by prolonged contact with conc. ammonia in the cold; but F. F. Beilstein and O. von Bläse observed no difference in the behaviour of the different hydrates towards the aq. ammonia. H. Rose found that nitric acid does not dissolve the hydrate; and H. Schiff, that phosphorus pentachloride yields phosphorus oxychloride and antimony pentachloride. According to F. Schultze, and G. Jander and A. Simon, the hydrates of antimony pentoxide adsorb phosphoric acid from aq. soln. According to J. J. Berzelius, the hydrate dissolves in tartaric acid; according to H. Rose, and C. Luckow, in oxalic acid; and, according to H. Rose, in a soln. of potassium oxalate. G. Jander and A. Simon found that the pentoxide adsorbs benzene vapour, and alcohol vapour. H. Rose showed that by the prolonged contact of the hydrate with an aq. soln. of potassium hydroxide or carbonate only a small amount of the hydrated pentoxide passes into soln.; while the molten alkali hydroxide or carbonate yields alkali antimonate. According to H. Schiff, when the hydrate is digested with a feebly (hydrochloric) acid soln. of stannous chloride, brick-red stannous antimonate is formed.

§ 14. The Antimonates

A review of the antimonates shows that our knowledge of these compounds is in an unsatisfactory state. The main difficulty encountered by previous workers turns on the constitutional water. An antimonate with the ratio R : Sb = 1 : 1 may be an orthoantimonate, $RH_2SbO_4 \cdot nH_2O$; a pyroantimonate, $R_2H_2Sb_2O_7 \cdot nH_2O$, or a metantimonate, $RSbO_3 \cdot (n-1)H_2O$. J. J. Berzelius,¹ and E. Frémy found that **ammonium metantimonate**, $NH_4SbO_3 \cdot nH_2O$, where n may be zero, 2, 2.5, or 3, separates on cooling a soln. of metantimonic acid in warm aq. ammonia. E. Frémy obtained it by adding alcohol to a soln. of pyroantimonic acid, or by adding ammonium chloride to the gum-like soln. of potassium metantimonate; and

J. B. Senderens, by treating an aq. soln. of antimony pentoxide with ammonium acetate. F. Raschig found that when freshly precipitated antimony sulphide, from 30 grms. of potassium antimonyl tartrate, is treated with 500 c.c. of conc. aq. ammonia, and 900 c.c. of a 2.5 per cent. soln. of hydrogen dioxide, about one-sixth is converted into antimonic acid which forms a flaky precipitate. The soln. contains ammonium sulphate and antimonate; the latter salt is precipitated by the addition of alcohol, and when dried at the ordinary temp., has the composition $\text{NH}_4\text{SbO}_3 \cdot 3\text{H}_2\text{O}$, and is therefore identical with E. Frémy's ammonium dihydro-pyroantimonate, $\text{H}_2(\text{NH}_4)_2\text{Sb}_2\text{O}_7 \cdot 5\text{H}_2\text{O}$. The white, crystalline powder precipitated by alcohol contains 3 mols. of water of crystallization, and it is soluble in water; that obtained by cooling the ammoniacal soln. contains 2 mols. of water of crystallization and is insoluble in water; while that obtained by precipitation with ammonium acetate contains 2.5 mols. of water of crystallization when dried for several months in air; it contains one mol. of water when dried over conc. sulphuric acid; and it becomes anhydrous at 300° . The crystals of the trihydrate lose a mol. of water at ordinary temp.; and also when boiled with water. E. Frémy found that the aq. soln. of the crystalline salt is a good reagent for sodium—a soln. with one of sodium chloride in 1000 parts of soln. precipitates sodium antimonate on standing a few days; with a 1 : 100 soln., a precipitate is produced in a short time. No precipitation occurs with potassium chloride; but magnesium salt soln. precipitate magnesium metantimonate; and ammoniacal soln. of copper salts were found by F. Raschig to give crystalline cupric ammonium antimonate. W. Müller showed that the vapour of carbon disulphide converts warm ammonium metantimonate into antimony and ammonium sulphides. According to F. Raschig, the **ammonium pyroantimonate**, $(\text{NH}_4)_4\text{Sb}_2\text{O}_7$, of E. Frémy is probably something else—*vide supra*. E. Frémy made it by the action of conc. ammonia on the antimonic acid obtained by the hydrolysis of antimony pentachloride.

According to J. B. Senderens,² the white precipitate obtained by treating an aq. soln. of antimony pentoxide with potassium acetate and drying over sulphuric acid, approximates to **potassium dihydroantimonate**, $\text{KH}_2\text{SbO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. It is stable up to 100° ; loses its water at 300° ; and does not decompose at a red-heat. F. F. Beilstein and O. von Bläse regarded many of the antimonates as salts of orthoantimonic acid, H_3SbO_4 —and J. B. Senderens, as salts of the same acid with a doubled molecule, $\text{H}_5\text{Sb}_2\text{O}_8$ —because many of the antimonates when dried over sulphuric acid can be represented by the formula RH_2SbO_4 . The alternative view is that they are metantimonates $\text{RSbO}_3 \cdot \text{H}_2\text{O}$. The analogy of the orthophosphates, orthoarsenates, does not apply to the so-called orthoantimonates. Soln. of these salts have an alkaline reaction. F. Raschig found that the product of the reaction with molten alkali hydroxide and antimony pentoxide; of antimony trisulphide and ammoniacal hydrogen dioxide; and of sodium thioorthoantimonate with copper oxide has the ratio R : Sb = 1 : 1, not 3 : 1; and F. Ebel regarded most of the antimonates as metantimonates, but the sparingly soluble sodium salt, and the granular potassium salt are considered to be dihydropyroantimonates because they retain a mol. of water when heated to 200° – 350° .

E. Frémy found that **sodium dihydropyroantimonate**, $\text{Na}_2\text{H}_2\text{Sb}_2\text{O}_7 \cdot 5$ or $6\text{H}_2\text{O}$, is obtained when a soln. of potassium dihydropyroantimonate, or metantimonate is added to one of a sodium salt—say chloride, or acetate. The reaction was employed by H. Rose, C. R. Fresenius, T. H. Behrens, F. F. Beilstein and O. von Bläse, etc., in analytical work. E. Frémy showed that the precipitation occurs with one part of the sodium salt in 500 parts of water, even when potassium salts are also present—organic salts should be absent. E. Frémy's method of preparing the salt was used by L. Heffter, F. Ebel, and G. von Knorre and P. Olschewsky. W. P. Dexter recommended washing the salt by decantation since it is liable to choke up the filter-paper; and F. F. Beilstein and O. von Bläse recommended washing it with 25 per cent. alcohol mixed with a little sodium acetate to prevent the peptization of the precipitate and its passage through the filter-paper. G. von

Knorre and P. Olschewsky obtained this salt by oxidizing a soln. of antimony trioxide in hot soda-lye by means of hydrogen dioxide, potassium dichromate, or potassium ferrocyanide—if the permanganate be employed, the product is contaminated with manganese dioxide; R. Robl found that the salt does not show fluorescence when exposed to ultra-violet light. E. S. Tomula measured the electrical conductivity of the salt at 25°, and found for the eq. conductivity, λ , for soln. with a mol of the salt in v litres:

v	.	.	32	64	128	256	512	1024
λ	.	.	93.5	93.8	95.5	95.2	93.7	103.4

which by the Ostwald-Walden rule—1. 15. 13—makes the basicity unity. The salt in soln. cannot therefore be the dihydropyroantimonate, $K_2H_2Sb_2O_7$, and since it has an acidic reaction it cannot be the metantimonate. It must therefore be the orthoantimonate—**potassium dihydroantimonate**, KH_2SbO_4 . The ionization constant is 0.957; and the hydrogen ion conc. for $v=1024$ is $C_H=10^{-6.3}$. F. E. Brown and J. E. Snyder observed no reaction with vanadium oxytrichloride and anhydrous potassium pyroantimonate. E. Mitscherlich, and B. Unger prepared the salt by boiling a soln. of antimony trioxide or trisulphide with sulphur—sodium ortho-sulphantimonate is formed at the same time. E. Mitscherlich obtained the same product by the action of soda-lye on antimony pentasulphide. Some of the commercial *kermes mineral* is sodium dihydropyroantimonate. It is formed by boiling antimony sulphide with a 10 per cent. aqueous soln. of sodium carbonate. The corresponding potassium compound is more difficult to crystallize than the sodium compound. W. Hampe obtained the product by treating antimony trisulphide with sodium dioxide, or a soln. of antimony trisulphide in soda-lye with hydrogen dioxide. G. Jander and L. Brandt added that the hydrated crystalline precipitates of sodium and lithium antimonates obtained by oxidizing alkaline soln. of antimony trisulphide with hydrogen dioxide, are not of fixed composition, the alkali content varying with the alkalinity of the mother-liquor and the temp. of precipitation. B. Unger said that some dihydropyroantimonate is formed by the action of soda-lye itself on the trisulphide which is simultaneously reduced; and E. Mitscherlich observed that the salt separates when a soln. of antimony trisulphide in aq. sodium carbonate is exposed to air.

The salt usually appears in the form of a white, crystalline powder. C. von Haushofer made crystals 0.5 mm. in length by allowing soln. of potassium metantimonate and sodium chloride to diffuse slowly into one another. The tetragonal crystals had the axial ratio $a:c=1:10079$. The crystals were also examined by E. Mitscherlich, L. Heffter, T. H. Behrens, and G. von Knorre and P. Olschewsky. Analyses by E. Frémy, G. von Knorre and P. Olschewsky, L. Heffter, and F. Ebel, agree with the formula $Na_2H_2Sb_2O_7 \cdot 6H_2O$ for the air-dried salt, or of the salt precipitated between 50° and 80°; and the analyses of G. von Knorre and P. Olschewsky, and B. Unger of the salt precipitated at 100° agree with $Na_2H_2Sb_2O_7 \cdot 5H_2O$. The percentage losses in weight of the hexa- and pentahydrates, at different temp., were found, by G. von Knorre and P. Olschewsky, to be:

	100°	125°	150°	165°	185°	200°	250°	350°	Red-heat.
6H ₂ O	0.58	1.11	4.96	8.42	15.28	17.92	18.71	20.64	20.30
5H ₂ O	0.00	0.01	0.39	0.87	9.13	16.29	16.72	18.69	22.39

Observations were also made by L. Heffter. E. S. Tomula found the eq. electrical conductivities of soln. of a mol of the sodium salt in 512 and 1024 litres of water were slightly smaller, but of the same order as those of the potassium salt—*vide infra*—being respectively 80.2 and 81.0; the low solubility of the salt prevented more conc. soln. being examined. By analogy with the potassium salt, it was therefore inferred that the soln. contains **sodium dihydroantimonate**, $Na(H_2SbO_4)$, and not the dihydropyroantimonate, $Na_2H_2Sb_2O_7$, or the metantimonate, $NaSbO_3$. The hydrogen-ion conc. for $v=1024$ is $C_H=10^{-6.4}$. According to F. Ebel, and

L. Heffter, 100 parts of boiling water dissolve rather less than 0.3 part of salt; while F. F. Beilstein and O. von Bläse found that at 12.3°, 100 parts of water dissolve 0.031 part of the hexahydrate; 100 parts of 15.8 per cent. alcohol, 0.013 part of the salt; and 100 parts of 25.6 per cent. alcohol, 0.007 part of the salt. E. S. Tomula found that the solubilities of sodium antimonate, $\text{Na}_2\text{O} \cdot \text{Sb}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, in water at 18°, 25°, and 33.5° are respectively 56.4, 73.8, and 101.8 mgrms. per 100 c.c. of soln.; with methyl alcohol of sp. gr. 0.9734, 12.0, 19.3, and 27.0 mgrms.; sp. gr. 0.9559, 4.4, 9.5, and 15.0 mgrms.; sp. gr. 0.9298, 0.6, 3.1, and 6.2 mgrms. respectively; with ethyl alcohol of sp. gr. 0.9774, 11.8, 15.0, and 40.3 mgrms.; sp. gr. 0.9618, 3.8, 6.0, and 14.0 mgrms.; and sp. gr. 0.9370, 0.1, 0.4, and 0.8 mgrms. respectively. With a one per cent. soln. of sodium acetate, 6.1, 14.6, and 20.5 mgrms.; with a 2.5 per cent. soln., 3.1, 4.0, and 9.4 mgrms.; and with a 5 per cent. soln., a feeble opalescence appeared at 18° and 25°, and at 33.5°, 4.2 mgrms. were dissolved per 100 c.c. of soln. The salt is less soluble in a 2.5 to 10 per cent. soln. of sodium hydroxide or carbonate than it is in water; while ammonium or potassium salt soln. have a greater solvent action than water. Thus, 100 parts of a soln. of 160 parts of potassium carbonate in 250 c.c. of water, dissolve 0.514 part NaSbO_3 ; 48 parts of potassium nitrate, 0.132 part NaSbO_3 ; and 27, 40, and 60 of potassium chloride, respectively 0.063, 0.079, and 0.145 part NaSbO_3 . Observations were made by E. Frémy, G. von Knorre and P. Olschewsky, H. Rose, E. S. Tomula, F. F. Beilstein and O. von Bläse, C. R. Fresenius, L. Garnier, and F. J. Otto. E. C. Franklin and C. A. Kraus found it to be insoluble in liquid ammonia. According to B. Unger, and W. Feit and C. Kubierschky, the dihydropyroantimonate dissolves slowly in a soln. of sodium sulphide, and acids precipitate antimony pentasulphide from the colourless soln. G. von Knorre and P. Olschewsky found the salt to be insoluble in acetic acid. A. Naumann said that it is insoluble in methyl and ethyl acetates, and in acetone.

E. Frémy obtained what might be **potassium pyroantimonate**, $\text{K}_4\text{Sb}_2\text{O}_7 \cdot n\text{H}_2\text{O}$, by melting antimony pentoxide or potassium metantimonate with three times its weight of potassium hydroxide; and evaporating an aq. soln. of the product. G. von Knorre and P. Olschewsky, and A. E. Delacroix were unable to establish the chemical individuality of the product. It may be a mixture of the metantimonate and alkali. E. Frémy said that when the dihydroantimonate is decomposed with cold water, it forms **potassium dihydropyroantimonate**, $\text{K}_2\text{H}_2\text{Sb}_2\text{O}_7 \cdot 4\text{H}_2\text{O}$, but G. von Knorre and P. Olschewsky were unable to verify this. E. Frémy heated antimony with four times its weight of nitre in a fireclay crucible at a red-heat, and extracted the nitrate and nitrite from the cold mass by cold water. The residue was boiled with water for 2 to 3 hrs., when almost all passed into the soln. The liquid was evaporated for crystallization; and the crystals were drained on a porous tile, and washed with cold water. The result was supposed to be the dihydropyroantimonate, but G. von Knorre and P. Olschewsky obtained the metantimonate by this process. L. Heffter also obtained poor yields of salt by this process; C. F. Rammelsberg used a somewhat similar process, and C. Brunner deflagrated a mixture of nitre and potassium antimonyl tartrate, but G. von Knorre and P. Olschewsky did not obtain a pure product by this process. A. E. Delacroix precipitated this salt by adding alcohol to a 2–2.5 per cent. soln. of potassium metantimonate, and A. Reynoso, by treating a soln. of potassium antimonite with potassium permanganate. J. D. van Leeuwen made potassium pyroantimonate for the determination of sodium by heating to redness a mixture of 20 grms. potassium antimonyl tartrate with an equal weight of potassium nitrate. When reaction has ceased, the lid is placed on the crucible, and heating continued for 15 mins. After cooling, 50 c.c. of warm water are added, and the mass stirred until it becomes powdery. It is then filtered through a porcelain vacuum filter, the residue is treated with 100 c.c. of cold water, and transferred with the filter-paper to a flask containing 500 c.c. of boiling water. After boiling for one minute and rapidly cooling, some aluminium hydroxide is added, the mixture is shaken, and

finally passed through an ordinary filter-paper. S. A. Schou prepared this salt as follows :

Grey stibnite is boiled with potassium hydroxide soln., cupric oxide is added, and the whole stirred and boiled for $\frac{1}{2}$ hr., and then filtered. The filtrate (which should be quite free from sulphur and give a pure white precipitate with lead acetate soln.) is evaporated to one-tenth of its original vol. and treated with alcohol. The precipitated potassium antimonate is filtered off, washed with 50 per cent. alcohol, left for 24 hrs., and then ground in a mortar and dried on filter-paper. This method gives a yield of 90 per cent. of the theoretical, whilst a yield of 98 per cent. can be obtained if very finely divided antimony trisulphide, prepared by the careful ignition of the pentasulphide, is used instead of the ore. The antimony trisulphide and potassium hydroxide react to form a mixture of antimonite and thioantimonite, which are then oxidized by the cupric oxide with the formation of an intermediate oxysulphide, K_3SbO_3S , which cannot be isolated.

The analyses of the white powder by G. von Knorre and P. Olschewsky, and C. F. Rammelsberg corresponded with a tetrahydrate; A. E. Delacroix represented the compound as a pentahydrate; and E. Frémy, L. Heffter, and C. Jander and W. Brüll, as a hexahydrate. G. von Knorre and P. Olschewsky, and A. E. Delacroix represented the salt dried at 100° as a trihydrate; and the salt dried at 100° lost 0.47 per cent. in weight at 122° ; 1.04, at 150° ; 1.64, at 170° ; 5.23, at 200° ; 9.26, at 225° ; 10.51, at 280° ; 10.70, at 330° ; and 15.80, at a red-heat. 100 parts of water at 20° dissolve 2.81 parts of the anhydrous salt; and the sp. gr. of the soln. is 1.0263 at 18° . G. Jander and W. Brüll found that the solubility of the *hexahydrated* sodium pyroantimonate, dried at room temp., is 3.01×10^{-3} mols per litre; and when dried at 100° the resulting *trihydrate* has the solubility of 2.52×10^{-3} to 2.55×10^{-3} mols per litre. The transition point is 10° . The mol. lowering of the f.p. is 27.3° for a 0.1970*N*-soln., and 33.9° for a 0.395*N*-soln. The effects of sodium chloride and of potassium antimonate on the solubility, *S*, of this sodium antimonate, are :

NaCl	0.03	0.01	0.003	0.001
<i>S</i>	0.00025	0.00066	0.00149	0.00213
K antimonate	0.03	0.01	0.003	0.001
<i>S</i>	0.00005	0.00067	0.000148	0.00208

The aq. soln. of this sodium pyroantimonate contains sodium ortho- or meta-antimonate involving either $Na^+ + H_2SbO_4^- = NaH_2SbO_4$; or else $Na^+ + SbO_3^- = NaSbO_3$. Likewise also with aq. soln. of potassium ortho- or meta-antimonate; both salts have similar ions in aq. soln., and hence they are assumed to be either ortho- or meta-antimonates—which is not evident. The conc. of the H^- ions in 0.1*N*-, 0.01*N*-, 0.005*N*-, and 0.002*N*-soln. are respectively $10^{-8.7}$, $10^{-8.2}$, $10^{-7.8}$, and $10^{-7.7}$ for the potassium salt, and for the 0.004*N*- and 0.0004*N*-soln. of the sodium salt, respectively, $10^{-7.8}$ and $10^{-7.7}$. The diffusion coeff. of the antimonate ion in *N*- and 0.1*N*-HCl are 0.44, and in strongly acid soln., a tetrantimonate is probably formed. When the cold sat. soln. is evaporated in vacuo, the original salt is obtained as a white, crystalline mass; but if the hot, sat., aq. soln. is evaporated to dryness on a water-bath, the metantimonate is formed. E. Mitscherlich obtained a similar product by the action of soda-lye on antimony pentasulphide. E. Frémy, and G. von Knorre and P. Olschewsky found that the dil. or conc. aq. soln. gives a white crystalline precipitate of sodium dihydropyroantimonate, with a soln. of sodium acetate. Unlike the metantimonate, the dihydropyroantimonate is decomposed when calcined 2 or 3 times with ammonium chloride. W. Ipatieff and co-workers observed that potassium hydropyroantimonate gives potassium hydroxide and antimony when heated with hydrogen under press. J. W. Thomas said that the action of hydrogen chloride on potassium antimonate is energetic, forming antimony and potassium chlorides.

F. F. Beilstein and O. von Bläse treated a soln. of potassium metantimonate with lithium sulphate and, after the liquid had stood some time, obtained a white powder consisting of hexagonal plates of **lithium metantimonate**, $LiSbO_3 \cdot 3H_2O$. It loses all its water of crystallization when ignited, and neither darkens in colour,

nor becomes calorescent. The product obtained by deflagrating and fusing antimony, or antimony pentoxide or trisulphide with sodium nitrate and an alkali furnishes an impure *sodium metantimonate*, which occurs in commerce under the trade name *leukonium*. The use of this substance as an opacifying agent for enamels, glasses, and glazes was discussed by P. Askenasy, and R. Rickmann. W. G. Mixer gave for the heat of formation of a possible sodium orthantimonate : $3\text{Na}_2\text{O} + 2\text{Sb} + 5\text{O} = 2\text{Na}_3\text{SbO}_4 + 393.3$ Cals.

The two important potassium antimonates are the granular dihydropyroantimonate, $\text{K}_2\text{H}_2\text{Sb}_2\text{O}_7 \cdot 4\text{H}_2\text{O}$; and the gummy **potassium metantimonate**, $\text{KSbO}_3 \cdot n\text{H}_2\text{O}$. The sodium salt eq. to the former has just been described, but the existence of a sodium eq. of the latter has not been established. Potassium metantimonate was prepared by J. J. Berzelius, and E. Frémy by melting a mixture of antimony, or antimony trioxide or trisulphide with 3-4 times its weight of potassium nitrate for an hour at dull redness. The mass is then washed with cold water to remove alkali nitrate and nitrite; boiled with water for 2-3 hrs., replacing the water as it evaporates, and the potassium antimonate is thereby converted into a gummy soluble antimonate. W. P. Dexter, and F. F. Beilstein and O. von Bläse treated a mixture of potassium antimonyl tartrate in an analogous way. G. Jander and L. Brandt found that the antimonate obtained by oxidizing alkaline soln. of antimony trioxide by hydrogen dioxide is difficult to crystallize. The value of the ratio $\text{K}_2\text{O} : \text{Sb}_2\text{O}_5$ is nearly unity. F. F. Beilstein and O. von Bläse purified potassium metantimonate by washing the powder with cold water; shaking it up with conc., aq. ammonia and allowing the mixture to stand in a closed flask for two days; and boiling the mixture diluted with much water to drive off the ammonia. T. Rieckher prepared potassium metantimonate by adding sufficient copper hydroxide to a boiling soln. of antimony pentasulphide in potash-lye to desulphurize the mixture; filtering off the precipitated copper sulphide; and evaporating the soln.; the product was washed with a little cold water, and dried on a porous tile. M. Duyk used a modification of this process. G. von Knorre and P. Olschewsky obtained the metantimonate by treating the dihydropyroantimonate with boiling water; and by adding alcohol to a soln. of antimony pentoxide or potassium antimonate in potash-lye. Analyses of air-dried potassium metantimonate by E. Frémy, L. Heffter, and G. von Knorre and P. Olschewsky correspond with $\text{KSbO}_3 \cdot n\text{H}_2\text{O}$, where n ranges from 5.66 to 7.99; and of the product dried at 100° , with $\text{KSbO}_3 \cdot 1.5\text{H}_2\text{O}$. According to G. von Knorre and P. Olschewsky, the salt prepared by E. Frémy's process and dried at 100° lost the following percentage amounts of water at the given temp. :

	125°	150°	175°	200°	225°	250°	280°	350°	Red-heat.
Loss	1.26	2.64	4.43	4.29	5.14	5.71	6.39	6.79	11.77

Observations were also made by E. Frémy. J. J. Berzelius found that the air-dried salt dissolves slowly in cold and quickly in hot water; G. von Knorre and P. Olschewsky, that the salt dried at 100° dissolves with difficulty in cold water, but readily in hot water; and E. Frémy, that the salt dried at 160° is insoluble in cold water, but is slowly dissolved by boiling water. L. Heffter, and G. von Knorre and P. Olschewsky found that acids precipitate hydrated antimony pentoxide from the aq. soln., and carbon dioxide, an acid salt containing no carbonate—L. Heffter thought a carbonate was present. The alkali antimonates were found by B. Unger to be converted into antimony trisulphide and alkali sulphate when fused with sulphur; and H. Rose, into sodium sulphantimonate when fused with sodium thiosulphate; or with a mixture of sulphur and sodium carbonate. E. Frémy said that soln. of ammonium chloride gave a precipitate with aq. soln. of the metantimonate. H. Rose, and F. Ebel found that ignition with ammonium chloride volatilizes the antimony completely from alkali and alkaline earth antimonates, but not completely from other antimonates. G. von Knorre and P. Olschewsky found that the salt is decomposed, but not completely unless the metantimonate has been

previously evaporated with hydrochloric acid. H. Rose, and O. Brunck showed that fused potassium cyanide reduces the antimonates to antimony. W. Müller found that when heated in a current of carbon disulphide, potassium metasulph-antimonate is produced. According to H. Rose, soln. of potassium metantimonate with acids—hydrochloric, nitric, or sulphuric acid—precipitate a hydrate soluble in an excess of hydrochloric acid; hydrogen sulphide precipitates antimony pentasulphide; carbon dioxide precipitates $3K_2O \cdot 3Sb_2O_5 \cdot nH_2O$; oxalic acid and potassium oxalate give no precipitate—although after long standing oxalic acid gives a flocculent precipitate; aq. ammonia has no effect or gives only a slight precipitation; most salts of the alkaline earths and of the heavy metals give precipitates—magnesium sulphate acts in the presence of ammonia; copper sulphate gives a bluish-green precipitate; silver nitrate, a white or pale yellow precipitate soluble in aq. ammonia; and auric chloride gives a precipitate only after standing a long time. Sodium salts give a flocculent precipitate when added to a soln. of potassium antimonate. Soln. of the metantimonate prepared in the cold give a flocculent precipitate with sodium acetate; if the soln. has been boiled and cooled before adding the acetate, a crystalline precipitate appears. A. Bartoli and G. Papisogli electrolyzed a soln. of potassium metantimonate with electrodes of wood-charcoal or gas-carbon, and found much gas evolved at the cathode, and very little at the anode. They obtained a black deposit and a liquid which when filtered and concentrated on the water-bath, and treated with hydrochloric acid, gives a black precipitate which, after washing and drying at 100° , (i) contains carbon, oxygen, hydrogen, and antimony; (ii) it dissolves in water and in alkaline hydrates, forming deep black soln., from which it is completely precipitated by mineral acids; (iii) it dissolves with rise of temp. in aq. potassium hypochlorite, forming mellic acid and other benzocarboxylic acids, together with potassium antimonate. This substance being analogous in modes of formation and in properties to mellogen, was called *stibiomellogen*. The graphite anode was much disintegrated; and the product corresponding with stibiomellogen was called *stibiographitic acid*. E. F. Smith and D. L. Wallace, and S. C. Schmucker found that in the presence of alkali tartrates, antimony is not precipitated by electrolysis, and may thus be separated from copper, cadmium, tin, bismuth, and mercury. L. Kahlenberg and W. J. Trautmann observed a strong reaction when the pyroantimonate is heated with silicon.

The alchemists obtained what they called *antimonium diaphoreticum ablutum*, *cerussa antimonii*, or *calx antimonii alba* by mixing antimony or antimony sulphide with an excess of nitre, projecting the mixture in small portions at a time into a red-hot crucible, and igniting the mass for some time after the deflagration has ceased. The mass is extracted with water to remove soluble impurities. The residue is boiled with 3 or 4 parts of water, and the soln. of metantimonate is treated with carbon dioxide; this yields a white precipitate with the composition $2K_2O \cdot 3Sb_2O_5 \cdot nH_2O$, usually represented $K_2H_3Sb_3O_{10} \cdot nH_2O$ —**potassium trihydrotriantimonate**, or $K_2HSb_3O_9 \cdot 6 \cdot 11H_2O$. The salt was so prepared by J. J. Berzelius, E. Frémy, O. Figuier, G. von Knorre and P. Olschewsky, and A. E. Delacroix. Instead of using carbon dioxide, J. A. Buchner recommended adding sufficient acetic acid to give the soln. a feeble acidic reaction; and L. Heffter, adding a soln. of potassium sulphate to one of potassium metantimonate. J. A. Buchner boiled hydrated antimony pentoxide with a soln. of potassium hydroxide; evaporated the soln. to dryness; heated the product to redness; and extracted the cold mass with boiling water. There remained undissolved a small yield of this salt. C. F. Rammelsberg prepared the salt by treating antimony pentasulphide with conc. potash-lye, when dioxydisulphantimonate passes into soln. Analyses of the air-dried, white powder by L. Heffter, and G. von Knorre and P. Olschewsky show between 19.05 and 24.09 per cent. of water; and for that dried at 100° , $K_2H_3Sb_3O_{10} \cdot 2H_2O$. The percentage losses of water at higher temp. are:

	125°	150°	175°	200°	225°	250°	280°	350°	Red-heat.
Loss	1.02	2.13	3.18	4.00	4.81	5.46	6.30	6.47	9.80

L. Heffter found that the powder reddens moist litmus-paper. According to G. von Knorre and P. Olschewsky, it is sparingly soluble in cold and hot water; and when heated with water in a sealed tube, at 180° , much potassium antimonate passes into soln. The **sodium trihydrotriantimonate**, $\text{Na}_2\text{H}_3\text{Sb}_3\text{O}_{10}\cdot 2\cdot 78\text{H}_2\text{O}$, can also be represented $\text{Na}_2\text{HSb}_3\text{O}_9\cdot 3\cdot 78\text{H}_2\text{O}$. The sat. soln. of the potassium salt at 20° contains $2\cdot 69 \times 10^{-3}$ gram-atoms per litre; while with the sodium salt there are $3\cdot 8 \times 10^{-5}$ gram-atoms per litre. If the formula is $\text{R}_2\text{HSb}_3\text{O}_9\cdot n\text{H}_2\text{O}$, the solubility of the potassium salt is $0\cdot 9 \times 10^{-3}$ mols per litre, and that of the sodium salt, $1\cdot 3 \times 10^{-5}$ mols per litre. G. Jander and W. Brüll found the diffusion coefficient for the two salts is equally great and amounts to 0.55 at $11\cdot 8^{\circ}$; the acid residue, in strongly acid soln., has a smaller diffusion coeff. due, it is assumed, to polymerization resulting in the formation of alkali tetrantimonate, $4\text{Sb}_3\text{O}_{10}'''' + 2\text{H}^+ = 3\text{Sb}_4\text{O}_3'''' + \text{H}_2\text{O}$. The conc. of the H^+ -ions in the aq. soln. of the potassium salt in 0.001*N*-soln. is $10^{-3\cdot 63}$; and the three hydrogen-ions are 69 per cent. ionized, so that it is a very strong acid—the dissociation constant is 0.00053. The *antimony oxide* used in glass painting and for enamels is really a potassium antimonate.

W. Hampe reported **copper orthoantimonate**, $\text{Cu}_3(\text{SbO}_4)_2$, to be formed as a dark red mass by heating a mixture of copper oxide and an excess of antimony trioxide to 1100° in an atm. of carbon dioxide. It is slowly soluble in hydrochloric acid; and is decomposed by nitric acid, and by heating in an atm. of carbon dioxide. J. J. Berzelius obtained a pale green crystalline powder by the action of a soln. of potassium metantimonate on one of copper sulphate; and C. L. Allen obtained a similar product—**copper metantimonate**, $\text{Cu}(\text{SbO}_3)_2\cdot 5\text{H}_2\text{O}$, by using eq. quantities of these two salts. F. Ebel used a somewhat similar process. J. B. Senderens treated antimony pentoxide with an aq. soln. of copper acetate, washed the product with cold water, and dried it in air. G. von Knorre and P. Olschewsky boiled antimony pentasulphide with potash-lye, precipitated the sulphur as cupric sulphide by the addition of copper hydroxide, and allowed the filtrate to stand for some time. Pale green crystals were deposited from the liquid. The above formula is based on the analyses of F. Ebel, and J. B. Senderens. J. B. Senderens found that it loses 3 mols. of water over conc. sulphuric acid, and the remainder at 300° , while at a red-heat it begins to decompose. C. L. Allen observed that at 100° , the salt loses a mol. of water; at 260° , 3 mols.; and at 360° , it is virtually freed from water and becomes yellowish-green. According to F. Ebel, the salt dried at 100° has 7.10 per cent. of water; at 125° , 5.45 per cent.; at 150° – 200° , 4.13 per cent.; and at 300° , 1.99 per cent. According to J. J. Berzelius, and C. L. Allen, when heated by a gas-blowpipe flame, dehydrated copper antimonate becomes incandescent, without losing weight. J. J. Berzelius said that the mass blackens when heated, but C. L. Allen attributed this to the presence of copper hydroxide, since the purified salt becomes pale greenish-grey. F. Ebel said that when melted with sodium carbonate and sulphur, the antimony is not completely removed by washing; nitric acid decomposes the salt incompletely; and it is completely soluble in hydrochloric acid provided it has been ignited. A. E. Delacroix obtained a basic salt approximating $5\text{CuO}\cdot 2\text{Sb}_2\text{O}_5\cdot 7\text{H}_2\text{O}$, by heating to 80° the green soln. of copper oxide, antimony pentoxide, and potash-lye; washing the precipitate with water, and drying at 100° . F. F. Beilstein and O. von Bläse obtained $3\text{CuO}\cdot 2\text{Sb}_2\text{O}_5\cdot 13\text{H}_2\text{O}$ as a pale green precipitate from a soln. of cupric sulphate and potassium antimonate. The more the product is washed the more basic the product. Both these substances are probably mixtures.

H. Schiff treated the precipitate, obtained by adding cupric sulphate to a soln. of potassium antimonate, with aq. ammonia, and found that it gradually passed into a pale blue granular powder of **copper tetramminopyroantimonate**, $\text{Cu}_2\text{Sb}_2\text{O}_7\cdot 4\text{NH}_3\cdot 4\text{H}_2\text{O}$, which was washed with aq. ammonia, and dried over conc. sulphuric acid. A. E. Delacroix crystallized a soln. of copper triantimonate in

aq. ammonia, and found that after drying in air, the **copper triamminometantimonate** had the composition $\text{Cu}(\text{SbO}_3)_2 \cdot 3\text{NH}_3 \cdot 9\text{H}_2\text{O}$. R. F. Weinland and H. Schmid found that when copper pentamminometachlorantimonate is allowed to stand in its mother-liquor, the triamminometantimonate separates out in hexagonal prisms or plates. F. Raschig found that a soln. of copper tetramminoxide and ammonium metantimonate furnishes dark blue crystals of **ammonium copper ammoniohydroxyantimonate**, $2\text{NH}_4\text{SbO}_3 \cdot \text{Cu}(\text{ONH}_4)(\text{OH}) \cdot 4\text{H}_2\text{O}$.

J. J. Berzelius obtained a white precipitate of **silver metantimonate**, AgSbO_3 , by adding silver nitrate to a soln. of alkali metantimonate; and F. Ebel obtained the same salt by using an excess of silver nitrate. The precipitate obtained with soln. at 80° – 86° had $2.5\text{H}_2\text{O}$; and when dried at 100° , $0.625\text{H}_2\text{O}$; at 125° , $0.5\text{H}_2\text{O}$; and at 150° – 200° , $0.3\text{H}_2\text{O}$. F. F. Beilstein and O. von Bläse obtained the trihydrate by this process. It is completely soluble in aq. ammonia when freshly precipitated, and only imperfectly soluble after drying. Gaseous ammonia reacts with the air-dried salt producing **silver diamminometantimonate**, $\text{AgSbO}_3 \cdot 2\text{NH}_3 \cdot 2\text{H}_2\text{O}$. T. Thomson found that a soln. of antimony pentoxide in alkali-lye gives with auric chloride a black precipitate thought to be **aurous antimonate**.

J. J. Berzelius precipitated a soln. of potassium metantimonate by the addition of a calcium salt. The mineral *romeite* has been already described as a calcium antimonite; the mineral *schneebergite* obtained by A. Brezina from Schneeberg, Tyrol, occurs in honey-yellow, octahedral crystals with a dodecahedral cleavage. This agrees with W. T. Schaller, who found that *schneebergite* is cubic in its geometrical symmetry. The mineral is probably dimorphous where the high temp. form is cubic. A. Brezina gave 4.1 for the sp. gr.; and W. T. Schaller, 5.41. The hardness is 6.5. C. Hlawatsch gave 2.10 for the refractive index of *schneebergite*, and W. T. Schaller, 2.09. The crystals may have an anomalous birefringence, but they become optically isotropic when heated. A. Brezina found that *schneebergite* is insoluble in acids; and is slowly decomposed by molten alkali carbonate. The paragenesis of *schneebergite* was discussed by R. Köchlin, and W. T. Schaller. *Schneebergite* is sometimes considered to be a calcium metantimonate admixed with traces of iron, copper, bismuth, magnesium, zinc, and sulphate. W. T. Schaller's analysis agrees with the empirical formula CaSbO_3 . He regards the mineral as a mixture of calcium pyroantimonite, $\text{Ca}_2\text{Sb}_2\text{O}_5$, and calcium pyroantimonate, $\text{Ca}_2\text{Sb}_3\text{O}_7$, because the contained antimony exists in two states of oxidation, and "to regard trivalent antimony as a base to be added on to the calcium throws too heavy a burden on quadrivalent antimony, which must then serve as an acid for an overwhelming base." According to P. Groth, *schneebergite* is probably identical with atopite—*vide infra*. The samples of *schneebergite* analyzed by A. von Elterlein, and A. S. Eakle and W. Muthmann were probably lime-iron garnet. J. B. Senderens obtained what may be **calcium metantimonate**, $\text{Ca}(\text{SbO}_3)_2 \cdot 6\text{H}_2\text{O}$, or **calcium dihydroxyantimonate**, $\text{Ca}(\text{H}_2\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, by treating an aq. soln. of antimony pentoxide with calcium acetate. The white precipitate loses 4 mols. of water over conc. sulphuric acid, and the residue at 100° is stable. All the water is expelled at a higher temp., and the residue is stable at a red-heat. L. Heffter treated a soln. of sodium dihydropyroantimonate with calcium chloride and obtained a white, flocculent precipitate with the composition $\text{Ca}(\text{SbO}_3)_2 \cdot 5\text{H}_2\text{O}$. It lost 6.17 per cent. of its water at 100° , 11.4 per cent. at 200° , 14.7 per cent. at 300° , and 18.6 per cent. at dull redness. He obtained **strontium metantimonate**, $\text{Sr}(\text{SbO}_3)_2 \cdot 6\text{H}_2\text{O}$, in an analogous manner as a white, amorphous powder which lost 8.17 per cent. of water at 100° , 12.42 per cent. at 200° , 14.62 per cent. at 300° , and 19.81 per cent. at a dull red-heat. L. Heffter obtained **barium metantimonate**, $\text{Ba}(\text{SbO}_3)_2 \cdot 6\text{H}_2\text{O}$, in an analogous way, and the same salt was also prepared by J. J. Berzelius, and F. Ebel. If the precipitate is allowed to stand for a long time in contact with the mother-liquid at 0° , small needle-like crystals are formed. The precipitate dried over sulphuric acid contained $6\text{H}_2\text{O}$, and dried at 80° – 100° , $5\text{H}_2\text{O}$. The loss at 125° – 175° was 1.66 per cent.; at 225° – 250° , 3.07 per cent.;

at 300°, 5.36 per cent.; and at a red heat, 8.48 per cent. When calcined, the salt becomes calescent. It is sparingly soluble in water; dissolves in hydrochloric acid; and is not decomposed by carbon dioxide. H. Rose said that when the antimonates of the alkalis and alkaline earths are heated with ammonium chloride, the whole of the antimony is volatilized as chloride. The reaction is incomplete with the other metal chlorides. H. Rose, and O. Brunck found that when fused with potassium cyanide, antimony is produced. The yellow or resin-brown mineral **atopite**—from *ἀτοπιος*, unusual—occurs at Langban, Sweden. It was described by A. E. Nordenskjöld. The analysis corresponds with **calcium pyroantimonate**, $\text{Ca}_2\text{Sb}_2\text{O}_7$, or, according to P. Groth, with **sodium calcium pyroantimonate**, $\text{CaNa}_2\text{Sb}_2\text{O}_8$, or $(\text{Ca}, \text{Na}_2, \text{Mn}, \text{Fe})_2\text{Sb}_2\text{O}_7$. C. F. Rammelsberg gave $\text{Na}_4\text{Sb}_2\text{O}_7 \cdot 5(\text{Ca}, \text{Fe}, \text{Mn})_2\text{Sb}_2\text{O}_7$. W. T. Schaller showed that atopite is probably the same mineral species as romeite (*q.v.*). Atopite furnishes octahedral and dodecahedral crystals of sp. gr. 5.03, and hardness 5.5–6.0. H. Rose found that the average index of refraction for Na-light is 1.836.

F. Ebel reported **beryllium metantimonate**, $\text{Be}(\text{SbO}_3)_2 \cdot 6\text{H}_2\text{O}$, to be formed as a white powder by precipitating a boiling soln. of sodium dihydropyroantimonate, with an excess of beryllium sulphate. The air-dried product has $6\text{H}_2\text{O}$; when dried at 100°, $4\text{H}_2\text{O}$; and the percentage losses at higher temp. are 4.56 at 125°; 7.01 at 175°–225°; 7.71 at 250°; 10.56 at 300°; and 16.71 at a red-heat. It is somewhat soluble in hot water, and is readily dissolved by hot hydrochloric acid. M. Obajdin prepared **magnesium dihydroantimonate**, $\text{Mg}(\text{H}_2\text{SbO}_4)_2 \cdot 10\text{H}_2\text{O}$, by the addition of a magnesium salt to a soln. of dipotassium dihydropyroantimonate. According to the conc. of the soln., it is obtained as hexagonal or monoclinic crystals or in the amorphous form. From a soln. containing 1 per cent. of the pyroantimonate, both hexagonal and monoclinic crystals and a large quantity of the amorphous precipitate are deposited; from a soln. containing 0.35 per cent. of the pyroantimonate, monoclinic crystals are alone deposited; whilst a soln. containing 0.07 per cent. of the potassium pyroantimonate yields hexagonal crystals only. The composition of both hexagonal and monoclinic crystals is the same. The crystals lose $8\text{H}_2\text{O}$ if heated at 176°. When heated further, they lose $2\text{H}_2\text{O}$, and change their colour successively from colourless to pink, orange-yellow, yellowish-green, greyish-green, greyish-blue, and violet, a fact which is probably due to the formation of various polymerides. Finally, the crystals spontaneously incandesce and turn white, forming magnesium metantimonate, $\text{Mg}(\text{SbO}_3)_2$. The magnesium dihydrorthantimonate has a sp. gr. 2.57; it is insoluble in alcohol; and the solubility in water at 16° is 0.7075 grm. in 1000 grms. of soln. L. Heffter prepared **magnesium metantimonate**, $\text{Mg}(\text{SbO}_3)_2 \cdot 10\text{--}12\text{H}_2\text{O}$, by treating a hot soln. of sodium dihydropyroantimonate with magnesium salt. H. Goguel used potassium dihydropyroantimonate. F. Raschig, prepared this salt by treating ammonium metantimonate with a magnesium salt. H. Goguel argued from his observations on the dehydration at different temp. that the salt is *magnesium dihydroantimonate*, $\text{Mg}(\text{H}_2\text{SbO}_4)_2 \cdot 10\text{H}_2\text{O}$.

C. von Haushofer obtained the salt by adding a magnesium salt to a conc. soln. of potassium metantimonate; he added that the salt is dimorphous, furnishing hexagonal and monoclinic crystals. The hexagonal form is obtained by precipitating the salt at a temp. between 80° and 100°, or by cooling the soln. to 100°. He was unable to obtain the monoclinic form alone. G. Rose found the salt obtained by L. Heffter's process is hexagonal; while H. W. F. Wackenroder obtained the monoclinic form. H. Goguel attributed the behaviour of the monoclinic or rhombic crystals in polarized light to *maclés multiple*. The hexagonal crystals consist of six sectors, and the cross or hyperbolas produced in parallel polarized

light is a result of *la compensation de ces trois zones à leur contact*. The hexagonal crystals were stated by C. von Haushofer, and G. Rose to be isomorphous with the corresponding salts of zinc, cobalt, and nickel. L. Heffter said that the air-dried salt is dodecahydrated, and C. von Haushofer, decahydrated. At 100°, it loses 3H₂O. L. Heffter said that the loss at 100° is 24·82 per cent.; at 200°, 32·29 per cent.; at 300°, 33·39 per cent.; and at a red-heat, 36·55 per cent. without showing any calorescence. H. Rose found that the whole of the antimony cannot be driven off by heating a mixture of the salt with ammonium chloride.

G. Aminoff described a mineral from Langban, Sweden, which he named **swedenborgite**—after E. Swedenborg. The analysis corresponds with Na₂O·2Al₂O₃·Sb₂O₅, **sodium dialuminyl antimonate**, Na(AlO)₂SbO₄, analogous with nordenskjöldine, Ca(BO)₂SnO₄; or it can be regarded as an aluminate, NaSb(AlO₃)₂. The mineral may be colourless or wine-yellow; the hexagonal prisms have the axial ratio *a:c*=1:1·6309. The (0001)-cleavage is distinct. The hardness is 8. The mineral is uniaxial, and negative. The X-radiogram corresponds with an elementary parallelepiped with *a*=8·81 Å., and *c*=5·40. The indices of refraction are ω =1·7724, and ϵ =1·7700 for the Na-light. The dispersion is strong. B. Gossner suggested that swedenborgite is an intergrowth of two corundum-like networks of alumina and sodium metantimonate.

J. J. Berzelius, and L. Heffter treated a soln. of zinc sulphate with potassium metantimonate, allowed the liquid to stand a few hours, and obtained a crystalline mass of **zinc metantimonate**, Zn(SbO₃)₂·5H₂O. J. B. Senderens said that the *hexahydrate* is produced from a soln. of antimonious acid and zinc acetate, by allowing the white precipitate to dry in air; it passes into the *dihydrate* when dried over conc. sulphuric acid; and becomes anhydrous at 300°. F. Ebel obtained the *pentahydrate* by treating a boiling soln. of sodium dihydropyroantimonate with zinc sulphate, washing the precipitate, and drying it in air. At 100°, it loses 8·03 per cent. of water. The hydrate dried at 100° loses 2·41 per cent. of water at 125°; 4·49 per cent. at 150°–200°; 4·79 per cent. at 250°; 5·83 per cent. at 300°–350°; and 8·03 per cent. at a red-heat. J. B. Senderens said the salt decomposes at a red-heat. F. Ebel found that the salt is not insoluble in cold water and is fairly soluble in hot water. F. Ebel obtained **cadmium metantimonate**, Cd(SbO₃)₂·3½H₂O, by the action of a boiling soln. of sodium dihydropyroantimonate on an excess of a boiling soln. of a cadmium salt; J. B. Senderens regarded the salt as a *pentahydrate*; if produced at 35°, F. Ebel found the salt to be a *hexahydrate*. At 100°, the salt loses 8·66 per cent. of water, and the remainder at 125° loses 1·75 per cent. of water; at 150°–200°, 4·37 per cent., at 250°, 5·24 per cent.; at 300°–350°, 6·11 per cent.; and at a red-heat, 8·66 per cent. The salt is sparingly soluble in water; and soluble in hydrochloric acid.

J. J. Berzelius obtained an orange-yellow precipitate of **mercurous metantimonate** by adding mercurous nitrate to a soln. of potassium metantimonate; a similar precipitate of **mercuric metantimonate**, Hg(SbO₃)₂·*n*H₂O, is obtained with soln. of a mercuric salt and potassium metantimonate; while F. Ebel obtained only a yellow turbidity but no precipitate with sodium dihydropyroantimonate and an excess of mercuric chloride. According to J. J. Berzelius, when a mixture of antimony with 8 times its weight of mercuric oxide is heated, calorescence occurs, metallic mercury distils off, and mercuric antimonate is formed as a dark olive-green powder. It can be heated to redness without decomposition, but is decomposed at a higher temp. It is scarcely attacked by alkali-lye and by a number of acids; sulphuric acid acts on it very slowly, and hydrochloric acid dissolves very little. J. B. Senderens said that the *pentahydrate* is formed by treating a soln. of antimony pentoxide with mercuric acetate, and allowing the washed precipitate to dry for some months in air. The ochre-yellow product loses 3 mols. of water over conc. sulphuric acid; 4 mols. at 170°; and 5 mols. at 300°. It does not alter at a red-heat. F. F. Beilstein and O. von Bläse obtained the *hexahydrate* as a yellow flocculent precipitate by adding mercuric chloride to a soln. of

potassium antimonate. There is no calorescence at 100° when the salt loses its water.

F. Ebel made **aluminium orthantimonate**, $\text{AlSbO}_4 \cdot 4\frac{1}{2}\text{H}_2\text{O}$, by the action of a boiling soln. of sodium dihydropyroantimonate on a boiling soln. of potash-alum. The voluminous white powder when dried at 100°, contains 1.5 mols. of water, and with a rise of temp., the salt loses 2.21 per cent. at 125°; 4.75 at 150°–200°; 6.62 at 250°; 7.57 at 300°–350°; and 11.38 per cent. at a red-heat. The calcined salt is pale yellow. The hydrated salt is freely soluble in hot, dil. hydrochloric acid, but the calcined salt in incompletely soluble. F. F. Beilstein and O. von Bläse found that a conc. soln. of potassium metantimonate precipitates **aluminium metantimonate**, $\text{Al}(\text{SbO}_3)_2 \cdot 15\text{H}_2\text{O}$, when added to a soln. of potash- or ammonia-alum. When the precipitate is allowed to stand some days in contact with the mother-liquid, it becomes crystalline. It contains when dried at 100°, 7 mols. of water; at 150°, 4.5 mols.; at 200°, 3 mols. It shows a calorescence when ignited. F. F. Beilstein and O. von Bläse made **thallous metantimonate**, $\text{TlSbO}_3 \cdot 2\text{H}_2\text{O}$, by precipitation from a soln. of potassium metantimonate and thalious sulphate. The colourless, needle-like crystals are soluble in water when freshly precipitated, but insoluble when dried. The salt gradually loses its water above 150°, when it becomes lemon-yellow when cold, dark orange when hot.

O. Kulka³ prepared **zirconyl pyroantimonate**, $\text{ZrO}_2 \cdot \text{Sb}_2\text{O}_5 \cdot 7.5\text{H}_2\text{O}$, or $(\text{ZrO})_2\text{Sb}_2\text{O}_7 \cdot 7.5\text{H}_2\text{O}$, by treating a soln. of zirconium sulphate with potassium metantimonate; the precipitate is slimy and difficult to wash; the precipitate with potassium pyroantimonate is easy to wash with hot water. It is an amorphous, white powder; insoluble in water, soluble in hydrochloric acid. E. Lenssen made **stannous pyroantimonate**, $\text{Sn}_2\text{Sb}_2\text{O}_7$, by adding potassium antimonate to an excess of a soln. of stannous chloride acidified with acetic acid; washing the precipitate with cold water, and drying it in air. H. Schiff made **stannous metantimonate**, $\text{Sn}(\text{SbO}_3)_2 \cdot 2\text{H}_2\text{O}$, by digesting hydrated antimony pentoxide with a feebly acid soln. of stannous chloride at 60°–80° for 12–24 hrs. The brick-red product becomes yellowish-grey when dehydrated in a current of carbon dioxide; and when heated in air, it oxidizes, becoming pale yellow. It is attacked by acids and alkalis very slowly; most readily by conc. sulphuric acid. If hydrated antimony pentoxide be digested with a soln. of stannous chloride for 8–10 hrs. at 35°–40°, the product has the composition $\text{Sn}_2\text{Sb}_6\text{O}_{17} \cdot 4\text{H}_2\text{O}$, **stannous hexantimonate**; and with a 4 hrs. digestion at 30°–40°, stannous tetrantimonate, $\text{SnSb}_4\text{O}_{11}$. L. J. Thénard obtained **stannic antimonate**, by adding water to a soln. of the two oxides in hydrochloric acid; A. Levöl mixed the liquids obtained by treating antimony and tin each with an excess of hot nitric acid, and obtained a yellow powder with the evolution of nitrous fumes owing to the union of antimony nitrate with the stannic oxide.

J. J. Berzelius⁴ treated a soln. of potassium antimonate with lead nitrate and obtained a white curdy precipitate of **lead antimonate**; the same compound was produced by the action of hot nitric acid on an alloy of lead and antimony. The product turns yellow and gives off water when heated; charcoal reduces it to lead antimonide; it is insoluble in water; and is partially decomposed by nitric acid. The so-called *Naples' yellow*, or *gialliolino*, is produced by igniting, in a fireclay crucible for 2 hrs., a mixture of potassium antimonyl tartrate, with twice its weight of lead nitrate, and four times its weight of sodium chloride. The cold mass is lixiviated with water. If the temp. of fusion has been too high, the product remains as a hard mass when treated with water, otherwise it disintegrates to a fine powder. The lower the temp. of preparation, the lighter the tint of the product. The proportion of lead oxide, affects the shade; too much lead oxide dulls the tint. Commercial *Naples' yellow* is graded into about six shades of colour, ranging from a pale greenish yellow to a pale orange colour with a pink tinge. C. Brunner made it by mixing a pulverized alloy of equal parts of lead and antimony with three times its weight of potassium nitrate, and six times its weight of sodium chloride. There are many other recipes. The simplest mode of preparation is to roast an intimate

mixture of antimony oxide and lead oxide until it has acquired the desired tint. J. B. Guimet made it by similarly roasting a mixture of potassium antimonate with twice its weight of red-lead. When ground with oil, Naples' yellow is used as a paint; and the pigment is largely used for producing yellow enamels; and in glass painting. This subject was discussed by J. Stenhouse and G. Hallett. The colour is an old one. J. Percy said that he found lead and antimony in the yellow enamel of an enamelled brick from the Kasr ruins of Babylon, and inferred that the colour was therefore due to lead antimonate. In 1548, C. Piccolpassi gave directions for making the colour; it was also described by G. Passeri, A. D. Fougereux de Bondaroy, and J. J. le F. de la Lande in the eighteenth century. The commercial product varies in composition and tint. Some varieties fuse at a red-heat, others require 3 or 4 times their weight of lead flux before fusion. Some varieties contain basic lead chromate, or ochre. Hydrochloric acid or nitric acid slowly acts on Naples' yellow, forming a colourless soln.

Lead antimonates occur in nature. For example, there is the *Bleiniere* of D. L. G. Karsten, altered to *bleinierite* by J. Nicol. Probably the same ore, contaminated with galena, was called by E. F. Glocker, *stibiogalenite*; and by M. Adam, *pfaffite*—after C. H. Pfaff. It is now generally called **bindheimite**—after J. J. Bindheim. The ore has been found at Nerchinok, Siberia; Endellion, Cornwall; Arkansas, Nevada, etc. It is a product of the decomposition of other antimonial ores. E. V. Shannon showed that it is of widespread occurrence. It occurs in white, greyish, brownish, or yellowish masses, as earth, and as an incrustation. Analyses were reported by J. J. Bindheim, C. H. Pfaff, R. Hermann, C. Stamm, M. F. Heddle, C. F. Rammelsberg, M. Tscherne, L. Fletcher, W. G. Mixter, W. F. Hillebrand, F. P. Dunnington, and C. E. Wait. The results show that it is a hydrated **lead orthoantimonate**, $Pb_3(SbO_4)_2 \cdot 4H_2O$ —*vide infra*, monimolite. W. F. Hillebrand, P. Groth, and C. E. Wait gave $3PbO \cdot 2Sb_2O_5 \cdot 6H_2O$. M. F. Heddle gave $3PbO \cdot 2Sb_2O_5 \cdot 10H_2O$; some varieties approximate $Pb_2Sb_2O_7 \cdot 3H_2O$; and W. T. Schaller gave $Pb_2Sb_2O_7 \cdot nH_2O$. R. Hermann gave for the sp. gr. 4.60–4.76; M. F. Heddle, 4.707–5.05; W. F. Hillebrand, 5.01; F. Gonnard, 4.75; M. Tscherne, 5.6. The hardness is 4. H. Leroux found that in an oxidizing atm., lead oxide reacts with antimony trioxide, forming **lead pyroantimonate**, $Pb_2Sb_2O_7$, thus: $6PbO + 2Sb_2O_3 + O_2 = 2Pb + 2Pb_2Sb_2O_7$; and if heated in a closed vessel, $2PbO + Sb_2O_3 = 2Pb + Sb_2O_5$. When lead and the pyroantimonate are heated together: $2Pb + Pb_2Sb_2O_7 = 4PbO + Sb_2O_3$. In the oxidation of the mixed metals, antimony oxidizes first; and the lead oxide, when formed, serves as a carrier of oxygen oxidizing more antimony as it mixes with the salt.

F. F. Beilstein and O. von Bläse treated potassium metantimonate with lead acetate, and after washing the product by decantation, and drying in air, they obtained colourless lead oxytetrametantimonate, $PbO \cdot 2Pb(SbO_3)_2 \cdot 11H_2O$. It retains $4H_2O$ at 100° ; $2H_2O$ at 150° ; H_2O at 250° ; and none at a red-heat. It shows a calorescence when ignited, and is then yellow. J. B. Senderens made lead metantimonate, $Pb(SbO_3)_2 \cdot 9H_2O$, as a white precipitate, by treating metantimonic acid with lead acetate. It becomes the *dihydrate* when kept a few months over sulphuric acid. F. Ebel obtained the *hexahydrate* by treating potassium metantimonate with lead nitrate; at 25° it becomes the *pentahydrate*; at 100° , the *hemitrihydrate*; and at 125° , the *monohydrate*. He obtained the *tetrahydrate* by mixing a boiling soln. of lead nitrate and sodium dihydropyroantimonate. The salt is somewhat soluble in hot water.

A variety of bindheimite found by A. Raimondi in Corongo, Peru, was called *coronguite*. It is a greyish-yellow earth with an analysis Sb_2O_5 , 58.97; PbO , 21.48; Ag_2O , 7.82; Fe_2O_3 , 0.52; and H_2O , 11.21, so that if homogeneous, it is silver lead antimonate. Its sp. gr. is 5.05; and its hardness, 2.5–3.0. L. J. Igelström reported a mineral from Pajsberg, Sweden, which he called **monimolite**—from *μόνιμος*, permanent, stable. Analyses by L. J. Igelström, and G. Flink indicate two varieties: one, free from calcium, corresponds with lead orthoanti-

monate, $Pb_3(SbO_4)_2$, or, as P. Groth represented it, $(Pb,Fe,Mn)_3(SbO_4)_2$; and the other, containing calcium, corresponds with $(Pb,Ca)_3(SbO_4)_2$, or **calcium lead orthoantimonate**. The colour ranges from yellow to brown, to black. It occurs massive, as an incrustation, and in octahedral and cubic crystals which have an indistinct octahedral cleavage. A. E. Nordenskjöld considered the crystals to be tetragonal with the axial ratio $a:c=1:0.9950$. The sp. gr. of the calciferous variety is 6.579, and the hardness 6; and the sp. gr. of the other variety is 7.287, and the hardness 5. The mineral is insoluble in strong acids, and is not decomposed by fusion with alkali carbonates and hydroxides—excepting in the case of the variety free from calcium. The mineral is reduced by hydrogen at a red-heat, and the product is soluble in acids.

For *tellurium antimonates*, *vide* antimony tellurates. F. F. Beilstein and O. von Bläse⁵ prepared **chromium metantimonate**, $Cr(SbO_3)_3 \cdot 14H_2O$, as a bluish-green precipitate, by the action of chrome-alum on a soln. of potassium metantimonate. The precipitate should be rapidly washed. When ignited, the salt becomes grey without showing any calorescence.

According to O. W. Gibbs, **ammonium antimonatomolybdate**, $5(NH_4)_2O \cdot 4Sb_2O_5 \cdot 7MoO_3 \cdot 12H_2O$, is a representative of the antimonatomolybdates. The **alkali antimonatomolybdates** are formed by the action of freshly precipitated, hydrated antimony pentoxide on acid molybdates; by the action of molybdic acid on antimonates; and by gradually adding a hydrochloric acid soln. of antimony pentachloride to a basic molybdate. The ammonium salt crystallizes from a boiling soln. of ammonium molybdate, sat. with hydrated antimony pentoxide. The colourless crystals are freely soluble in hot water; the salt decomposes when the aq. soln. is evaporated. The aq. soln. gives a canary-yellow precipitate with manganese sulphate.

O. W. Gibbs obtained **potassium antimonatotungstate**, $3K_2O \cdot 2Sb_2O_5 \cdot 6WO_5 \cdot 12\frac{1}{2}H_2O$, by boiling a soln. of potassium dihydropyroantimonate for a long time with potassium tungstate. The colourless crystals are sparingly soluble in water. The alkali salt is also obtained by oxidizing the antimonitotungstate, and by the action of tungstic acid on an antimonate. According to A. L. Hallopeau, when an excess of antimonic acid is boiled for several hours with a soln. of potassium paratungstate, it dissolves, and, on filtering, crystals of potassium antimonatotungstate are deposited having the composition $2WO_3 \cdot 3KSbO_3 \cdot 8H_2O$, and differing from the antimonatotungstate described by O. W. Gibbs. This compound forms small botryoidal masses, composed of a very large number of prismatic, twinned crystals, which are highly refractive and act powerfully on polarized light. They are permanent in the air, lose $6H_2O$ at 100° , and, on ignition, yield potassium tungstate, tungstic acid, and antimonic acid. When fused with an excess of sodium carbonate, carbon dioxide is evolved and sodium tungstate, potassium tungstate, and sodium antimonate are formed. On treating the fused mass with water, a crystalline sodium metantimonate is left. Potassium antimonatotungstate is decomposed by hydrochloric, sulphuric, and nitric acids with the formation of tungstic acid; and by hydrogen sulphide, with the precipitation of antimony and tungsten. When well-washed silver antimonatotungstate is treated with the theoretical quantity of hydrochloric acid, and the soln. evaporated in vacuo, a transparent, vitreous residue of **antimonatotungstic acid**, $4WO_3 \cdot 3Sb_2O_5 \cdot 11H_2O$, remains, which does not lose weight at 100° . O. W. Gibbs obtained **copper antimonatotungstate** by the action of copper sulphate on a soln. of the potassium salt; O. W. Gibbs, and A. L. Hallopeau, **silver antimonatotungstate** by the action of silver nitrate; and O. W. Gibbs obtained **barium antimonatotungstate** by the action of barium chloride; and **mercurous antimonatotungstate**, by the action of mercurous nitrate.

C. F. Rammelsberg obtained **uranyl antimonate**, $UO_2 \cdot 1.22Sb_2O_5 \cdot 6.4H_2O$, by treating a hydrochloric acid soln. of uranium tetrachloride with an excess of potassium metantimonate. The green gelatinous precipitate becomes yellowish-

brown when calcined with nitric acid, there is a separation of antimony pentoxide and the formation of uranyl nitrate; potash-lye precipitates uranium dioxide.

According to J. F. L. Mérimée, when a mixture of bismuth with 8 times its weight of antimony sulphide, and 21 times its weight of nitre, is projected into a heated crucible in small portions at a time, then fused, powdered, washed, and dried, bismuth antimonate is produced. When one part of this is mixed with 8 parts of ammonium chloride, and 128 parts of litharge, and fused, it furnishes a yellow glass. The tint depends on the time and temp. The product is used as a pigment—*Mérimée's yellow*. W. Hampe obtained **bismuth metantimonate**, $\text{Bi}(\text{SbO}_3)_3$, as a residue when copper containing these two elements is dissolved in nitric acid. A. Cavazzi made **bismuth orthoantimonate**, $\text{BiSbO}_4 \cdot \text{H}_2\text{O}$, or **bismuthyl metantimonate**, $(\text{BiO})\text{SbO}_3 \cdot \text{H}_2\text{O}$, as a white, amorphous precipitate by adding a conc. soln. of potassium metantimonate to a dil. soln. of ammonium bismuth citrate. The precipitate is washed with boiling water. The product is insoluble in water; soluble in hydrochloric acid; and fusible only at a high temp. It is not decomposed by boiling water; and it becomes yellow when heated. If the preparation is conducted in the presence of an excess of ammonia, **bismuthyl orthoantimonate**, $(\text{BiO})_3\text{SbO}_4 \cdot \text{H}_2\text{O}$, is produced as a gelatinous precipitate, insoluble in water, and soluble in hydrochloric acid. He obtained evidence of the possible existence of *potassium bismuthyl metantimonate*, $\text{K}(\text{BiO})(\text{SbO}_3)_2$, in the unwashed precipitate of bismuthyl metantimonate, *vide stibiotantalite*.

J. J. Berzelius,⁶ and F. F. Beilstein and O. von Bläse prepared **manganous metantimonate**, $\text{Mn}(\text{SbO}_3)_2 \cdot n\text{H}_2\text{O}$, by the action of manganous sulphate on a soln. of potassium metantimonate; F. Ebel, by the action of manganous sulphate on a soln. of sodium dihydropyroantimonate; and J. B. Senderens, by the action of manganous acetate on an aq. soln. of antimony pentoxide. Analyses of the white amorphous powder by F. F. Beilstein and O. von Bläse corresponded with the *heptahydrate*; J. B. Senderens, with the *hexahydrate*; and F. Ebel, with the *pentahydrate*. The salt dried at 100° is the *dihydrate*, and F. Ebel found that the loss when the salt is heated to 125° is 2.63 per cent.; to 150° – 200° , 5.49 per cent.; to 250° , 5.82 per cent.; to 300° – 350° , 6.15 per cent.; and at a red-heat, 8.61 per cent. F. Ebel said that the action of heat on the salt supports the hypothesis that it is a metantimonate. J. J. Berzelius said that the salt is sparingly soluble in water; and when ignited it turns grey, but at a higher temp. becomes white without exhibiting any glow; after this, acids do not separate manganous oxide. When exposed to air, the salt becomes reddish-grey. A steel-blue mineral found by L. J. Igelström at Oerebro, Sweden, was named **basilite**—after Basil Valentine. According to C. F. Rammelsberg, the analyses correspond with **manganic antimonate**, $11(\text{Mn}_2\text{O}_3, \text{Fe}_2\text{O}_3) \cdot \text{Sb}_2\text{O}_5 \cdot 21\text{H}_2\text{O}$; P. Groth represented it by $(\text{Mn}_3\text{O}_4)_4 \cdot \text{Sb}_2\text{O}_5 \cdot 7\text{Mn}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$. It dissolves in warm hydrochloric acid with the evolution of chlorine. L. J. Igelström described two **manganese oxyantimonates**: black *manganostibiite*, $10\text{MnO} \cdot \text{Sb}_2\text{O}_5$, from Nordmark, Sweden; and black *hæmatostibiite* or *hematostibiite*, $8\text{MnO} \cdot \text{Sb}_2\text{O}_5$, or $9\text{MnO} \cdot \text{Sb}_2\text{O}_5$, from Oerebro, Sweden. The two minerals are optically negative, and the optic axial angle is small. E. S. Larsen gave for the indices of refraction of monoclinic manganostibiite $\alpha = \beta = 1.92$, and $\gamma = 1.96$; and said that the optical character is positive. Some arsenic may replace the antimony.

J. J. Berzelius reported **ferrous metantimonate** to be formed by the action of potassium antimonate on a ferrous salt. The white powder becomes yellowish-grey on drying, and at a red-heat gives off water, and becomes red. It is slightly soluble in water. This salt was also prepared by J. B. Senderens, and F. Ebel. According to F. F. Beilstein and O. von Bläse, the salt does not glow when ignited. E. Hussak and G. T. Prior described greenish-yellow, microcrystalline aggregates of a mineral from Tripuhy, Mines Geraco, which they called *tripuhyite*. Its sp. gr. is 5.82; and the index of refraction and birefringence are high. E. S. Larsen gave $\alpha = 2.19$, $\beta = 2.20$, and $\gamma = 2.33$. The analyses correspond with **ferrous pyroanti-**

monate, $\text{Fe}_2\text{Sb}_2\text{O}_7$. L. J. Igelström described black, monoclinic crystals of a weakly magnetic mineral from Oerebro, Sweden; they called it *ferrostibian*. Its hardness is 4. The analysis is Sb_2O_5 , 11.80; FeO , 22.60; MnO , 46.97; MgO , CaO , 2.14; H_2O , 10.34; SiO_2 , 2.24. It is therefore a **manganese ferrous antimonate**. Similar remarks apply to *stibiatile* from the same locality. It occurs in black prisms, presumably monoclinic. It is not magnetic. The hardness is 5.0–5.5. The analyses is Sb_2O_5 , 30; Mn_2O_3 , 44; and FeO , 26. The **ferrous pentametitanodimetantimonate**, $\text{Fe}(\text{SbO}_3)_2 \cdot 5\text{FeTiO}_3$, or $3\text{FeTiO}_5 \cdot \text{Fe}_3(\text{SbO}_4)_2$, named *derbylite*—after O. A. Derby—is a brownish-black mineral from Ouro Preto, Brazil. It was described by E. Hussak and G. T. Prior. The axial ratios of the rhombic crystals are $a : b : c = 0.9661 : 0.5502$; the sp. gr. is 4.5; and its hardness, 5—*vide* *derbylite*, and *mauzeliite*. G. Flink described honey-yellow, cubic crystals of a mineral from Langban, Stockholm; he called the mineral **weslienite**—after J. G. H. Weslien. Its analysis corresponds with **sodium calcium ferrous tetrantimonate**, $\text{Na}_2\text{O} \cdot \text{FeO} \cdot 3\text{CaO} \cdot 2\text{Sb}_2\text{O}_5$, or $5\text{RO} \cdot 2\text{Sb}_2\text{O}_5$. The crystals are optically anomalous; the sp. gr. is 4.967; and the hardness, 6.5. The corresponding **ferric metantimonate** was found by J. J. Berzelius to be light yellow. A. Lacroix obtained a lemon-yellow, compact or earthy mineral from Constantine, Algeria. It was named *flajolotite*—after M. Flajolot. The analysis agrees with **ferric orthoantimonate**, $\text{FeSbO}_4 \cdot \frac{3}{4}\text{H}_2\text{O}$. J. J. Berzelius obtained **cobalt metantimonate**, $\text{Co}(\text{SbO}_3)_3 \cdot n\text{H}_2\text{O}$, as a rose-coloured, crystalline powder, from a soln. of a cobalt salt and of potassium metantimonate; L. Heffter, from boiling a soln. of sodium antimonate and cobalt sulphate; F. Ebel, from boiling soln. of sodium dihydropyroantimonate and cobalt nitrate; and J. B. Senderens, from soln. of cobalt acetate and hydrated antimony pentoxide. F. Ebel found that the microscopic, monoclinic crystals are *dodecahydrated* when dried in air; the crystals precipitated from the boiling soln. are *hexahydrated*. J. B. Senderens' crystals were *pentahydrated*, and when dried over sulphuric acid, *dihydrated*. F. Ebel said that when dried at 100° , the crystals are *hemipentahydrated*; and when heated to 120° – 175° , have $2\text{H}_2\text{O}$; and at 225° , $1\frac{3}{4}\text{H}_2\text{O}$. He therefore argued that no constitutional water is present, and the salt is the metantimonate. J. J. Berzelius found that the crystals become violet-blue when heated, and blackish-grey when the water is all removed. The salt glows vividly when ignited, and appears reddish-white when cold. It is slightly soluble in water. H. Goguel inferred from the loss of water on ignition that the hexagonal, or pseudohexagonal, crystals, obtained from boiling soln. of cobalt chloride and potassium dihydropyroantimonate, are really **cobalt dihydroantimonate**, $\text{Co}(\text{H}_2\text{SbO}_4)_2 \cdot 10\text{H}_2\text{O}$. J. J. Berzelius prepared **nickel metantimonate**, $\text{Ni}(\text{SbO}_3)_2 \cdot n\text{H}_2\text{O}$, as a greenish-white, insoluble precipitate by the action of nickel salt on a soln. of potassium metantimonate. L. Heffter obtained the *hexahydrate* by precipitation from boiling soln. of sodium metantimonate and nickel sulphate. When ignited it glows vividly and loses all its water. The *dodecahydrate* separates in crystals slowly from the mother-liquid of the preceding operation. The crystals lose 22.96 per cent. of water at 100° ; 27.91 per cent. at 200° ; 31.49 per cent. at 300° ; and 34.9 per cent. at a red-heat. H. Goguel inferred that the hexagonal plates, obtained by the action of boiling soln. of nickel chloride and potassium dihydropyroantimonate, are really **nickel dihydroantimonate**, $\text{Ni}(\text{H}_2\text{SbO}_4)_2 \cdot 10\text{H}_2\text{O}$. The salt glows when ignited.

§ 15. Antimony Trifluoride

In 1824, J. J. Berzelius¹ first prepared **antimony trifluoride**, SbF₃, by crystallization from a soln. of antimony trioxide in an excess of hydrofluoric acid. The soln. is concentrated on a water-bath, and cooled. The crystals are separated from the mother-liquor, and dried between bibulous paper. F. A. Flückiger, and A. Guntz used this process. The product is preserved in bottles of guttapercha, or platinum. T. Swarts sublimed the crystals in a platinum vessel. F. A. Flückiger could not prepare the trifluoride by the action of hydrofluoric acid on antimony, or of a mixture of calcium fluoride and sulphuric acid on antimony or antimony trioxide. J. B. A. Dumas, however, made the trifluoride by distillation from a mixture of powdered antimony and mercuric fluoride. A. Rosenheim and H. Grünbaum found that the trifluoride prepared from antimony trioxide and hydrofluoric acid, is best stored in white celluloid vessels. Salts containing the trifluoride can be used as mordants. C. and H. Sunder mixed the hydrofluoric acid soln. of antimony trioxide with 3 mols of anhydrous sodium sulphate per mol of trifluoride and dried the resulting white crystalline mass.

According to F. A. Flückiger, antimony trifluoride obtained by the slow evaporation of the soln. at 79°–90° appears in colourless, transparent, rhombic plates; and when obtained by rapid evaporation, it appears in small prisms or scales. O. Ruff and W. Plato gave 4.379 for the sp. gr. at 20.9°; and W. Biltz and E. Rahlfs gave 4.385 at 25°/4°, and for the mol. vol., 40.78. The trifluoride was found by J. B. A. Dumas to volatilize more easily than sulphuric acid; and T. Swarts said that the salt is readily sublimed. T. Carnelley gave 292° ± 8° for the b.p. A. Guntz found the heat of formation to be Sb_{solid} + 3F = SbF_{3solid} + 144.3 Cals.; H. von Wartenberg gave for the molar heat of formation, 210.6 Cals. A. Guntz found that the heat of soln. of a mol of rhombic antimony trioxide in hydrofluoric acid is 19 Cals.; and of the octahedral trioxide, 20.2 Cals. The heat of soln. of a mol. of the trifluoride in 58 mols of water is –1.16 Cals., and in 407 mols of water, –2.0 Cals. The eq. electrical conductivity, λ, for soln. containing one-third of a mol in *v* litres was found by H. Grünbaum to be at 0°, and at 25°:

<i>v</i>	8	16	32	64	256	512	1024
λ	20.31	25.0	32.0	42.5	58.6	82.8	115.8
λ	25.84	33.20	43.14	52.74	74.14	105.4	146.2
λHF _{25°}	35.8	44.3	59.5	76.6	104.7	138.0	177.0

The great increase in the conductivity with increasing dilution is supposed to be conditioned by hydrolysis and not by the ionization of the trifluoride. This is

confirmed by the eq. conductivity of that acid included in the above table. The electrical conductivities of mixtures of antimony trifluoride with various salts—potassium fluoride, nitrate, sulphate, oxalate, hydroxalate, tartrate, and antimonioxalate, and ammonium oxalate—are often smaller than the values calculated by the mixture rule. This shows that complex salts are formed. Unlike the other three halides, antimony trifluoride is not dissolved by electrolytic antimony deposited from trifluoride soln.—*vide supra*, explosive antimony.

F. A. Flückiger found that antimony trifluoride tastes acid, and later is styptic; it does not form in air; but in the presence of air it cannot be volatilized without some decomposition—leaving a residue of antimony trioxide. The trifluoride is freely soluble in water, and the soln. can be diluted without appreciable hydrolysis. H. Grünbaum found that 100 grms. of water at 0° dissolve 384.7 grms. of the trifluoride; at 20°, 444.7 grms.; at 22.5°, 452.8 grms.; at 25°, 492.4 grms.; and at 30°, 563.6 grms. The effect of various additions on the solubility—expressed in grams of trifluoride per 100 grms. of the given soln. at 0°—is indicated in Table II.

TABLE II.—THE SOLUBILITY OF ANTIMONY TRIFLUORIDE IN SALT SOLUTIONS.

Solution.	Normality of the dissolved salt.				
	2N-	N-	$\frac{1}{2}$ N-	$\frac{1}{4}$ N-	$\frac{1}{8}$ N-
Hydrofluoric acid . . .	474.9	432.5	404.0	—	—
Potass. chloride . . .	—	461.8	448.3	431.9	407.3
Potass. bromide . . .	—	448.7	450.0	455.6	417.2
Potass. nitrate . . .	—	458.2	451.9	418.3	401.4
Potass. sulphate . . .	—	419.9	408.5	406.6	—
Potass. oxalate . . .	—	465.7	481.2	451.3	405.2
Amm. oxalate . . .	—	—	431.9	442.3	433.3
Potass. tartrate . . .	—	461.4	430.5	430.8	435.2

F. A. Flückiger found that the trifluoride is very hygroscopic, and rapidly deliquesces, and decomposes on exposure to air. The product no longer forms a clear soln. with water. According to P. Redenz, when antimony pentoxide is dissolved in hydrofluoric acid, and the soln. evaporated, a hygroscopic syrupy mass is formed which is not completely soluble in water, and which may be antimony tetrahydroheptafluoride, $\text{SbF}_3 \cdot 4\text{HF}$ —this statement is not well supported by evidence. The trifluoride form complex salts with antimony pentafluoride; and with antimony pentachloride. T. Swarts observed the formation of antimony difluotrichloride. According to O. Ruff and K. Albert, the aq. soln. of the trifluoride forms with bromine a colourless liquid; and in the solid state it absorbs bromine slowly, forming antimony tribromide; and similarly with chlorine. G. Gore found antimony fluoride to be insoluble in liquid ammonia. W. Biltz and E. Rahlfs found that **antimony hexamminotrifluoride**, $\text{SbF}_3 \cdot 6\text{NH}_3$, has a vap. press. of 13.0 mm. at -78.5° ; 46.5 mm. at -65° ; 72.0 mm. at -60° ; 108.0 mm. at -55° ; and 158.2 mm. at -50° ; and a heat of formation of 7.5 Cals.; **antimony tetramminotrifluoride**, $\text{SbF}_3 \cdot 4\text{NH}_3$, has a vap. press. of 52.7 mm. at -60° ; 79.5 mm. at -55° ; and 118.0 mm. at -50° , and a heat of formation of 7.6 Cals.; while **antimony triamminotrifluoride**, $\text{SbF}_2 \cdot 3\text{NH}_3$, has a sp. gr. of 2.324 at $25^\circ/4^\circ$; a mol. vol. of 98.92; a vap. press. of 42.0 mm. at -21° ; 85.0 mm. at -11° ; and 174 mm. at 0° ; and a heat of formation of 9.2 Cals. O. Ruff obtained **antimony diamminotrifluoride**, $\text{SbF}_3 \cdot 2\text{NH}_3$, by the action of liquid ammonia on antimony trifluoride. The yellow powder loses ammonia in contact with moist air, and is less stable than the product with antimony pentafluoride—*vide infra*. W. Biltz and E. Rahlfs found the sp. gr. to be 2.95 at $625^\circ/4^\circ$; the mol. vol. 79.00; the vap. press. at 17° , 3.0 mm.; at 25° , 13 mm.; at 34° , 24 mm.; and at 62° , 107.5 mm.; while the heat of formation is 12.0 Cals. They also found that **antimony monammino-**

trifluoride, $\text{SbF}_3 \cdot \text{NH}_3$, has a sp. gr. of 3.302 at $25^\circ/4^\circ$; a mol. vol. of 59.3; a vap. press. of 7.5 mm. at 61.5° ; 9.0 mm. at 64° ; 25.5 mm. at 80° ; 70.5 mm. at 100° ; and 114.5 at 110° ; and a heat of formation of 14.1 Cals. T. Swarts observed that with carbon tetrachloride, carbon fluotrichloride is produced; with chloroform, carbon hydrofluodichloride is formed; and with carbon hydrochlorodibromide, carbon hydrofluochlorodibromide is produced. O. Ruff and K. Albert represented the reaction with silicon-chloroform by the equation: $3\text{SiHCl}_3 + 4\text{SbF}_3 = 3\text{SiF}_4 + 2\text{Sb} + 2\text{SbCl}_3 + 3\text{HCl}$. F. A. Flückiger found that a soln. of auric chloride is reduced by antimony trifluoride.

Antimony trifluoride forms a number of complex salts with the metal fluorides. Complex salts were obtained by F. A. Flückiger from aq. soln. of the component salts; and from a soln. of antimony trioxide and the metal carbonate in hydrofluoric acid. A. von Rad and G. Hauser obtained them from a soln. of antimony trioxide and the metal hydrophosphate in hydrofluoric acid; O. Frölich, by the action of sulphuric acid on a mixture of antimony trisulphide, calcium fluoride, and alkali nitrate. F. A. Flückiger obtained **ammonium pentafluoantimonite**, $(\text{NH}_4)_2\text{SbF}_5$, by crystallization from a soln. of antimony trioxide and ammonium carbonate in an excess of hydrofluoric acid; and H. von Helmolt, from a soln. of antimony trioxide in one of ammonium fluoride. F. Ephraim also obtained this salt. F. A. Flückiger said that the colourless plates or prisms belong to the rhombic system; when heated, sublimation occurs with some decomposition. No ammonia is lost at 140° . After lying in air for some time, the crystals do not all dissolve in water, but the residue dissolves in dil. hydrofluoric acid. 100 parts of water dissolve 111.1 parts of salt with a considerable lowering of the temp. The aq. soln. reacts acid; attacks glass; and gives a precipitate with alcohol and ether. Sulphuric acid decomposes the salt. Glass containing vessels are attacked by the salt. A. von Rad and G. Hauser prepared **ammonium tridecafluotetrantimonite**, $\text{NH}_4\text{Sb}_4\text{F}_{13}$, or $\text{NH}_4\text{F} \cdot 4\text{SbF}_3$. The crystals are stable in dry air; 100 parts of water dissolve 150 parts of salt. H. Grünbaum tried to obtain f.p. curves of fused mixtures of the alkali fluorides and antimony trifluoride, but the volatility of the latter was too great to allow satisfactory measurements to be made. G. Stein prepared six-sided plates of **lithium tetrafluoantimonite**, LiSbF_4 ; F. A. Flückiger, colourless prisms of **lithium ennefluodiantimonite**, $\text{Li}_3\text{Sb}_2\text{F}_9$, which require over 20 times their weight of water for dissolution. F. Ephraim studied this salt. G. Stein prepared **lithium hydropentafluoantimonite**, LiSbHF_5 . G. Stein also made crystals of **sodium tetrafluoantimonite**, NaSbHF_4 ; 93 parts of which require 100 parts of cold water, while 166 parts require 100 parts of hot water for dissolution. A. von Rad and G. Hauser made **sodium tridecafluotetrantimonite**, $\text{NaSb}_4\text{F}_{13}$; and F. A. Flückiger rhombic prisms of **sodium hexafluoantimonite**, Na_3SbF_6 . 100 parts of cold water dissolve 7.1 parts of salt and hot water, 25 parts of salt. F. Ephraim studied this salt. A. von Rad and G. Hauser made **potassium tridecafluotetrantimonite**, $\text{KF} \cdot 4\text{SbF}_3$; F. A. Flückiger, **potassium tetrafluoantimonite**, KSbF_4 , 36.3 parts of which dissolve in 100 parts of water; and F. A. Flückiger, **potassium pentafluoantimonite**, K_2SbF_5 , with which 100 parts of water dissolve 11.1 parts of salt at ordinary temp., and 50 parts of salt when the water is boiling. F. Ephraim studied this salt. H. L. Wells and F. J. Metzger prepared **caesium defluoantimonite**, $\text{CsSb}_3\text{F}_{10}$, in transparent prisms; **caesium heptafluodiantimonite**, CsSb_2F_7 , in transparent needles; **caesium pentacosifluoheptantimonite**, $\text{Cs}_4\text{Sb}_7\text{F}_{25}$, in transparent plates; **caesium tetrafluoantimonite**, CsSbF_4 , in regular prisms; and **caesium pentafluoantimonite**, Cs_2SbF_5 , in rhombic prisms. According to F. A. Flückiger, these salts are generally free from water of crystallization; when dry they are usually stable in air; and dissolve in water easily without turbidity. The aq. soln. can be diluted without turbidity; it reacts acid; it attacks glass; and on evaporation furnishes the original salt. When triturated with sodium, a feeble detonation may occur; zinc and tin precipitate antimony from the soln., but not completely. The ammonium salt gives precipitates with soln. of salts of

lithium, the alkaline earths, mercury(ic), aluminium, tin(ic), lead, manganese, iron(ic), cobalt, and nickel; no change occurs with salts of copper, zinc, cadmium, tin(ous), and iron(ous). Hydrochloroplatinic acid gives a precipitate of potassium or ammonium chloroplatinate respectively with potassium or ammonium fluoantimonite; silver and mercurous salts give white precipitates, but reduction soon occurs; and auric chloride is reduced. Tannin gives a precipitate, but not so with salts of morphine, quinine, etc. F. Ephraim and L. Heymann prepared crystals of **thallous tetrafluoantimonite**, $\text{TlF}_3 \cdot \text{SbF}_3$; **thallous heptafluodiantimonite**, TlSb_2F_7 ; and **thallous decafluotriantimonite**, $\text{TlSb}_3\text{F}_{10}$.

Antimony trifluoride produces complex salts with alkali chlorides. G. Stein made **lithium chlorotrifluoantimonite**, $\text{LiCl} \cdot \text{SbF}_3$, from a soln. of the component salts; E. de Haën, **sodium chlorotrifluoantimonite**, $\text{NaCl} \cdot \text{SbF}_3$, freely soluble in water; and **potassium chlorotrifluoantimonite**, $\text{KCl} \cdot \text{SbF}_3$, in crystals. 100 parts of water at ordinary temp. dissolve 51 parts of the salt, and 300 parts at 100° . H. Grünbaum prepared **potassium trinitratotrifluoantimonite**, $3\text{KNO}_3 \cdot \text{SbF}_3$; and **potassium tetranitratoennefluotriantimonite**, $4\text{KNO}_3 \cdot 3\text{SbF}_3$. O. Frölich, and H. Grünbaum made a number of **oxalato fluoantimonites**.

Antimony trifluoride forms complex salts with several sulphates. E. de Haën, and F. Hasslacher obtained the complex salts from an aq. soln. of the component salts; F. Hasslacher, from a soln. of basic antimony sulphate in one of the given fluoride; T. Meyer, from a soln. of the component salts in hydrochloric acid; O. Frölich, by the action of sulphuric acid on a mixture of antimony trisulphide, calcium fluoride, and alkali nitrate; and A. von Rad, by the action of an excess of sodium hydrosulphate on the double fluoride. T. Meyer obtained **ammonium sulphatohexafluodiantimonite**, $(\text{NH}_4)_2\text{SO}_4 \cdot 2\text{SbF}_6$. F. Hasslacher, **ammonium trisulphatododecafluotetranitimonite**, $3(\text{NH}_4)_2\text{SO}_4 \cdot 4\text{SbF}_3$, in trigonal crystals which, according to A. Fock, have the axial ratio $a : c = 1 : 0.4413$; and E. de Haën, **ammonium sulphatotrifluoantimonite**, $(\text{NH}_4)_2\text{SO}_4 \cdot \text{SbF}_3$, in rhombic prisms which, according to A. Fock, have the axial ratios $a : b : c = 0.6245 : 1 : 0.5008$. E. de Haën said that 100 parts of water at 24° dissolve 140 parts of the salt, and at the b.p., 1500 parts of salt. H. Grünbaum also made this salt. E. de Haën also prepared **sodium sulphatotrifluoantimonite**, $\text{Na}_2\text{SO}_4 \cdot \text{SbF}_3$, in small prisms; he also made **potassium sulphatotrifluoantimonite**, $\text{K}_2\text{SO}_4 \cdot \text{SbF}_3$; T. Meyer, **potassium sulphatohexafluodiantimonite**, $\text{K}_2\text{SO}_4 \cdot 2\text{SbF}_3$; and A. Rosenheim and H. Grünbaum also prepared complexes with ammonium or sodium oxalate, and with potassium antimonyl oxalate.

§ 16. The Higher Antimony Fluorides

In addition to antimony fluoride, J. J. Berzelius¹ also mentioned the existence of **antimony tetrafluoride**, SbF_4 , which he said unites with alkali fluorides to form

double salts. F. A. Flückiger showed that it is doubtful if the tetrafluoride or its complex salts really exist. J. J. Berzelius likewise mentioned **antimony pentafluoride**, SbF_5 , which also forms a series of complex salts, but F. A. Flückiger was unable to confirm this statement. According to P. Redenz, when antimonious acid is dissolved in pure hydrofluoric acid, and the soln. evaporated, a very hygroscopic, syrupy mass is left which is not completely soluble in water; neither by this method nor by dissolving antimonious oxide in hydrofluoric acid could a crystalline antimony pentafluoride be obtained. J. C. G. de Marignac evaporated in vacuo a soln. of hydrated antimony pentoxide in hydrofluoric acid, and obtained a gummy mass which, when heated, formed an oxyfluoride. He obtained a number of complex salts with antimony pentafluoride. H. Moissan obtained the pentafluoride by burning powdered antimony in fluorine gas. O. Ruff and W. Plato prepared the pentafluoride by boiling at $25^\circ\text{--}30^\circ$ a mixture of anhydrous hydrogen fluoride with about half the calculated quantity of antimony trifluoride, sat. with chlorine, in a vessel fitted with a reflux condenser cooled by iced-water. The boiling is continued until hydrogen chloride is no longer given off. This occupies about three days. The hydrogen fluoride is then distilled off, and the b.p., rising to 155° , enables the antimony pentafluoride to be distilled off.

According to O. Ruff and co-workers, antimony pentafluoride is a colourless, viscid liquid which freezes in the cold. Its sp. gr. is 2.993 at $22.7^\circ/4^\circ$; and the b.p. $149^\circ\text{--}150^\circ$. The pentafluoride dissolves in **water** with a hissing noise, forming a clear soln. which, when sat. with sodium hydrocarbonate, does not decolorize iodine. The pentafluoride is very hygroscopic, forming *dihydrated* antimony pentafluoride, $\text{SbF}_5 \cdot 2\text{H}_2\text{O}$, when exposed to humid air. Antimony pentafluoride is not attacked by **chlorine**; **bromine** forms a viscid, dark brown mass, possibly SbF_5Br ; **iodine** forms some mixed halides (*q.v.*); **sulphur** forms sulphopentafluoride; **hydrogen sulphide** produces sulphur, hydrogen fluoride, and antimony thiofluoride. The pentafluoride reacts with **sulphur dichloride**. When a current of dry **ammonia** is passed over the pentafluoride, there is a vigorous reaction and a protective yellowish-red crust is formed. With liquid ammonia there is a vigorous reaction, and when the product is heated 12 hrs. at 100° , the product has the composition of **antimony hemitriamminotetrafluoride**, $2\text{SbF}_4 \cdot 3\text{NH}_3$, but it is considered to be **antimony imidohydrofluoridotrifluoride**, $\text{NH}(\text{SbF}_3 \cdot \text{NH}_2 \cdot \text{HF})_2$. This product is a white powder very readily decomposed by atm. moisture; is slowly hydrolyzed by water, and the aq. soln. is acid to litmus. Antimony pentafluoride reacts with **nitrogen sulphide**. O. Ruff made **antimony fluonitrosylpentafluoride**, $\text{SbF}_5 \cdot \text{NOF}$, by the action of **nitrosyl fluoride** on the pentafluoride as in the case of the corresponding arsenic compound or by the interaction of solid antimony chlorofluoride and nitrosyl fluoride at -80° . The compound occurs in slender, colourless needles, which sublime without decomposition below a red-heat; it is very hygroscopic, and is decomposed by water and by alcohol. On warming with arsenic trifluoride, it gives arsenic pentafluoride mixed with excess of the trifluoride, and, on heating with potassium fluoride, it yields nitrosyl fluoride and a compound of antimony pentafluoride and potassium fluoride. **Phosphorus** inflames in contact with antimony pentafluoride producing a yellow vapour which sublimes; with **phosphorus trichloride** it forms phosphorus trifluoride; with **phosphorus pentoxide** it forms phosphorus oxyfluoride; with **arsenic trifluoride** it forms crystalline compounds; with **antimony** it forms antimony trifluoride; with **antimony trifluoride** it forms compounds varying in composition from $\text{SbF}_5 \cdot 2\text{SbF}_3$ to $\text{SbF}_5 \cdot 5\text{SbF}_3$ —*vide infra*. The pentafluoride quickly attacks **organic substances**, e.g. the skin, filter-paper, cork, wood, and india-rubber. It attacks **hydrocarbons**—thus, with **benzene** hydrogen fluoride is evolved. It also reacts with **alcohol**, **ether**, **acetone**, **glacial acetic acid**, **ethyl acetate**, **carbon disulphide**, **light petroleum**, **toluene**, and **chloroform**. P. Redenz made a number of complex salts with the chlorides of a number of organic bases—pyridine, picoline, *p*-toluidine, and quinine. A gas—possibly CCl_3F —is evolved by the action of the pentafluoride

on **carbon tetrachloride** at 45°. The pentafluoride reacts with **silicon tetrachloride**. Colloidal **silicic acid** forms antimonious acid and silicon tetrafluoride when warmed with the pentafluoride. The dry purified pentafluoride does not attack dry **glass**—if hydrogen fluoride be present as an impurity, glass is attacked. **Copper and lead** are attacked very slowly by the pentafluoride; indeed, if the substances are all dry, the **metals** do not usually react with the pentafluoride. When heated with **sodium**, rapid combustion with the formation of a white vapour occurs. With sodium hydroxide or carbonate, the pyroantimonite is formed. The pentafluoride reacts with **chromyl chloride**; with **molybdenum pentachloride**, above 100°, molybdenum fluoride and antimony pentachloride are formed, and the latter parting with some of its chlorine forms a complex compound with the excess of pentafluoride. The pentafluoride reacts with **tungsten hexachloride**, forming the hexafluoride; and it reacts with **tin and titanium tetrachlorides**.

O. Ruff and W. Plato prepared some complex compounds of antimony tri- and penta-fluorides. By boiling a mixture of anhydrous hydrogen fluoride and antimony pentachloride for about 8 hrs., in an apparatus fitted with a well-cooled reflux condenser and distilling the product so as to collect the fraction boiling at 390°, **antimonidiantimonious heptafluoride**, $\text{SbF}_5 \cdot 2\text{SbF}_3$, is produced. The same compound was obtained by distilling a mixture of the component chlorides. This compound is a colourless, transparent, crystalline substance, with a sp. gr. 4.188 at 21°/4°. It boils at 390°. It dissolves completely in water; but if distilled in the presence of traces of moisture, some antimony tri- or tetra-oxide is formed. The vapour density shows that a considerable contraction takes place in the formation of this compound, and if heated to about 445°, the vapour dissociates. If a mixture of antimony pentafluoride with an excess of the trifluoride be distilled, the fraction boiling at 384° is **antimonipentantimonious icosifluoride**, $\text{SbF}_5 \cdot 5\text{SbF}_3$. The colourless liquid solidifies when cold. Fractions corresponding with **antimoni-tetrantimonious heptadecafluoride**, $\text{SbF}_5 \cdot 4\text{SbF}_3$, and **antimonitriantimonious tetradecafluoride**, $\text{SbF}_5 \cdot 3\text{SbF}_3$, were obtained, but their b.p. were too close together to enable their existence to be established with certainty.

J. C. G. de Marignac prepared a series of complex alkali fluorides by adding alkali (or ammonium) hydroxide to an acid soln. of antimony pentafluoride; or by dissolving the proper antimonate in hydrofluoric acid. According to H. von Helmholtz, freshly precipitated hydrated antimony pentoxide dissolves freely in a soln. of ammonium fluoride, but no crystalline salt can be separated from the liquid. J. C. G. de Marignac obtained **ammonium heptafluoantimonate**, $2\text{NH}_4\text{F} \cdot \text{SbF}_5 \cdot \frac{1}{2}\text{H}_2\text{O}$, in rhombic crystals with the axial ratios $a : b : c = 0.9827 : 1 : 1.142$, from a soln. of the component salts with the ammonium fluoride in excess; otherwise, small hexagonal prisms of **ammonium hexafluoantimonate**, $\text{NH}_4\text{F} \cdot \text{SbF}_5$, are formed. The salt is deliquescent. J. C. G. de Marignac obtained cubic deliquescent crystals of **sodium hexafluoantimonate**, $\text{NaF} \cdot \text{SbF}_5$; **potassium hexafluoantimonate**, $\text{KF} \cdot \text{SbF}_5$, in rhombic plates freely soluble in water; and when potassium fluoride is in excess, monoclinic prisms of **potassium heptafluoantimonate**, $2\text{K}_2\text{F} \cdot \text{SbF}_5 \cdot 2\text{H}_2\text{O}$. The axial ratios are $a : b : c = 1.805 : 1 : 1.136$, and $\beta = 91^\circ 30'$. The salt melts in its water of crystallization at 90°, and loses water and hydrofluoric acid at the same time. The fluoantimonates can be preserved in a dry atm. They are freely soluble in water, and deliquesce in air. By repeatedly evaporating the aq. soln., an oxyfluoride is formed. The aq. soln. are not at once affected chemically by hydrogen sulphide, by acids, or by alkali hydroxides or carbonates. In attempting to make **copper fluoantimonate**, and **zinc fluoantimonate**, only viscid products were obtained.

§ 17. Antimony Trichloride

In the seventeenth century, J. R. Glauber,¹ and Basil Valentine prepared **antimony trichloride**, SbCl_3 , by distillation from a mixture of antimony sulphide with mercuric chloride, salt and clay, or hydrochloric acid. The product was named *butyrum antimonii*—butter of antimony; and also *causticum antimoniale*, *Spiessglanzbutter*, and, from the idea that it contained mercury, *cinnabaris antimonii*. J. R. Glauber showed that no mercury is present; and he gave a correct interpretation of the reaction between mercuric chloride (sublimed mercury) and antimony sulphide (antimony):

Butyrum antimonii is nothing else but the regulus of antimony dissolved with spirit of salt; for sublimed mercury, being mixed with antimony, feeling the heat of the fire, is forsaken by the corrosive spirits associating themselves with the antimony, whence comes the thick oyle; whilst which is done the sulphur of antimony is joyned to the quick-silver, and yields a cinnabar, sticking to the neck of the retort; but the residue of the mercury remains in the bottom with the *caput mortuum*, because a little part thereof doth distill off: and if thou hast skill thou mayst recover the whole weight of the mercury again. . . . Whence it doth necessarily follow that the thick oyle is nothing else but antimony dissolved in spirit of salt.

The theory of J. R. Glauber was accepted by J. C. Barchusen, and H. Boerhaave. C. Hensgen obtained the trichloride by passing chlorine through a tube containing antimony, and joined on to a bulb. The mixture of antimony tri- and penta-chlorides which collects in the bulb was mixed with antimony and distilled for the trichloride.

The antimony trichloride to be distilled is placed in a distillation-flask provided with a side-tube, and of about $1\frac{1}{2}$ to 2 litres capacity; the flask is placed on a water-bath with the neck inclined downwards, and fitted by means of a good cork into a smaller flask serving as a receiver; the side tube passes vertically upwards, and is then bent and fitted with a drying tube. The water-bath is of such a size that the part of the flask containing liquid antimony trichloride is completely immersed in water-vapour when the sublimation is going on. The upper part of the flask is cooled by cold water dropped on to a piece of filter-paper. When a sufficient quantity of the long, lanceolate crystals of the sublimate has collected on the cooled portion of the flask, the whole is allowed to cool slowly; and as soon as the trichloride on the bottom of the flask has solidified, the sublimate is shaken carefully into the receiver. The operation is then repeated until the whole of the charge has been sublimed.

P. S. Brallier used a modification of the process. A. W. Hofmann also described an apparatus for this purpose. B. H. Jacobson obtained the chloride by the action of chlorine on the metal with a trace of bromine as catalyst, and in the presence of alkali halides to keep the product liquid. P. J. Robiquet obtained the trichloride by dissolving antimony in a mixture of four parts of hydrochloric acid and one part of nitric acid. The latter is to be added in small portions at a time and a gentle heat applied. If too much chlorine is given off on evaporation, too much nitric acid is present, and more hydrochloric acid and antimony should be added. It is advisable to have a little antimony in excess at the bottom of the retort. G. Oddo and E. Serra prepared antimony trichloride by heating the trioxide with sulphur monochloride in an apparatus fitted with a reflux condenser; and G. Oddo and U. Giarchery, by passing chlorine through a heated mixture of the trioxide and powdered sulphur. As indicated in connection with the chemical properties of antimony, some trichloride is formed by the slow action of hydrochloric acid, in the presence of air, on antimony; and also by the action of phosphorus trichloride, chlorosulphonic acid, and sulphur oxychlorides on antimony. As indicated above, Basil Valentine obtained the trichloride by distillation from a mixture of mercuric chloride and antimony; P. J. Malouin, from a mixture of silver chloride and antimony; and L. D. l'Hôte, by the action of other metal chlorides on antimony.

Antimony trioxide is chlorinated by heating it in a current of chlorine, or in the presence of the chlorides of phosphorus, sulphur, etc.—*vide supra*, antimony trioxide. J. R. Glauber, and P. L. Robiquet obtained a soln. of the trichloride by the action of hydrochloric acid on antimony trioxide, or oxychloride. The excess of hydrochloric acid can be removed from the soln. by a current of air, and the buttery residue distilled for the trichloride. H. Rose found that the trichloride is produced by distilling a soln. of antimony pentoxide in hydrochloric acid. H. Rose obtained the trichloride, by the action of chlorine on heated antimony trisulphide, but separated the sulphur monochloride produced simultaneously, by volatilization at a gentle heat. E. Mitscherlich added that the affinity of sulphur monochloride for chlorine prevents the trichloride from passing into the pentachloride. The Rhenania Verein Chemische Fabrik heated the sulphide with chlorine. Gaseous hydrogen chloride also converts antimony trisulphide into the trichloride; and, according to J. R. Glauber, when antimony trisulphide is heated with hydrochloric acid, the trichloride is formed; and, according to F. Göbel, J. von Liebig, A. Larocque, R. Brandes, and P. L. Geiger and L. Reimann, the presence of a little nitric acid favours the reaction. The Hooker Electrochemical Co. passed chlorine into hydrochloric acid in the presence of antimony. J. R. Glauber distilled the antimony trisulphide with sodium chloride and sulphuric acid; C. R. Fresenius, and P. de Clermont heated it with ammonium chloride; Basil Valentine, with mercuric chloride; and J. Linder, with ferric chloride. J. M. Scherer, A. Classen and O. Bauer, and G. C. Wittstein heated antimony pentasulphide with hydrochloric acid; and J. J. Berzelius heated antimony sulphate with sodium chloride. Antimony trichloride is formed when chlorine, or phosphorus pentachloride, etc., acts on stibine (*q.v.*), and when antimony acts on the pentachloride.

Fairly pure antimony trichloride is obtained by the action of hydrochloric acid on the oxychloride. If the antimony trichloride is contaminated with arsenic trichloride (*q.v.*), the impurity can be volatilized by the action of hydrogen chloride; lead chloride as an impurity remains behind when the antimony trichloride is sublimed; and ferric chloride can be removed by subliming the antimony trichloride mixed with powdered antimony. H. Rose² obtained well-developed crystals by cooling a hot soln. of antimony trichloride in sulphur monochloride, and J. P. Cooke used carbon disulphide as solvent. Good crystals can also be obtained by sublimation, and by pouring the molten chloride from a partially solidified mass.

The analyses of J. Davy, F. Göbel, H. Rose, J. B. A. Dumas, and J. P. Cooke are in agreement with the empirical formula SbCl_3 . E. Mitscherlich gave 7.8 for the vapour density when the value calculated for SbCl_3 is 7.82; and C. P. Worcester, 7.96. P. Walden found the mol. wt. of antimony trichloride from its effect on the f.p. of arsenic tribromide to be $(\text{SbCl}_3)_2$; and with nitrobenzene, the mol. wt. was 256 when the normal value is 225.1. L. Kahlenberg and A. T. Lincoln also measured the effect of antimony trichloride on the f.p. of nitrobenzene. S. Tolloczko measured the effect of bismuth chloride, sulphur, iodine, arsenic bromide and iodide, xylene, anthracene, diphenylmethane, acetophenone, and benzophenone on the f.p. of antimony trichloride; and E. Beckmann, the effect of arsenic triiodide and trioxide, antimony triiodide, and stannic iodide. H. Henstock discussed the electronic structure of the family of trihalides.

Antimony trichloride forms colourless, prismatic, or octahedral **crystals** or a colourless, crystalline mass. The crystals examined by H. Töpsöe, and J. P. Cooke, belong to the rhombic system. J. Kendall and co-workers found three breaks in the cooling curves, corresponding with three allotropic forms: $\alpha\text{-SbCl}_3 \rightleftharpoons \beta\text{-SbCl}_3 \rightleftharpoons \gamma\text{-SbCl}_3$. The **specific gravity** given by J. P. Cooke is 3.064 at 26°, and E. Cohen and T. Strengers, 3.14 at 20°/4°; and Z. Klemensiewicz, 2.681 at 75°, and 2.647 at 97°. H. Kopp found that the compound melts to a colourless or yellow oil of sp. gr. 2.675 at 73.2°/4°. W. Biltz, R. Lorenz and W. Herz, O. Masson, and J. A. Groshans studied the mol. vols. of this family of elements. I. I. Saslawsky found a 1.11 per cent. contraction in the formation

of this compound from its elements. J. D. Sullivan discussed the use of the trichloride as a heavy liquid in mineral analyses. F. M. Jäger found the sp. gr. of the liquid at different temp. indicated below, and he represented the sp. gr., D , at θ , by $D=2.6712-0.002166(\theta-75)-0.0672(\theta-75)^2$. F. M. Jäger found the **specific cohesion**, a^2 sq. mm., to be 3.79 at 74.5°, 3.43 at 137.0°, and 3.20 at 178.0°; and the **surface tension**, σ dynes per cm., and the mol. **surface energy**, $\sigma(mv)^{\frac{2}{3}}$ ergs per sq. cm.—**L. 13, 22**—at different temp. to be :

	74.5°	90.4°	105°	120.6°	137°	149.8°	165°	178°
σ	49.6	47.8	46.0	44.3	42.6	41.2	39.6	38.3
$\sigma(mv)$	957.4	930.3	902.8	899.3	851.8	830.2	805.2	785.2

S. Motylewsky found the drop-weight to be 67 when that of water at 0° is 100. R. Lorenz and W. Herz studied the relations of the surface tensions of this family of halides. Z. Klemensiewicz measured the **viscosity** of antimony trichloride between 797° and 200°. The viscosity is 0.0241 at 79.1°; 0.01955 at 99.1°; 0.0148 at 119.0°; 0.0124 at 139.2°; 0.0108 at 159.7°; 0.0097 at 181.2°; and 0.0091 at 191.6°. He found there is a slight change of direction at 120°. He also measured the viscosities of soln. of antimony trichloride and potassium, rubidium, thallium, and mercuric chlorides. N. S. Kurnakoff and co-workers measured the viscosity of binary systems of antimony trichloride with ethyl ether and acetone. F. Schuster gave 220 atm. for the **internal pressure**. According to H. Kopp, the **thermal expansion** represented by the vol. of the liquid at different temp., θ° , is given by $v=1+0.0008054(\theta-73.2)+0.000001033(\theta-73.2)^2$. R. Lorenz and W. Herz gave 0.000811; the sp. ht. found by L. von Pebal and H. Jahn is 0.110 between 0° and 33°; 0.100 between 0° and -21°; and 0.102 between -21° and -77°. H. Capitaine, G. B. Bernardis, and J. P. Cooke gave 72° for the **melting point**; H. Kopp, and F. M. Jäger, 73.2°; W. Biltz and K. Jeep, 72.5°; J. Kendall and co-workers, 73.4°; R. Lorenz and W. Herz, 73°; and E. K. Rideal, 73°. J. P. Cooke said that when heated near its m.p., antimony trichloride can be readily triturated to a powder. H. Braune and W. Tiedje found the vap. press., p mm., of **antimony trichloride** to be :

p	100.2°	115.1°	121.7°	130.0°	141.2°	155.1°
	13.7	25.0	33.0	44.1	66.1	100.3

For the **boiling point** H. Capitaine gave 230°; H. Kopp, 223° at 748 mm.; J. P. Cooke, 216°; P. Walden, 219.0°-219.5° at 757 mm.; F. M. Jäger, 111° at 20 mm.; T. Carnelley and W. C. Williams, 221°; C. G. Maier, 220.2°; and R. Anschütz and P. N. Evans, 233° at 760 mm., 143°-144° at 70 mm., and 102° at 11 mm., and L. Rotinjanz and W. Suchodsky, 223°. W. Böttger found that antimony trichloride can be distilled from conc. sulphuric acid soln. if 47 per cent. hydrobromic acid be continually dropped into the liquid. C. G. Maier gave for the vap. press., p mm. :

p	50.3°	84.4°	112.0°	145.3°	173.3°	204.5°	216.9°	226.4°
	12.6	20.2	45.0	112.0	263.5	538.8	718.9	797.3

L. Rotinjanz and W. Suchodsky gave 524° for the **critical temperature**, and $T_m/T_c=0.622$ for the ratio of the m.p. to the critical temp. M. Prud'homme, and E. van Aubel found the relation between the m.p., the b.p., and the critical temp., to be normal. S. Tolloczko calculated the mol. latent **heat of fusion** to be 3010 cal. per mol, or 12.9 to 13.27 cal. per gram; W. Herz gave 13.29 cal. per gram; S. Tolloczko and M. Meyer gave 13.29 cal.; and the **freezing-point constant**, 184; H. Braune and W. Tiedje gave 11,050 cal. for the **heat of vaporization** at 123°; and E. K. Rideal gave for the mol. heat of vaporization, 3.0 Cals.; and C. G. Maier, 10.7 Cals. J. Thomsen gave for the **heat of formation**, $\text{Sb}_{\text{solid}}+3\text{Cl}_{\text{gas}}=\text{SbCl}_{3\text{solid}}+91.39$ Cals.; and A. Guntz, $\text{Sb}_2\text{O}_{3\text{solid}}+6\text{HCl}_{\text{gas}}=2\text{SbCl}_{3\text{solid}}+3\text{H}_2\text{O}_{\text{solid}}+90.90$ Cals. H. Becquerel found the **refractive index** for Na-light to be 1.460; and the **electromagnetic rotatory**

power of a soln. in conc. hydrochloric acid, 0.703. A. K. Macbeth and N. I. Maxwell measured the **absorption of light** by hydrochloric acid soln. of antimony trichloride; C. R. Crymble, the **absorption spectrum**; and O. Gosmann, the emission of positive ions by the trichloride. W. Herz gave 2.60×10^{12} for the **vibration frequency**.

H. Buff found antimony trichloride to be a bad conductor of electricity; Z. Klemensiewicz found the **electrical conductivity** to be 0.0685 mho at 75°. This is smaller than the value obtained by P. Walden, and L. Graetz, 0.000109 mho at 80°. Possibly the latter preparations were moist. P. Walden assumed that the salt is ionized step by step: $\text{SbCl}_3 \rightleftharpoons \text{SbCl}_2^+ + \text{Cl}^- \rightleftharpoons \text{SbCl}^{2+} + 2\text{Cl}^- \rightleftharpoons \text{Sb}^{3+} + 3\text{Cl}^-$. L. Kahlenberg and A. T. Lincoln found the molar conductivity in methyl alcohol soln. to be $\mu_{8.15} = 15.7$, and $\mu_{1044} = 156.3$; for ethyl alcohol, $\mu_{8.1} = 4.2$, and $\mu_{280} = 29.4$. They also measured the conductivity in soln. of the trichloride in acetone, ethyl acetate, ethyl acetoacetate, benzaldehyde, nitrobenzene, nitrotoluene, paraldehyde, and ethyl monochloracetate. G. N. Guam and J. A. Wilkinson found antimony halide dissolved in liquid hydrogen sulphide is a conductor. S. Tolloczko found that ionization occurs with soln. of potassium chloride and bromide. Z. Klemensiewicz measured the electrical conductivities of soln. of thallium, ammonium, potassium, and rubidium in antimony trichloride at different temp., and he found the conductivities in dil. soln. greater, and in conc. soln. less than for the corresponding aq. soln. The conductivity increases regularly with temp. from 70°–200°. The degree of ionization for soln. in antimony trichloride is less than for water, but the ionic velocity is greater with the trichloride. K. Frycz and S. Tolloczko found that with soln. of ammonium and potassium chlorides in antimony trichloride at 90°, with increasing dilution the transport numbers of the Cl⁻ ions increase more rapidly than with aq. soln. In general, the ions which have the higher transport numbers are those which are common to the electrolyte and solvent. T. C. Sanderson separated gold from antimony by electrolyzing the soln. of the chlorides of the two elements in hydrochloric acid and sodium chloride. For the absorption of antimony trichloride by electrolytic antimony, *vide supra*, explosive antimony. G. Hänsel found the electrode potential $\text{Sb} | 0.33N\text{-SbCl}_3$ in 0.3N-HCl to be 0.131 volt, and in 3N-HCl, 0.101 volt. W. Finkelstein measured the **decomposition potential** of the trichloride in nitrobenzene soln. H. Schlundt found the **dielectric constant** to be 5.4 at 18°, and 33.2 at 75°.

J. P. Cooke³ found that antimony trichloride can be distilled without decomposition in a current of **hydrogen**. W. D. Bancroft and H. B. Weiser observed that when added to the colourless gas-flame, antimony trichloride furnishes a bright metallic mirror and also pulverulent black antimony, but no yellow antimony. J. P. Cooke found that a soln. of antimony trichloride in hydrochloric acid is rapidly oxidized by exposure to **air**. The soln. which at first has no action on iodized starch paste, will strike the blue colour after it has been exposed a few minutes. This property was also noticed by W. P. Dexter. Antimony trichloride is very hygroscopic, and it rapidly absorbs moisture from the atm. to form a liquid. R. Brandes said that antimony chloride absorbs more than its own weight of **water** from the atm. in 70 days; and H. Rose added that deliquescence without turbidity occurs only if the trichloride contains hydrochloric acid. H. von Wartenberg devised the reaction as a demonstration experiment to illustrate the law of mass action. E. Baudrimont found that the composition of the oxychloride depends on the temp. and the proportion of water which is present. If hydrochloric acid be added, the turbidity disappears, and if water be again added, the turbidity reappears. When the trichloride is hydrolyzed by water, the acid liquid simultaneously formed was once called *spiritus vitrioli philosophicus*, and also *liquor stibiumuriatici*. According to A. Sabaneeff, the nature of the precipitate depends on the relative amounts of water and trichloride; a mol of the solid trichloride is dissolved by 2 mols of water, and can be recovered unchanged by evaporating the soln.; with a larger proportion of water, the trichloride is hydrolyzed, forming

various oxychlorides ranging from SbOCl to $\text{Sb}_4\text{O}_5\text{Cl}_2$ with 8–27 mols of water to a mol of the solid trichloride; with still higher proportions of water, the amorphous products supposed to be mixtures of antimony trioxide and $\text{Sb}_4\text{O}_5\text{Cl}_2$ were produced, but the complete removal of the chlorine can be affected only by prolonged washing with a very large proportion of water. The change from SbOCl to $\text{Sb}_4\text{O}_5\text{Cl}_2$ occurred with soln. more dil. than 2.5*N*-HCl; and the change from $\text{Sb}_4\text{O}_5\text{Cl}_2$ to Sb_2O_5 occurred with soln. less conc. than 0.25*N*-HCl. H. le Chatelier gave 2.12*N*-HCl for the former transition point at 15°; and C. Lea and J. K. Wood gave 8.0*N*-HCl for the former transition point and 0.1*N*-HCl for the latter. The errors in observation are due to the slowness of the change from the metastable to the stable solid phases. They noted that the following proportions of antimony trichloride were dissolved by soln. of hydrochloric acid in 1000 grms. of water, at 15°:

HCl	8.6	19.3	40.5	56	72.5	88	95	97.5	104	105
SbCl_3	0.11	0.18	0.36	2.10	9.9	34	111	319	590	850

The soln. were allowed to stand for 3 months. At a higher temp., 50°, the soln. were allowed to stand for a week. Antimony trichloride is decomposed at the higher temp. The results at 50° were:

HCl	3.65	32	40.2	56	68	77.2	84.5	88
SbCl_3	0.1	1	1.5	5.8	21.8	50.5	136.5	337

Observations were also made by A. Ditte, M. Berthelot, and E. Baudrimont. H. E. Causse found the following proportions of antimony trioxide were dissolved by 100 c.c. of hydrochloric acid:

HCl	5	10	15	20	25	30	35
Sb_2O_3	0.28	2.13	5.53	13.0	18.77	24.30	30.80
HCl { bound	0.21	1.62	4.85	9.93	14.26	18.47	23.42
free	4.79	8.38	10.15	10.07	10.74	11.53	11.57

Expressing the results in mols of SbCl_3 per 100 mols of water, J. M. van Bemmelen gave for the solubility of antimony trichloride in water at different temp.:

	0	15	20	25	30	35	40	50	60	72
SbCl_3	47.9	64.9	72.8	78.6	84.9	91.6	108.8	152.5	360.4	∞

The equilibrium diagram for the ternary system SbCl_3 -HCl- H_2O at 20° has four curves, Fig. 35, with the solid phases SbCl_3 , *DE*; $\text{SbCl}_3 \cdot \text{SbOCl}$, or $\text{SbCl}_3 \cdot 2\text{SbOCl}$, *BC*; SbOCl , *AB*; and $\text{Sb}_4\text{O}_5\text{Cl}_2$, *OA*. The three quadruple points are *A*, *B*, and *C*. The curve *DE* represents the saturation curve of SbCl_3 in dil. hydrochloric acid. The solubility of the trichloride decreases with increasing conc. of the acid. The part *CE* is stable, the part *DC* is labile. J. M. van Bemmelen and co-workers said that the oxychloride $\text{SbCl}_3 \cdot \text{SbOCl}$, or Sb_2OCl_4 , is deposited from soln. with between 1.38 and 4 mols. of water to a mol. of SbCl_3 , but C. Lea and J. K. Wood said that this substance is really the oxychloride, $\text{Sb}_4\text{O}_5\text{Cl}_2$, and that the only stable oxychlorides at 25° are SbOCl and $\text{Sb}_4\text{O}_5\text{Cl}_2$. The addition of a sufficient amount of water to antimony trichloride brings about the complete hydrolysis of that compound, with the formation of hydrochloric acid and a highly-hydrated form of antimony trioxide, which forms a bulky, white precipitate. The precipitate tends to adsorb hydrochloric acid from the surrounding liquid, the amount of acid adsorbed and the composition of the absorption product depending on the conc. of the soln. The amorphous oxychloride, SbOCl , referred to in literature is an adsorption product whose composition depends on the conc. of the soln. with which it is in contact. C. Lea and J. K. Wood continue: The adsorption product

FIG. 35.—Equilibrium in the Ternary System: SbCl_3 -HCl- H_2O at 20°.

then tends to change into an oxychloride of antimony as a result of interaction between the adsorbed acid and the adsorbent ; the oxychloride so formed, however, may not be able to exist in stable equilibrium with the soln., but may in its turn suffer slow conversion into a crystalline product of different composition ; probably the adsorption product changes first into that oxychloride the composition of which most nearly approximates to its own. One of these metastable substances is J. P. Cooke's oxychloride to which the formula $\text{Sb}_4\text{O}_3(\text{OH})_5\text{Cl}$ has been assigned, whilst the other is the compound deposited in the form of fine needles from the more conc. mixtures ; as the latter can apparently suffer change into either SbOCl or $\text{Sb}_4\text{O}_5\text{Cl}_2$, according to the conditions, it would appear to have the composition intermediate between those of the substances mentioned, and the formula $\text{Sb}_4\text{O}_3(\text{OH})_3\text{Cl}_3$ is suggested as suitable for this substance. The process of conversion of these metastable compounds into the stable ones varies according to the nature of the final product ; thus, the conversion of $\text{Sb}_4\text{O}_3(\text{OH})_3\text{Cl}_3$ into SbOCl and $\text{Sb}_4\text{O}_5\text{Cl}_2$, respectively, will take place in accordance with the following equations : $\text{Sb}_4\text{O}_3(\text{OH})_3\text{Cl}_3 + \text{HCl} = 4\text{SbOCl} + 2\text{H}_2\text{O}$; and $\text{Sb}_4\text{O}_3(\text{OH})_3\text{Cl}_3 = \text{Sb}_4\text{O}_5\text{Cl}_2 + \text{H}_2\text{O} + \text{HCl}$. In the second reaction the solid simply gives up acid to the soln. until the necessary equilibrium is established, but in the first it is necessary for interaction between the solid and the soln. to occur ; this difference in the nature of the process probably accounts for the more rapid attainment of equilibrium when the stable solid phase is $\text{Sb}_4\text{O}_5\text{Cl}_2$ than when it is SbOCl . In a similar manner, when a smaller proportion of hydrochloric acid is contained in the adsorption product, the latter suffers change into J. P. Cooke's oxychloride, and subsequently, according to the conc., into $\text{Sb}_4\text{O}_5\text{Cl}_2$ or antimonious oxide. The non-production of any appreciable quantity of J. P. Cooke's oxychloride from boiling soln. is probably due to dehydration of the amorphous adsorption product at the higher temp., which makes the separation of a crystalline hydrated oxychloride impossible. The dehydration adsorption product was, in the most conc. soln. investigated, mixed with crystals of $\text{Sb}_4\text{O}_5\text{Cl}_2$, and from this it would appear that the latter oxychloride may, under certain conditions, be formed directly from the adsorption compound.

The hydrolysis of antimony trichloride by water is retarded by the presence of hydrochloric acid, by the alkali and alkaline earth chlorides, and by tartaric acid. H. E. Causse obtained a neutral soln. by saturating a hydrochloric acid soln. of the trichloride with sodium chloride, and then neutralized the acid with sodium carbonate. G. Watson found that antimony trichloride forms clear soln. with sat. soln. of sodium, ammonium, calcium, and magnesium chlorides ; while potassium and barium chlorides gave turbid soln. He compared the effect of sodium, ammonium, and magnesium chlorides in preventing the decomposition of antimony trichloride by water. He also said (*cf.* 2. 19, 12) :

If some antimony trichloride be dissolved in a sat. soln. of sodium chloride, a liquid is obtained which is quite clear at first, but which, being in a state of instability, deposits, on standing, a portion of its antimony as basic salt. If scratches be made on the glass, however, in the newly-prepared liquid, such scratches are in a very short time—indeed almost at once—coated by a deposit of basic salt, the liquid otherwise remaining clear. This result is due to the slight increase of surface energy produced locally by the scratching, and inasmuch as a certain quantity of muscular energy is expended in producing an abrasion, causing the disappearance of its equivalent of cohesive force, and the appearance of the same amount of surface energy, it is evident that the surface energy of all solids is dependent on their intrinsic cohesive force ; for any mass of solid may be viewed as having been originally part of a larger mass, and as having been formed from it by breaking or sub-division. Increase of surface is the inevitable concomitant of comminution, and comminution is the disappearance of so much cohesive force.

H. Moissan found that **fluorine** reacts vigorously with antimony trichloride, forming the trifluoride. T. Karantassis studied the interchange of halogens—chlorine, bromine, and iodine. J. von Liebig showed that **chlorine** converts the tri- into the penta-chloride. W. Biltz and E. Meinecke, and K. H. Butler and D. McIntosh said that the trichloride is insoluble in liquid chlorine ; and W. Biltz

and K. Jeep observed that the f.p. curve of antimony trichloride and chlorine, Fig. 36, shows the presence of the pentachloride, as well as of a complex $\text{SbCl}_5 \cdot 2\text{Cl}_2$, or **antimony enneachloride**, SbCl_9 . The action of **hydrochloric acid** on the hydrolysis of antimony trichloride has just been discussed. H. Rose, and M. Schleier found that when the hydrochloric acid soln. of the trichloride is heated, hydrochloric acid is first evolved; then follows the acid containing some antimony trichloride; and later, the trichloride alone. E. Fischer found that unlike arsenic trichloride (*q.v.*) the volatility of antimony trichloride is very much reduced if ferrous chloride be present in the soln. F. Hufschmidt, and F. A. Gooch and co-workers observed that no antimony trichloride is volatilized when a current of hydrogen chloride is passed through a hot dil. soln. L. Duparc and L. Ramadier showed that the presence of methyl alcohol favoured the volatility of antimony trichloride. M. Berthelot said that molten antimony trichloride, at as low a temp. as possible absorbs 8–10 vols. of hydrogen chloride, which is retained during the solidification; but is expelled by heat, and re-absorbed on cooling. A deliquescent, crystalline mass is produced when antimony trichloride and one-fifth of its weight of conc. hydrochloric acid, $\text{HCl} \cdot 3 \cdot 73\text{H}_2\text{O}$, is cooled below 0° . A. Ditte believed that with hydrogen

FIG. 36. — Freezing-point Curve of the System: $\text{SbCl}_3\text{-Cl}_2$.

chloride, **antimony trichlorotrihydrochloride**, $\text{SbCl}_3 \cdot 3\text{HCl}$, is formed; while R. Engel passed dry hydrogen chloride at ordinary temp. into a soln. of antimony trichloride sat. at 0° so long as gas was absorbed. On cooling the liquid to 0° , crystals of **antimony trichlorohemihydrochloride**, $2\text{SbCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$, were formed. The crystals melt at 16° , and give off hydrogen chloride when warmed. H. L. Snape⁴ found that when the solid trichloride and **potassium iodide** are heated while being protected from oxygen, antimony triiodide is formed; and A. Naumann found that a similar reaction occurs when in acetone soln.; similarly, silver nitrate forms antimony nitrate and silver chloride. For reactions with various chlorides, *vide infra*. F. Feigl and O. Schummer represented the reaction with **sodium hypochlorite**: $\text{SbCl}_3 + \text{NaOCl} + 2\text{HCl} = \text{NaCl} + \text{H}_2\text{O} + \text{SbCl}_5$; and with **potassium bromate**: $3\text{SbCl}_3 + \text{KBrO}_3 + 6\text{HCl} = \text{KBr} + 3\text{H}_2\text{O} + 3\text{SbCl}_5$.

H. A. von Vogel found that antimony trichloride decomposes when heated with **sulphur**, and grey trisulphide is formed; but, according to G. Vortmann and C. Padberg, a boiling soln. of the trichloride is not affected by sulphur. The action of **hydrogen sulphide** is discussed in part in connection with the analytical reactions of antimony, and in part in connection with the trisulphide—*vide infra*, sulphurochlorides. W. Biltz and H. Keuncke observed that dry liquid hydrogen sulphide has no action on antimony trichloride. A. Naumann observed no precipitation occurs when hydrogen sulphide acts on an acetone soln. of the trichloride. G. N. Guam and J. A. Wilkinson, and A. W. Ralston and J. A. Wilkinson measured the conductivity of soln. of antimony trichloride in liquid hydrogen sulphide, and found that it is about 10,000 times that of phosphorus chloride—the sp. conductivity of the sat. soln. is 4244×10^7 mhos. H. A. von Vogel said that conc. **sulphuric acid** does not act on antimony trichloride in the cold, but when heated, hydrogen chloride is evolved, and antimony sulphate formed. H. Friedrich also found that while tin and germanium tetrachlorides can be distilled from their sulphuric acid soln., the higher chlorides of iron and antimony are decomposed with the evolution of hydrogen chloride. H. Rose found that when a hydrochloric acid soln. of the trichloride is heated with conc. sulphuric acid, hydrogen chloride is first evolved, then antimony trichloride, and when the sulphuric acid distils over, the distillate is free from antimony. Antimony sulphate remains in the retort. If more hydrochloric acid is added, the sequence is repeated; and by repeating the addition of hydrochloric acid a number of times,

all the antimony may be distilled as chloride. F. Clausnizer found that **chlorosulphonic acid** dissolves a little antimony trichloride at ordinary temp.; and when heated in a sealed tube, the trichloride melts without mixing the acid, but as the temp. is raised, the two fluids mix, and the trichloride crystallizes out unchanged on cooling. H. Rose, and P. Walden found the trichloride to be soluble in **sulphur monochloride**.

G. Gore⁵ found antimony trichloride to be insoluble in liquid **ammonia**; and J. Persoz, and P. Grouvelle observed that the trichloride absorbs ammonia. H. Rose added that the absorption by this solid is very slow, and when the molten trichloride is cooled in an atm. of ammonia, **antimony aminotrichloride**, $\text{SbCl}_3 \cdot \text{NH}_3$, is formed. All the ammonia is expelled when the ammine is heated; and on exposure to air, the ammine is decomposed more slowly than the trichloride alone. P. P. Déherain said that hydrochloric acid converts it into ammonium tetrachlorantimonite, and he prepared **antimony diamminotrichloride**, $\text{SbCl}_3 \cdot 2\text{NH}_3$, by passing ammonia into the melted trichloride, or into warm pentachloride. The yellowish-white, crystalline diammine is stable, and volatile; and is converted by hydrochloric acid into ammonium pentachlorantimonite. A. Naumann supposed **antimony triaminotrichloride**, $\text{SbCl}_3 \cdot 3\text{NH}_3$, to be the chief product of the action of ammonia on a soln. of antimony trichloride in acetone. The white compound is stable in air, and the ammonia is expelled by heat. O. C. M. Davis found that **nitrogen sulphide** yields **antimony nitrogen sulphopentachloride**, $\text{N}_4\text{S}_4 \cdot \text{SbCl}_5$. H. Rheinboldt and R. Wasserfuhr, and H. Gall and H. Mengdehl found that antimony trichloride reacts with **nitrosyl chloride**, forming **antimonic nitrosyl chloride**, $\text{SbCl}_5 \cdot \text{NOCl}$. V. Thomas said that **nitric oxide** is without action on a chloroform or carbon disulphide soln. of antimony trichloride, and **nitrogen peroxide** forms a moderately stable compound approximating $\text{Sb}_4\text{O}_{11}\text{Cl}_4\text{N}_2$; or $\text{Sb}_2\text{O}_4 \cdot 2\text{SbOCl}_2 \cdot \text{N}_2\text{O}_5$; or **nitroxyl tetrantimonytetrachloride**, $(\text{SbO} \cdot \text{O})_2 : \text{NO} \cdot \text{O} \cdot \text{O} \cdot \text{NO} : (\text{O} \cdot \text{SbOCl}_2)_2$. The product is decomposed by warming; by water; and is dissolved by hydrochloric acid. The soln. liberates iodine from potassium iodide; and in alkaline soln., blackens silver nitrate. A. Besson found that antimony trichloride reacts with nitrogen peroxide, forming an unstable compound; V. Thomas said that very little nitrogen peroxide is absorbed in the cold, but at the m.p. it readily absorbs the gas, becoming pale yellow, dark yellow, and finally red. If the product be slowly cooled, it drops its yellow colour and retains a certain quantity of peroxide; the gas is given off when the product is placed in vacuo, or exposed for some time to dry air. The vap. press. of the product varied from 3 mm. to 491 mm. for the same temp., thus indicating that the peroxide forms no definite compound with antimony trichloride, but remains simply dissolved. H. A. von Vogel found that conc. **nitric acid** oxidizes antimony trichloride to the hydrated pentoxide; and H. Rose added that when a soln. of the trichloride in hydrochloric acid is distilled with nitric acid, after hydrogen chloride and nitrogen oxides have passed over, antimony pentachloride partially dissociated distils over, and the pentoxide remains as a residue. O. Ruff found that **phosphorus** scarcely reacts with antimony trichloride at 200° , but in the presence of aluminium trichloride the phosphorus is rapidly dissolved, and when the product is digested with carbon disulphide, an unstable red substance is formed. P. Walden found antimony trichloride is readily soluble in **phosphorus trichloride** and **tribromide**. H. Köhler observed that with **phosphorus pentachloride**, a complex, $\text{SbCl}_5 \cdot \text{PCl}_5$, is formed (*q.v.*). T. Karantassis observed that **phosphorus triiodide** reacts with antimony trichloride by double decomposition, but the reverse reaction does not occur. According to R. Mahn, **stibine** reacts with the molten trichloride, forming a black substance, which, after washing with hydrochloric acid and water, contained 76.86 per cent. of Sb; 12.85, P; 3.45, Cl; and 6.84, O. The hot trichloride dissolves **antimony trioxide**—*vide* oxychlorides—and **antimony trisulphide**—*vide* sulphochlorides. P. Walden said that antimony trichloride is readily dissolved by **arsenic trichloride**. L. Kahlenberg and J. V. Steinle observed that no

replacement of the antimony could be observed when an acetone soln. of antimony trichloride is treated with arsenic or bismuth.

J. Tarible found that with **boron tribromide**, antimony tribromide and boron trichloride are formed: $\text{SbCl}_3 + \text{BBr}_3 = \text{SbBr}_3 + \text{BCl}_3 + 20.9 \text{ cal.}$ L. Schäffer found that when antimony trichloride is heated with **alcohol** in a sealed tube at 160° , an oxychloride is formed. E. R. Schneider, and J. P. Cooke observed the solubility of the trichloride in absolute alcohol; A. Sabaneeff, in **chloroform**; J. P. Cooke, in **carbon disulphide**; M. Centnerszwer, in liquid **cyanogen**; and F. Oberhauser studied the reaction with **cyanogen chloride**. J. P. Cooke found the trichloride dissolves in **alcohol** without decomposition. A. Naumann found that 100 grms. of **acetone** dissolve 537.6 grms. of the trichloride at 18° , and the soln. has a sp. gr. of 2.216 at $18^\circ/4^\circ$; the soln. is at first yellow, and it then becomes black. At 18° , the sat. soln. has 532 grms. of salt per 100 grms. of solvent. F. Swarts found it to be insoluble in **carbon tetrachloride**. A. Naumann found that the trichloride is soluble in **benzonitrile**; and that 100 parts of **ethyl acetate** dissolve 5.89 parts of the trichloride at 18° , and the sp. gr. of the sat. soln. is 1.7968 at $18^\circ/4^\circ$. W. Eidmann found the trichloride to be soluble in **methylal**. J. Nicklès, and A. Sabaneeff found that the trichloride reacts with **ether**, forming a sticky liquid. W. Smith and G. W. Davis, and A. Rosenheim and W. Stellmann found that a complex compound, $3\text{SbCl}_3 \cdot \text{C}_6\text{H}_6$, is formed with **benzene**. B. N. Menshutkin measured the solubility of the trichloride in a number of organic liquids. Expressing the results in mols of trichloride per 100 mols of solvent, he found for benzene:

W. Smith and G. W. Davis observed the formation of a complex compound with **naphthalene** : J. P. Claësson, one with **mercaptan** ; C. Vincent, one with **dimethylamine** ; G. Bruni and A. Manuelli, with **formamide**, a product with a composition ranging between SbCl(NH.CO.H)₂ and Sb(NH.CO.H)₃ ; and similarly with **acetamide**. N. S. Kurnakoff studied the viscosity and m.p. of mixtures of antimony trichloride with **benzene**, **naphthalene**, **diphenylmethane**, **triphenylmethane**, **aniline**, ethyl ether and **acetone**. F. Feigl and O. Schummer represented the reaction with **potassium ferricyanide** : $2K_3FeCy_6 + SbCl_3 + 4HCl = K_4FeCy_6 + H_4FeCy_6 + SbCl_5 + 2KCl$. L. Belladen and R. Astengo obtained a compound with **benzamide** ; F. Ephraim and S. Weinberg, with **methylamine** ; and L. Vanino and F. Mussgnug, with **thiocarbamide**. W. Smith observed the colour reactions with **aromatic hydrocarbons**, and with **alkaloids**. The trichloride also reacts with many other **organic compounds** ; thus, E. Vanstone, P. May, B. N. Menshutkin, observed that it reacts with benzaldehyde, benzonitrile, chlorotoluene, nitrotoluene, methyl-, ethyl-, propyl-, and isoamyl-benzenes, xylenes, toluenes, and various other substitution products, mesitylene, *ψ*-cumene, anisole, phenol, aniline, propylbenzene, etc. ; S. Hakomori, complex with tartaric acid ; P. May, azonium chlorides ; J. Hasenbäumer, A. Michaelis and A. Günther, P. May, G. T. Morgan and F. M. G. Micklethwait, and G. Grüttner and M. Wiernik studied the action of antimony trichloride on **triphenylstibine** ; V. Auger and M. Billy, on organo-magnesium compounds ; W. H. Gray, on **diazotized diamines** ; L. Barthe and A. Minet, on **cacodylic acid** and **methylarsenic acid** ; and A. M. Wasilieff, **chloronaphthalenes** and **nitronaphthalenes**. This subject is discussed in G. T. Morgan's *Organic Compounds of Arsenic and Antimony* (London, 1918) ; and in W. G. Christiansen's *Organic Derivatives of Antimony* (New York, 1925). For the action of antimony trichloride on organic halides, *vide infra*, antimony triiodide. The use of antimony trichloride as a chlorinating agent for organic compounds was discussed by Lassar Cohn.

A. C. Vournasos ⁶ found that antimony trichloride in boiling toluene soln. reacts with **potassium**, forming antimony and potassium chloride. K. Seubert and A. Schmidt observed that the vapour of antimony trichloride passed over red-hot **magnesium** furnishes magnesium chloride and antimony—*vide supra*, metallic precipitation of antimony. V. A. Jacquelain noticed that when small pieces of the trichloride are laid on **mercury**, they revolve about for some time until the mercury is covered with a film of the trichloride. A. Mazzucchelli and A. Vercillo found that a soln. of antimony trichloride in hydrochloric acid is almost inert towards **copper** at ordinary temp., but at 100°, a protective film is formed on the copper, if cuprous chloride be present, Cu₂Sb is formed ; with **tin** in place of copper, Sn₂Sb₂ is formed ; with **bismuth**, no alloy is formed. F. Ducelliez found that **cobalt** reacts with the trichloride at 700°–1200°, forming antimonides ; E. Vigouroux obtained a similar result with **nickel**. A. Levallois observed that when heated with **lead sulphide** (galena) in a sealed tube at 160°, a crystalline substance is formed which was not investigated ; and when a dil. soln. is allowed to stand in contact with plumbiferrous **iron sulphide** (pyrites) for a long time—5 years—E. Masing noticed that needle-like crystals containing Sb₂O₃, Fe₂O₃, and PbO are formed. F. Kessler observed that **manganese dioxide** oxidizes the trichloride to the hydrated pentoxide ; similarly also with **potassium permanganate**.

Antimony trichloride forms a number of complex salts with various other halides. Thus, A. Ferratini ⁷ boiled an alcoholic soln. of antimony trichloride with hydrazine

hydrochloride, and obtained silky needles of **hydrazine hexachlorantimonite**, $\text{SbCl}_3 \cdot 3\text{N}_2\text{H}_5\text{Cl}$. J. Kendall and co-workers observed no evidence of the existence of the 2 : 1 and the 3 : 1 compounds in their study of the f.p. curve of NH_4Cl - SbCl_3 mixtures. They did obtain evidence of the existence of the 1 : 1 compound, and of **ammonium enneachlorodiantimonite**, $(\text{NH}_4)_3\text{Sb}_2\text{Cl}_9$. The α -, β -, and γ -forms of antimony trichloride are represented by breaks on the curve. P. P. Déherain obtained **ammonium tetrachlorantimonite**, $\text{NH}_4\text{Cl} \cdot \text{SbCl}_3$, in colourless, deliquescent needles, by the action of hydrochloric acid on the monamine—*vide supra*. V. A. Jacquelin prepared **ammonium pentachlorantimonite**, $2\text{NH}_4\text{Cl} \cdot \text{SbCl}_3$, from a soln. containing theoretical proportions of the two salts; A. B. Poggiale said that crystals of **ammonium hexachlorantimonite**, $3\text{NH}_4\text{Cl} \cdot \text{SbCl}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, separates before the crystals of the pentachlorantimonite appear. P. P. Déherain obtained the pentachlorantimonite by the action of hydrochloric acid on the diammine—*vide supra*. A. B. Poggiale said that the salt is *monohydrated*. The crystals belong to the cubic system, and are decomposed by water. F. Ephraim studied this salt, he also prepared **lithium pentachlorantimonite**, $2\text{LiCl} \cdot \text{SbCl}_3 \cdot 5\text{H}_2\text{O}$, as a *pentahydrate*, from a conc. hydrochloric acid soln. of a mol of antimony trichloride and three or more mols of lithium chloride. The acicular crystals are deliquescent; they melt when warmed; decompose at 110° ; dissolve sparingly in hydrochloric

FIG. 37.—Freezing-point Curves of Mixtures of Ammonium and Antimonious Chlorides.

FIG. 38.—Freezing-point Curves of Mixtures of Potassium and Antimonious Chlorides.

acid; and are decomposed by water. If 8 mols of lithium chloride are used in the preparation, the *hexahydrate* is formed. The same hydrate is produced by evaporating over sulphuric acid a soln. of equimolar parts of antimony trichloride and lithium chloride; heating the syrup on a water-bath when antimony trichloride volatilizes and the required crystals are formed. J. Kendall and co-workers could not obtain a thermal diagram for the LiCl - SbCl_3 system because clear soln. containing more than 0.6 per cent. of lithium chloride were not obtained at 300° . A. B. Poggiale, and J. von Liebig obtained tabular crystals of **sodium tetrachloroantimonite**, $\text{NaCl} \cdot \text{SbCl}_3$, from a soln. of the component salts. F. Ephraim studied this salt. J. Kendall and co-workers found that sodium chloride is virtually insoluble in antimony trichloride at 300° .

K. Seidel found the f.p. of antimony trichloride to be 67° - 68° ; and when a mol of the trichloride is mixed with 0.1, 0.2, 0.3, 0.4, and 0.5 mol of potassium chloride, the respective f.p. are 59° , 53° , *c.* 45° , 47° , and 50° , showing that there is a eutectic temp. below 50° . He also examined in part the ternary system SbCl_3 - KCl - H_2O at temp. between 0° and 70° , more particularly the conc. of the potassium chloride soln. when a turbidity appears. J. Kendall and co-workers' observations on the f.p. of the KCl - SbCl_3 system are indicated in Fig. 38. There is no evidence of the existence of the 1 : 2, 3 : 7, or 1 : 3 compound, but there is shown **potassium tetrachloroantimonite**, KSbCl_4 , and **potassium enneachlorodiantimonite**, $\text{K}_3\text{Sb}_2\text{Cl}_9$.

There are transition temp. representing α -, β -, and γ -forms of antimony trichloride. R. Benedikt obtained *hexagonal* crystals of **potassium pentachlorantimonite**, $2\text{KCl}\cdot\text{SbCl}_3$, from a conc. soln. of the component salts—with or without hydrochloric acid. O. Bosek found this salt amongst the products of the action of potassium chlorate on a soln. of antimony in hydrochloric acid. The tabular crystals are stable in air; they lose antimony trichloride when heated in a current of carbon dioxide; they are decomposed by water; they can be recrystallized from their soln. in hydrochloric acid—but the first crop of crystals consists of potassium chloride. The salt is soluble in tartaric acid. F. Ephraim studied this salt. If potassium pentachlorantimonite be allowed to stand in its mother-liquor for some days, prismatic and tabular crystals belonging to the *monoclinic* system were obtained by R. Benedikt. The axial ratios are $a : b : c = 0.7241 : 1 : 0.7222$, and $\beta = 111^\circ 3'$. The salt is therefore dimorphous. C. F. Rammelsberg described what he regarded as rhombic crystals of this salt. The hexagonal crystals were also obtained by V. A. Jacquelin. R. Benedikt obtained tabular monoclinic prisms of the *dihydrate* by crystallizing the soln. at about -10° . A. B. Poggiale seems to have obtained this salt in crystals, which he supposed belonged to the cubic system. The crystals do not lose their lustre at -5° ; but they do so at 15° in consequence of the loss of water; all the water is lost over sulphuric acid, or at 105° , and hydrogen chloride is given off at 110° . C. H. Herty evaporated a soln. of a mol of antimony trichloride and 3 mols of potassium chloride at 35° and obtained six-sided colourless crystals of a complex salt, $23\text{KCl}\cdot 10\text{SbCl}_3\cdot 27\text{H}_2\text{O}$; H. L. Wells and H. W. Foote favoured the formula $7\text{KCl}\cdot 3\text{SbCl}_3\cdot 8\text{H}_2\text{O}$ —**potassium hexadecachlorotriantimonite**. S. Miyake studied the system $\text{KCl}\text{--}\text{SbCl}_3\text{--}\text{HCl}\text{--}\text{H}_2\text{O}$ at 25° with the conc. of the hydrochloric acid constant, and this acid was ignored. The solubilities of potassium chloride in water and 10.55 per cent. hydrochloric acid at 25° were respectively 26.27 and 12.75 grms. per 100 grms. of soln. The solubilities of antimony trichloride in the same menstrua were respectively 90.90 and 90.07 grms. respectively. Only two complex salts were found to be stable—prisms or plates of potassium pentachlorantimonite, $2\text{KCl}\cdot\text{SbCl}_3$, and hexagonal plates of potassium hexadecachlorotriantimonite, $7\text{KCl}\cdot 3\text{SbCl}_3$. According to E. Jordis, when a mixed soln. of the component salts is evaporated, potassium chloride first separates, the next crop of crystals had the composition $23\text{KCl}\cdot\text{SbCl}_3$, after that there appeared a crop with the composition $0.78\text{KCl}\cdot\text{SbCl}_3$. The solid products are crystallographically uniform, and are not mixtures. S. Miyake could not confirm the existences of E. Jordis' mixtures. A. B. Poggiale reported crystals of **potassium hexachlorantimonite**, $3\text{KCl}\cdot\text{SbCl}_3$; but R. Benedikt believed that the product was really the salt indicated above.

F. Godeffroy first prepared complex salts with rubidium and caesium chlorides. H. J. Wheeler reported crystals of **rubidium heptachlorodiantimonite**, $\text{RbCl}\cdot 2\text{SbCl}_3\cdot \text{H}_2\text{O}$, from a hydrochloric acid soln. of a mol of rubidium chloride and 6–10 mols of antimony trichloride. The tabular crystals belong to the monoclinic system, and have the axial ratios $a : b : c = 1.699 : 1 : 0.820$, and $\beta = 90^\circ 31.5'$. The m.p. is 77° ; with a hydrochloric acid soln. containing a mol of rubidium chloride and 2.5–4 mols of antimony trichloride, I. Remsen and A. P. Saunders, and H. J. Wheeler obtained colourless, monoclinic crystals of rubidium tetrachlorantimonite, $\text{KCl}\cdot\text{SbCl}_3$, with the axial ratios $a : b : c = 1.732 : 1 : 1.085$, and $\beta = 114^\circ 26'$. The m.p. was not definite. H. J. Wheeler prepared crystals of rubidium enneachlorodiantimonite, $3\text{RbCl}\cdot 2\text{SbCl}_3$, by crystallization from a hydrochloric acid soln. of rubidium chloride and antimony trichloride in the molar proportions 1 : 1.5 to 2.0. I. Remsen and A. P. Saunders also prepared this salt. The pale yellow, trigonal crystals have the axial ratio $a : c = 1 : 0.5625$, and $\alpha = 110^\circ 54'$. They are stable in dry air. F. Godeffroy obtained a salt to which he attributed the formula $6\text{PbCl}\cdot\text{SbCl}_3$, but which was shown by H. L. Wells and H. W. Foote, and I. Remsen and A. P. Saunders to be more probably **rubidium hexadecachlorotriantimonite**, $7\text{RbCl}\cdot 3\text{SbCl}_3$, or $23\text{RbCl}\cdot 10\text{SbCl}_3$. The crystals separate from a

hydrochloric acid soln. of rubidium chloride and antimony trichloride in the mol. proportions 1.4–1.6RbCl : SbCl₃. The colourless, hexagonal plates can be heated to 200° without decomposition; dissociation begins at 230°. The salt is decomposed by water; it is soluble in hydrochloric acid, or in alcoholic hydrogen chloride, from which it can be crystallized unchanged. It is less soluble in conc. hydrochloric acid. The crystals become opaque in air. When crystallized from dil. hydrochloric acid, the salt passes into an oxychloride. F. Ephraim, F. Godeffroy, and I. Remsen and A. P. Saunders obtained **cæsius enneachlorodiantimonite**, 3CsCl.2SbCl₃, by precipitation by adding a conc. hydrochloric acid soln. of antimony trichloride to a soln. of cæsius chloride. F. Godeffroy first gave CsCl.SbCl₃ for the formula, and later altered it to 6CsCl.SbCl₃, but C. Setterberg, W. Muthmann, and I. Remsen and A. P. Saunders showed that this is not correct. The salt can be obtained in very pale yellow prisms or needles by recrystallization from hydrochloric acid. I. Remsen and A. P. Saunders, and T. H. Behrens said that the crystals belong to the rhombic system and appear hexagonal because of trilling. The plates are stable in air; and are decomposed by heat, and by water. They are sparingly soluble in conc. hydrochloric acid, but readily soluble in the dil. acid. The salt was studied by F. Ephraim; and employed by E. H. Duclaux in the micro-detection of antimony.

J. Kendall and co-workers did not succeed in measuring the f.p. curve of *cuprous and antimonious chlorides* because of the low solubility—less than 0.3 per cent.—of the former in the latter at 300°; similar remarks apply to the system *silver and antimonious chlorides*. R. Benedikt obtained an unstable **calcium pentachloroantimonite**, CaCl₂.SbCl₃.8H₂O, by evaporating a hydrochloric acid soln. of the component salts over sulphuric acid at 0°. The colourless plates are probably triclinic; they decompose at ordinary temp. into their component salts. A. B. Poggiale made needle-like crystals of **barium pentachloroantimonite**, BaCl₂.SbCl₃.2½H₂O, by evaporating a hydrochloric acid soln. of the component salts, at a low temp. J. Kendall and co-workers did not measure the f.p. curve of the system *barium and antimonious chlorides*, because the solubility of the former in the latter is less than 0.4 per cent. at 300°. F. Ephraim prepared a crystalline mass of crystals of **beryllium pentachloroantimonite**, BeCl₂.SbCl₃.3H₂O, by evaporating a hydrochloric acid soln. of the equimolar parts of the component salts over conc. sulphuric acid. The crystals are very hygroscopic; are freely soluble in hydrochloric acid, and are decomposed by water; besides the *trihydrate*, a *tetrahydrate* was made by evaporating a similar soln. containing the component salts in the molar ratio BeCl₂ : SbCl₃ = 3 : 2. A. B. Poggiale first prepared a complex salt with magnesium chloride; and F. Ephraim obtained **magnesium octochlorodiantimonite**, MgCl₂.2SbCl₃.10H₂O, by evaporating on a water-bath a hydrochloric acid soln. of the component salts in theoretical proportions, and cooling the syrup to 40°. The crystals are very hygroscopic; melt at a gentle heat; dissolve freely in hydrochloric acid; and are decomposed by water. He also obtained **magnesium pentachloroantimonite**, MgCl₂.SbCl₃.5H₂O, from a soln. of the component salts in the proportions MgCl₂ : SbCl₃ = 1.0 to 1.5 : 1. The salt can be recrystallized from hydrochloric acid. The crystals are deliquescent, and are decomposed by water. Part of the contained antimony is volatilized at a red-heat.

P. Lohmann⁸ found that at the first moment of the action of stibine on a 5 per cent. soln. of mercuric chloride containing 10 per cent. of ammonium chloride, brown flecks of **antimony trichloromercuriate**, Sb(HgCl)₃, are formed. The compound is immediately decomposed into mercury or mercurous chloride and antimony trichloride and oxychloride. G. Franceschi obtained **antimony hydrobischloromercuriate**, SbH(HgCl)₂.3H₂O, by the action of stibine on an aq. or alcoholic soln. of mercuric chloride. The precipitate is decomposed by water—*vide* the corresponding arsenic compounds. D. Vitali obtained this compound by the action of nascent stibine on mercuric chloride soln.

F. Ephraim⁹ could not prepare a complex *aluminium chloroantimonite*.

J. Kendall and co-workers found that in the system *mercurous and antimonious chlorides*, 0.42 and 0.61 per cent. of the former in the latter gave clear soln. at 74° and 235°, but complete soln. was not obtained with 2 per cent. of HgCl at 300°. With the system *mercuric and antimonious chlorides*, there was no evidence of the formation of a compound on the f.p. curve shown in Fig. 39. Similar remarks apply to the f.p. curve of the system *aluminium and antimonious chlorides*, Fig. 40.

FIG. 39.—Freezing-point Curve of the System: $\text{HgCl}_2\text{-SbCl}_3$.

FIG. 40.—Freezing-point Curve of the System: $\text{AlCl}_3\text{-SbCl}_3$.

F. Ephraim and P. Barteczko prepared **thallous pentachloroantimonite**, Tl_3SbCl_6 , in light yellow, lustrous scales, by dissolving thallous chloride in molten antimony trichloride, and adding conc. hydrochloric acid.

FIG. 41.—Freezing-point Curve of Mixtures: $\text{SnCl}_2\text{-SbCl}_3$.

FIG. 42.—Freezing-point Curve of Mixtures: $\text{SnCl}_4\text{-SbCl}_3$.

J. Kendall and co-workers found that the f.p. curves of the system *stannous and antimonious chlorides*, show the existence of no compound, but there is a two-liquid region extending from 1.4 to 91.2 per cent. of stannous chloride in equilibrium with the solid phase $m\text{SnCl}_2 \cdot n\text{SbCl}_3$, at 243.1°—*vide* Fig. 41. The f.p. curve of mixtures of *stannic and antimonious chlorides* is shown in Fig. 42. No complex salt is

formed. A coalescence temp. in a metastable two-liquid region was observed with between 35.8 and 73.5 per cent. of stannic chloride.

§ 18. The Higher Antimony Chlorides

According to H. Rose,¹ when hydrated antimony tetroxide is dissolved in conc. hydrochloric acid, the pale yellow soln. gives a white precipitate when treated with a small proportion of water, but with more water no precipitation occurs; hydrogen sulphide precipitates antimony tetrasulphide from the soln. (*q.v.*). If this be correct, it might be inferred that the soln. contained Sb_2Cl_8 , or **antimony tetrachloride**, SbCl_4 ; but it has not been possible to isolate such a compound, although many complex salts are known which probably contain this compound. F. Ephraim and S. A. Weinberg found that on adding solid ammonium chloride to a fused mixture of antimony tri- and penta-chlorides, the liquid becomes black, and solidifies on cooling to a violet mass, which slowly loses its colour at the ordinary temp., ultimately becoming white. The dark metastable salt is best obtained by pouring the hot mixture into chloroform; it then remains for some hours without change. A. H. W. Aten's observations on the f.p. of mixtures of antimony tri- and penta-

chlorides, Fig. 43, show no evidence of the formation of the tetrachloride. Similarly with W. Biltz and K. Jeep's observations, Fig. 36. According to R. F. Weinland and H. Schmid, and F. Ephraim and S. A. Weinberg, a state of equilibrium ensues when antimony tri- and penta-chlorides are mixed in hydrochloric acid soln.:

$SbCl_3 + SbCl_5 \rightleftharpoons 2SbCl_4$. The dark brown colour of the soln. is supposed to be due to the presence of the chloride of quadrivalent antimony. The amount of tetrachloride increases as the temp. is raised, or the conc. of the hydrochloric acid is augmented. F. Ephraim and S. A. Weinberg were able to prepare **ammonium hexachlorohypoantimonate**, $(NH_4)_2SbCl_6$, and **potassium hexachlorohypoantimonate**, $2KCl.SbCl_4$, only in isomorphous mixture with tin or platinum—*e.g.* $(NH_4)_2(Sb,Pt)Cl_6$; $(NH_4)_2(Sb,Sn)Cl_6$; $K_2(Sb,Pt)Cl_6$; and $K_2(Sb,Sn)Cl_6$. O. Bosek found that when a soln. of antimony in hydrochloric acid and potassium chlorate was evaporated in vacuo, crystals of potassium pentachloroantimonate were produced—*vide supra*—there were also formed transparent, deliquescent, monoclinic, lemon-yellow crystals of **potassium henachlorodihypoantimonate**, $3KCl.2SbCl_4$. He added :

Repeated attempts were made to obtain this substance again by mixing antimony trichloride, pentachloride, and potassium chloride in different proportions and evaporating the hydrochloric soln. of these constituents in a vacuum, but the crystals could not be obtained again; it is uncertain, therefore, whether they are the double compound of the new antimony tetrachloride, $SbCl_4$, or a mixture of double salts of the trichloride and pentachloride.

R. F. Weinland and H. Schmid prepared **rubidium hexachlorohypoantimonate**, $2RbCl.SbCl_4$, by adding rubidium chloride to a hydrochloric acid soln. of equimolar proportions of antimony tri- and penta-chlorides in hot conc. hydrochloric acid. The black, microcrystalline powder is composed of octahedra. Their splinters are reddish-violet in transmitted light. The salt is decomposed by water. If the soln. of the two antimony chlorides, just indicated, is treated with rubidium chloride at ordinary temp., a complex salt **rubidium octodecachlorodiantimonitohypoantimonate**, $Rb_2SbCl_6.2Rb_3SbCl_6$, separates in brown, transparent, hexagonal plates. By working with ammonium chloride, **ammonium henachloroantimonitohypoantimonate**, $(NH_4)SbCl_5.(NH_4)_3SbCl_6$, was obtained in brown, hexagonal plates. C. Setterberg obtained black, transparent prisms of **caesium hexachlorohypoantimonate**, $2CsCl.SbCl_4$, by boiling a conc. hydrochloric acid soln. of antimony tri- and penta-chlorides with an excess of caesium chloride. H. L. Wells and F. J. Metzger said that the crystals are octahedra, and the powder in thin layers is dark blue. The dark colour of these compounds may mean that the products are not direct derivatives of the tetroxide. The crystals are said to be isomorphous with caesium hexachloroplumbate. E. H. Duclaux also made this salt. C. Setterberg found that the salt is not decomposed by conc. hydrochloric acid; but is converted into caesium enneachlorodiantimonate by the dil. acid. According to F. Ephraim and P. Barteczko, thallos chloride dissolves in molten antimony pentachloride, chlorine is evolved, and a dark violet solid **thallos pentachlorohypoantimonate**, $TlCl.SbCl_4$, is formed; and by passing chlorine into a soln. of thallos chloride in antimony trichloride, a black felted mass of **thallosic tridecachlorodihypoantimonate**, $TlCl_3.2TlCl.2SbCl_4$, is formed. R. F. Weinland and H. Schmid found that a conc. hydrochloric acid soln. of ammonium chloride, quadrivalent antimony, and tin tetrachloride furnishes **ammonium hexachlorostannatohypoantimonate**, $(NH_4)_2(Sb,Sn)Cl_6$, in dark violet crystals; and similarly, by using potassium chloride in place of the ammonium salt, **potassium hexachlorostannatohypoantimonate**, $K_2(Sb,Sn)Cl_6$, is formed. If platinum tetrachloride be used in place of tin tetrachloride, **ammonium hexachloroplatinatohypoantimonate**, $(NH_4)_2(Sb,Pt)Cl_4$, is formed in transparent, brownish-violet to opaque

FIG. 43.—Freezing-point Curve of the System: $SbCl_3-SbCl_5$.

black crystals; and also **potassium hexachloroplatinatohypoantimonate**, $K_2(Sb,Pt)Cl_6$, appears as a dark violet powder. F. Ephraim and S. A. Weinberg found that **ammonium ferric heptacosichlorotrihyoantimonate**, a ferric ammonium antimony chloride, $9NH_4Cl, 2FeCl_3, 3SbCl_4$, is obtained by mixing the chlorides in conc. hydrochloric acid and forms black octahedra. It may be regarded as $3(NH_4)_2SbCl_6 + 3NH_4Cl, 2FeCl_3$. Pyridine salts were also prepared.

H. Rose² said that **antimony pentachloride**, $SbCl_5$, not the trichloride, is produced when antimony burns in chlorine gas; and J. von Liebig obtained the pentachloride by the action of chlorine on the trichloride—*vide* Fig. 37. H. Rose obtained very little pentachloride when a soln. of hydrated antimony pentoxide in hydrochloric acid is distilled. R. Anschütz and P. N. Evans prepared the pentachloride by saturating antimony trichloride with chlorine, and distilling the product under reduced press.

Antimony pentachloride is a colourless, mobile, or pale-yellow liquid which, according to E. Moles,³ acquires an orange tint if chlorine is present. Analyses by H. Rose, and R. Anschütz and P. N. Evans, are in agreement with the formula $SbCl_5$. S. Sugden discussed the electronic structure—*vide* phosphorus pentachloride. M. Nothomb measured the **vapour density** at various temp. between 180° and 386° , and found that decomposition into antimony trichloride and chlorine occurs in a way quite analogous to phosphorus pentachloride. R. Anschütz and P. N. Evans found that the vapour density, at about 218° and 55 mm. press., is 10.03, which corresponds with the theoretical value 10.27. The vapour is probably partially dissociated at these temp., and it is supposed that equilibrium was not attained owing to the short duration of the experiment. A. Haagen gave 2.346 for the **specific gravity** of the liquid at 20° ; W. Herz gave 2.346; O. Ruff and W. Plato, 2.340 at 22.7° ; and E. Moles, 2.3356 at $20^\circ/4^\circ$. F. Kammerer found that the liquid freezes at -20° , forming a mass of acicular crystals with the **melting point** -6° . The sample was probably contaminated with chlorine because E. Moles found the m.p. to be 3° ; and W. Biltz and K. Jeep, 3.5° . H. Braune and W. Tiedje found the **vapour pressure**, p mm., to be:

	55.1°	72.1°	84.1°	93°	106.2°	111.7°	117.5°
p	7.1	16.5	28.8	43.7	76.7	95.2	119.2

R. Anschütz and P. N. Evans found that the **boiling point** is 68° at 14 mm.; 79° at 22 mm.; 102° – 103° at 68 mm.; and 143° – 144° at 70 mm. The **dissociation** is very small when the liquid is boiled under reduced press., but H. Rose found that when heated at ordinary press., the compound is dissociated into the trichloride and chlorine, and very little pentachloride distils over unchanged. R. Anschütz and P. N. Evans said that dissociation becomes appreciable between 140° – 150° ; chlorine can be observed between 160° – 170° ; and there is a lively evolution of chlorine between 180° – 190° . The dissociation was studied by M. Nothomb—*vide supra*—he gave for the equilibrium constant $K_p = a^2/(1-a^2)$, where $a = (p_0 - p)/p$, and p_0 mm. denotes the total press., and p mm. the press. of the undecomposed pentachloride $K_p = 2.22$ at 293° and 3.38 at 356° ; and H. Braune and W. Tiedje, $\log K_p = 0.548$ at 119° and 3.161 at 266° , or $\log K_p = 9.740 - 3570T^{-1}$. P. Fireman and E. G. Portner said that dissociation can be detected even at ordinary temp. because solid potassium or ammonium iodide is coloured brown in consequence of the separation of iodine by the free chlorine. E. Moles found the **heat of fusion** to be 8.17 cal.; and W. Herz gave 8.18 cal. per gram. E. Moles found the **freezing-point constant** to be 18.5. H. Braune and W. Tiedje found the **heat of vaporization** to be 11,050 cal. at 67° . J. Thomsen gave for the **heat of formation**: $SbCl_{3(solid)} + Cl_{2(gas)} = SbCl_{5(liquid)} + 13.8$ Cals.; since the heat of formation of the trichloride is 91.4 Cals., the heat of formation of the pentachloride from its elements is $Sb_{solid} + 5Cl_{gas} = SbCl_{5(liquid)} + 104.8$ Cals. Hence, 30.5 Cals. per atom are evolved with the fixing of the first three atoms of chlorine, and 6.7 Cals. per atom with the fourth and fifth atoms. H. Braune and

W. Tiedje gave for $\text{SbCl}_{3\text{gas}} + \text{Cl}_{2\text{gas}} = \text{SbCl}_{5\text{gas}} + 17$ Cals. at 200° . H. Becquerel found the **index of refraction** of the pentachloride for Na-light is 1.5910; and the **electromagnetic rotatory power**, 1.656. C. R. Crymble measured the **absorption spectrum** of the pentachloride. W. Herz gave 238×10^{12} for the **vibration frequency**. H. Buff, and L. Bleekrode found the **electric conductivity** is very small, and P. Walden regarded the salt as a non-conductor, but found that when dissolved in liquid sulphur dioxide at 0° the eq. conductivities in 11.3, 46.0, and 224.0 litres are respectively 0.212, 0.737, and 27.29. The dissolved pentachloride is not ionized. H. Schlundt found the **dielectric constant** to be 3.58 at 21.5° .

Antimony pentachloride fumes in air and has a sharp acid odour; it is very hygroscopic and rapidly attracts moisture from the air, forming a crystalline hydrate. These hydrates are produced by a small proportion of **water**, but a large proportion yields hydrates of antimony pentoxide (*q.v.*). R. Anschütz and P. N. Evans⁴ prepared **monohydrated antimony pentachloride**, $\text{SbCl}_5 \cdot \text{H}_2\text{O}$, as a yellow crystalline mass, by slowly adding the calculated quantity of water to the well-cooled pentachloride; or by cooling a mixture of the calculated quantity of water with a chloroform soln. of the pentachloride. No hydrogen chloride is given off. It can be crystallized from its soln. in chloroform. The yellowish-white plates melt between 87° and 92° ; and when heated to 105° at 20 mm. press., antimony pentachloride distils over; the last fraction contains some trichloride, and a waxy mass remains. H. Daubrawa's antimony trichloride is probably this hydrate, which when heated under ordinary press., gives off chlorine but not water. The monohydrate deliquesces in air, forming a clear liquid which yields acicular crystals when evaporated over sulphuric acid. The compound is hydrolyzed by water, forming hydrated pentoxide; conc. soln. of sodium carbonate precipitate antimony trioxide. The monohydrate is soluble in alcohol, and in chloroform. When the alcoholic soln. is evaporated, hydrogen chloride is evolved, and there remains a viscid yellow mass which with water forms a white precipitate, and alcohol. When the monohydrate is heated with chloroform in a closed tube, or in an open vessel on a water-bath, the reaction is symbolized: $\text{SbCl}_5 \cdot \text{H}_2\text{O} + \text{CHCl}_3 = \text{COCl}_2 + 3\text{HCl} + \text{SbCl}_3$; and carbonyl chloride is also formed when the monohydrate is heated in carbon tetrachloride. H. Rose, and R. Weber obtained **tetrahydrated antimony pentachloride**, $\text{SbCl}_5 \cdot 4\text{H}_2\text{O}$, by mixing the pentachloride with as little water as is necessary for its soln., and evaporating the liquid over sulphuric acid; or, according to R. Anschütz and P. N. Evans, by adding the calculated quantity of water to a well-cooled soln. of the pentachloride in twice its vol. of chloroform, and keeping the liquid in vacuo for crystallization. The mass of colourless, transparent, rhombic crystals gradually become opaque in dry air; they deliquesce in air without becoming turbid; water hydrolyzes the compound, forming the hydrated pentoxide, but the tetrahydrate can be obtained by crystallization from its soln. in a small proportion of water. The tetrahydrate is insoluble in chloroform. H. B. Kosmann made some observations on these hydrates.

E. Beckmann found that antimony pentachloride is insoluble in liquid **chlorine**; W. Biltz and K. Jeep found that antimony pentachloride can react with chlorine, forming **antimony enneachloride**, $\text{SbCl}_5 \cdot 2\text{Cl}_2$. E. Beckmann found that antimony pentachloride dissolves in conc. **hydrochloric acid**, forming chloroantimonic acids—*vide infra*. R. Engel reported crystals of *antimony pentachloropentahydrochloride*, $\text{SbCl}_5 \cdot 5\text{HCl} \cdot 10\text{H}_2\text{O}$, by passing a current of hydrogen chloride through an aq. soln. of tetrahydrated antimony pentachloride, and cooling the soln. to 0° . The crystals are said to be stable in air. R. F. Weinland and H. Schmid could not verify these statements. O. Ruff found that **bromine** does not react with antimony pentachloride, but it does react with **iodine**. The main results are symbolized by the three equations: (i) $\text{SbCl}_5 + 2\text{I} = \text{SbCl}_3 + 2\text{ICl}$; (ii) $2\text{SbCl}_5 + 2\text{I} = \text{SbCl}_5 + 2\text{ICl} + \text{SbCl}_3$; (iii) $3\text{SbCl}_5 + 4\text{I} = \text{SbCl}_5 \cdot 3\text{ICl} + 2\text{SbCl}_3 + \text{ICl}$. Equation (i) represents the reaction which takes place when less than 1.5 per cent. of iodine is dissolved in the

antimony pentachloride. Some iodine trichloride, antimony tri-iodide, and possibly a chloro-iodide of quinquevalent antimony are formed in addition, but no evidence can be adduced of the formation of a compound, SbCl_5I , analogous to SbF_5I . E. Moles found the mol. wt. of iodine, and of the iodine chlorides from their effect on the f.p. of antimony trichloride. E. Moles found that antimony pentachloride and **potassium iodide** form iodine monochloride; while **sulphur, selenium, and tellurium** furnish double compounds of their tetrachlorides with antimony pentachloride. S. Cloëz, and A. Bertrand and E. Finot observed that with **hydrogen sulphide**, antimony sulphotrichloride is formed—*vide supra*, reactions of antimony. W. Biltz and H. Krunecke found antimony pentachloride is thiohydrolyzed by dry liquid hydrogen sulphide. H. Rose, O. Ruff and W. Plato, O. Ruff and G. Fischer, and R. Weber obtained a complex $\text{SbCl}_5 \cdot \text{SbCl}_4$ with **sulphur tetrachloride**; R. Weber, $\text{SbCl}_5 \cdot \text{SeCl}_4$ with **selenium tetrachloride**; and $\text{SbCl}_5 \cdot \text{SeOCl}_2$ with **selenium oxydichloride**. The reduction of antimony pentachloride in hydrochloric acid soln. by means of **sulphur dioxide** or by **sulphites** was examined by G. von Knorre, B. Brauner, and A. Jolles. H. Friedrich observed that hot and cold **sulphuric acid** reacts with the pentachloride. F. Clausnizer found that equimolar parts of antimony pentachloride and **chlorosulphonic acid** form a greenish-yellow liquid which, when gently heated, gives off chlorine, hydrogen chloride, and sulphur dioxide and becomes brown; at 160° , a white crystalline mass is formed which is hydrolyzed by water. If equimolar parts of chlorosulphonic acid and antimony pentachloride be heated in a sealed tube on the water-bath, no decomposition occurs; nor does any appreciable reaction occur if the mixture be exposed to sunlight for a month.

H. Rose found that **ammonia** is strongly absorbed by antimony pentachloride, forming a brown substance which when warmed becomes colourless without any other perceptible change; and it then sublimes. J. Persoz's analysis agrees with antimony hexamminopentachloride, $\text{SbCl}_5 \cdot 6\text{NH}_3$, and J. Persoz represented the action of water: $\text{SbCl}_5 \cdot 6\text{NH}_3 + 3\text{H}_2\text{O} = \text{NH}_4\text{SbO}_3 + 5\text{NH}_4\text{Cl}$. A. Rosenheim and F. Jacobsohn obtained a white crystalline powder by the action of liquid ammonia on monohydrated antimony pentachloride, but no definite formula could be assigned to the product. P. P. Déherain found that when ammonia is passed into a cold soln. of antimony pentachloride, and the red substance is heated in a retort, ammonium octochloroantimonate sublimes, and crystalline needles of **antimony triamminopentachloride**, $\text{SbCl}_5 \cdot 3\text{NH}_3$, are formed. Hydrochloric acid converts it into the ammonium octochloroantimonate. There is simultaneously produced volatile **antimony tetramminopentachloride**, $\text{SbCl}_5 \cdot 4\text{NH}_3$, which is converted by hydrochloric acid into ammonium ennechloroantimonate. A. Besson found that antimony pentachloride unites with **nitric oxide**, forming yellow crystals of **antimony heminitrosylpentachloride**, $2\text{SbCl}_5 \cdot \text{NO}$. It forms good crystals when heated for some hours in a sealed tube at 100° ; it is decomposed by water. With **nitrogen peroxide**, A. Besson obtained **antimony dinitroxytrispentachloride**, $3\text{SbCl}_5 \cdot 2\text{NO}$, which after heating in a sealed tube at 100° for some time furnished yellow crystals which are decomposed by water. R. Weber found that when the vapour from **aqua regia** is passed into antimony pentachloride a yellow, hygroscopic powder of **antimony chloronitrosylpentachloride**, $\text{SbCl}_5 \cdot \text{NOCl}$, is formed. It is decomposed by water. J. J. Sudborough found that **nitrosyl chloride** reacts with antimony pentachloride, forming lemon-yellow crystals of **antimony hemipentachloronitrosylpentachloride**, $2\text{SbCl}_5 \cdot 5\text{NOCl}$. It is decomposed by water. W. J. van Heteren heated it in a sealed tube at 180° without decomposition. H. Rose found that antimony pentachloride absorbs **phosphine** with the evolution of a little hydrogen chloride, forming a red solid which, with water, and aq. ammonia, gives off phosphine. R. Mahn did not obtain this compound, and he represented the reaction: $\text{PH}_3 + 4\text{SbCl}_5 = 4\text{SbCl}_3 + \text{PCl}_5 + 3\text{HCl}$. P. Fireman found that, in an open vessel, the pentachloride reacts explosively with **phosphonium iodide**, forming iodine, etc.; and in a sealed tube so arranged that the substances only come

in contact when heated, the reaction can be represented: $3\text{PH}_4\text{I} + 3\text{SbCl}_5 = \text{SbI}_3 + 2\text{SbCl}_3 + 9\text{HCl} + 2\text{P} + \text{PH}_3$. R. Weber, and A. W. Cronander obtained **antimony phosphorus decachloride**, $\text{PCl}_5 \cdot \text{SbCl}_5$, by heating a mixture of **phosphorus pentachloride** and antimony pentachloride, and by the action of an excess of phosphorus pentachloride on antimony trichloride: and H. Köhler, by the action of a mol of **phosphorus trichloride** on 2 mols of antimony pentachloride dissolved in chloroform. The yellow crystals of the complex decachloride, when heated, volatilize without melting; and they are decomposed by water. T. Karantassis also made the complex **phosphorus diantimony pentadecachloride**, $\text{PCl}_5 \cdot 2\text{SbCl}_5$. R. Weber found that with **phosphoryl chloride**, a white, deliquescent, crystalline mass of **antimony phosphoryl octochloride**, $\text{SbCl}_5 \cdot \text{PCl}_3$, is formed. T. Karantassis observed that **phosphorus triiodide** reacts by double decomposition with antimony pentachloride, but the reverse action does not occur. C. von Uslar found that **phosphoric acid** has no action on a hydrochloric acid soln. of antimony pentachloride.

J. Tarble represented the reaction with **boron tribromide**: $3\text{SbCl}_5 + 5\text{BBr}_3 = 5\text{BCl}_3 + 3\text{SbBr}_3 + 3\text{Br}_2 + 9\text{I}$ cal. When antimony chloride is mixed with a half-molar proportion of **carbon disulphide**, A. W. Hofmann observed that in a short time a vigorous reaction occurs: $2\text{SbCl}_5 + \text{CS}_2 = \text{CCl}_4 + 2\text{SbCl}_3 + 2\text{S}$; A. Bertrand and E. Finot said that if the mixture be cooled before the vigorous reaction occurs, crystals of antimony sulphotrichloride are formed: $2\text{SbCl}_5 + \text{CS}_2 = 2\text{SbSCl}_3 + \text{CCl}_4$; and when warmed, these decompose: $2\text{SbSCl}_3 = 2\text{SbCl}_3 + 2\text{S}$. According to A. Husemann, if the vapour of carbon disulphide be passed through a red-hot tube—*vide* 6. 39, 42—and then over antimony pentachloride, carbon tetrachloride and sulphur monochloride are formed. As emphasized by A. W. Hofmann, antimony pentachloride is a good chlorinating agent for **organic compounds**. Lassar Cohn has discussed this subject. H. Müller chlorinated benzene, and arsenic acid; R. Anschütz and P. N. Evans, oxalic acid. Antimony pentachloride also reacts with many organic compounds, *e.g.*, R. F. Weinland and H. Schmid, and A. Rosenheim and co-workers prepared compounds with pyridine; L. Klein, with hydrogen cyanide and cyanogen chloride; W. C. Williams, with acetylene, alcohols, and ethers; A. Rosenheim and co-workers, with aldehydes, ketones, organic acids, acid amides, and chlorides, acid anhydrides, oxy-acids, and nitrobenzene, but not with quinoline, phenols, and hydrocarbons. K. Steiner and co-workers, T. Diehl, A. Zetter, and V. Merz and W. Weith studied the effect of antimony pentachloride on anthraquinone, fluorenone, phenanthrene, phenanthraquinone, xanthone, acridone, methylacridone, benzophenone, benzoic acid, benzoyl chloride, and benzoylbenzoic acid: S. Hilpert and L. Wolf, on benzene, naphthalene, phenanthrene, carbazole, anthraquinone, fluorene, diphenyl methane, and triphenyl methane; and P. Pfeifer, ethyl oxalate. T. S. Thomsen studied compounds of the pentachloride with many alkaloids—quinine, cinchonine, cinchonidine, morphine, codeine, strychnine, cocaine, caffeine, and nicotine. Summaries of the organic compounds of antimony will be found in G. T. Morgan's *Organic Compounds of Antimony* (London, 1918); and W. G. Christiansen's *Organic Derivatives of Antimony* (New York, 1925). R. Mahn found that **silane** reduces the pentachloride to trichloride, forming silicon tetrachloride.

A. C. Vournasos observed that antimony pentachloride, in boiling toluene soln., reacts like the trichloride towards **potassium**. The action of **metals**, and of **alkali hydroxides and carbonates** on hydrochloric acid soln. of antimony pentachloride, has been previously discussed. L. Wolf studied the reducing action of **mercury** on the pentachloride. The retarding action of the presence of tartaric acid on the precipitation by alkali hydroxides and carbonates was observed by H. Rose, and C. A. Winkler; of aq. ammonia, and potassium cyanide, by C. A. Winkler; and of magnesium sulphate and ammonia, by E. Lesser. The retarding action of oxalic acid on the precipitation by water, and aq. ammonia was observed by C. Luckow. The reducing action of **stannous chloride** was discussed by A. Streng, F. Weil, and F. Jean; F. Kessler found that the soln. is not reduced

by **ferrous salts**; and H. N. Warren, that **potassium ferrocyanide** has no action.

Chloroantimonic acids and chloroantimonates.—A number of complex salts formed by the union of metal chlorides with antimony pentachloride have been prepared. R. F. Weinland and co-workers⁵ consider them to be salts of a series of hypothetical complex chloroantimonic acids analogous with the hypothetical antimonic acids.

Orthoantimonic acid, H_3SbO_4
 Pyroantimonic acid, $H_4Sb_2O_7$
 Metantimonic acid, $HSbO_3$

Orthochloroantimonic acid, H_3SbCl_8
 Pyrochloroantimonic acid, H_2SbCl_7
 Metachloroantimonic acid, $HSbCl_6$

There are also some organic derivatives of pyridine, quinoline, and dimethylaniline which can be referred to more complex acids—*e.g.* to $H_6Sb_4O_{13}$, or $4H_3SbO_3 \cdot 6HCl$. A. Rosenheim and W. Stellmann also prepared a quinoline salt, $H_3Sb_2Cl_{13} \cdot 3C_9H_7N$. According to P. Pfeifer, this hypothesis of the constitution of these acids means that the chlorine and antimony are all contained in the negative radicle, and that the positive radicle is free from chlorine. He thinks that this does not explain the constitution of the chromium salts—*vide infra*. Neither **orthochloroantimonic acid**, H_3SbCl_8 , nor **pyrochloroantimonic acid**, H_2SbCl_7 , is known in the free state, although ferric and chromic salts can be referred to the former, and magnesium, and quinoline salts to the latter. R. F. Weinland and H. Schmid prepared **metachloroantimonic acid**, $HSbCl_6 \cdot 4\frac{1}{2}H_2O$, by dissolving antimony trioxide in twice its weight of conc. hydrochloric acid; saturating the soln. with chlorine; concentrating the liquid on the water-bath; saturating the soln. with hydrogen chloride; and allowing the soln. to crystallize over sulphuric acid at a temp. not exceeding 0° . The greenish-yellow, prismatic crystals are very hygroscopic, but gradually effloresce over sulphuric acid. The compound forms clear soln. with water, alcohol, acetone, and acetic acid; the aq. soln. deposits hydrated antimony pentoxide after standing some time, but it remains clear if 10 per cent. of hydrochloric acid is present; nitric acid also retards the precipitation. The soln. in organic solvents remains clear even when boiled. Addition products are formed with ammonia, pyridine, and quinoline. White, four-sided, pyramidal crystals of **diamminometachloroantimonic acid**, $HSbCl_6 \cdot 2NH_3$, are formed by treating a soln. of the acid with an excess of ammonia. The aq. soln. in water is opalescent and feebly acid; the acid is soluble in alcohol. The salts with pyridine were $HSbCl_6 \cdot C_2H_5N$, and $HSbCl_6 \cdot 2C_5H_5N$; and with quinoline, $HSbCl_6 \cdot C_9H_7N$, and $HSbCl_6 \cdot 2C_9H_7N$. Alkali hydroxides and carbonates precipitate hydrated antimony pentoxide. It is inferred that two ions are produced in aq. soln. because the mol. wt. deduced from the f.p. is about half that required for $HSbCl_6 \cdot 4\frac{1}{2}H_2O$. A soln. of silver nitrate does not immediately give a precipitate with the acid. This is taken to mean that the ions are H^+ and $SbCl_3'$.

P. Fireman heated theoretical proportions of ammonium chloride and antimony pentachloride in a sealed tube at 230° – 250° for 12 hrs. and obtained a compact mass of **ammonium metachloroantimonate**, $NH_4Cl \cdot SbCl_5$, which when heated to 350° decomposes: $3NH_4SbCl_6 = 3SbCl_3 + 8HCl + NH_4Cl + N_2$. R. F. Weinland and C. Feige obtained the monohydrate from a soln. of the two chlorides in dil. hydrochloric acid evaporated over sulphuric acid. R. F. Weinland and F. Schlegelmilch at first thought the salt was constituted $NH_4SbCl_6 \cdot NH_4SbCl_5(OH)$. The rhombic crystals have the axial ratios $a : b : c = 0.8909 : 1 : 0.7748$. P. P. Déherain also reported red, hexagonal plates of **ammonium octochloroantimonate**, $3NH_4Cl \cdot SbCl_5$, or orthochloroantimonate, $(NH_4)_3SbCl_8$, by the action of hydrochloric acid on antimony triaminopentachloride, and reddish cubes or octahedra of **ammonium ennechloroantimonate**, $4NH_4Cl \cdot SbCl_5$, by the action of hydrochloric acid on the tetramminopentachloride, or from a soln. of ammonium chloride and antimony pentachloride. A. Gutbier and W. Haussmann prepared salts with pyridine, and quinoline; and F. Ephraim and S. Weinberg, salts with methyl- and ethyl-ammonium.

R. F. Weinland and C. Feige obtained rectangular, four-sided, hygroscopic plates of **lithium metachloroantimonate**, $\text{LiSbCl}_6 \cdot 4\text{H}_2\text{O}$; but did not succeed in making **sodium metachloroantimonate**. They made **potassium metachloroantimonate**, $\text{KSbCl}_6 \cdot \text{H}_2\text{O}$, which R. F. Weinland and F. Schlegelmilch represented by the formula $\text{KSbCl}_6 \cdot \text{KSbCl}_5(\text{OH})$. The rhombic crystals, isomorphous with the ammonium salt, were shown by R. F. Weinland and C. Feige to have the axial ratios $a : b : c = 0.8889 : 1 : 0.7794$. The crystals gradually become moist in air; and effloresce when dried over sulphuric acid or calcium chloride; and R. F. Weinland and H. Schmid found that they behave towards silver nitrate like the free acid. The rhombic crystals of **rubidium metachloroantimonate**, RbSbCl_6 , were found by R. F. Weinland and C. Feige to have the axial ratios $a : b : c = 0.6719 : 1 : 0.8136$. The corresponding **caesium metachloroantimonate**, CsSbCl_6 , was obtained by C. Setterberg, and H. L. Wells and F. J. Metzger by crystallization from a soln. of the component salts. E. H. Duclaux also made this salt. The salt is decomposed by water.

According to R. F. Weinland and H. Schmid, sky-blue prisms of **copper pentamminometachloroantimonate**, $\text{Cu}(\text{SbCl}_6)_2$, are obtained from a mixture of the acid and a cupric salt, and not too great an excess of ammonia. The crystals become green by the loss of ammonia, but the blue colour is restored in ammonia. An ultramarine salt with pyridine in place of ammonia was also prepared. Golden-yellow, hexagonal plates of **silver diamminometachloroantimonate**, $\text{AgSbCl}_6 \cdot 2\text{NH}_3$, were obtained; they gradually become white and finally violet; the salt is decomposed by water. A pyridine salt was also prepared. L. Lindet found that antimony pentachloride dissolves auric chloride without forming **gold chloroantimonate**. R. F. Weinland and C. Feige prepared long, hygroscopic needles of **calcium metachloroantimonate**, $\text{Ca}(\text{SbCl}_6)_2 \cdot 9\text{H}_2\text{O}$, and R. F. Weinland and F. Schlegelmilch previously assigned the formula $\text{SbCl}_5 \cdot \text{SbCl}_4(\text{OH}) \cdot \text{CaCl}_2 \cdot 9\text{H}_2\text{O}$ to a similar product. R. F. Weinland and C. Feige obtained no **strontium chloroantimonate**, or **barium chloroantimonate**, but they prepared **beryllium metachloroantimonate**, $\text{Be}(\text{SbCl}_6)_2 \cdot 10\text{H}_2\text{O}$, in small, yellow, hygroscopic needles; greenish-yellow, hygroscopic triclinic plates of **magnesium pyrochloroantimonate**, $\text{Mg}(\text{SbCl}_7) \cdot 10\text{H}_2\text{O}$, or $[(\text{Cl})\text{Mg}(\text{H}_4\text{O}_2)_5]\text{SbCl}_6$, were obtained with the axial ratios $a : b : c = 0.714 : 1 : 2.595$, and $\alpha = 100^\circ 22'$, $\beta = 88^\circ 3'$, and $\gamma = 91^\circ 16'$. R. F. Weinland and H. Schmid found that silver nitrate precipitated from the soln. about one-fourth the chlorine. They also prepared **zinc tetramminometachloroantimonate**, $\text{Zn}(\text{SbCl}_6)_2 \cdot 4\text{NH}_3$, from an ammoniacal soln. of the acid, and a zinc salt. It appears as a white, crystalline powder; and a pale yellow crystalline powder of **cadmium heptamminometachloroantimonate**, $\text{Cd}(\text{SbCl}_6)_2 \cdot 7\text{NH}_3$, has also been reported. No **mercury chloroantimonate** was obtained.

R. F. Weinland and C. Feige prepared **aluminium metachloroantimonate**, $\text{Al}(\text{SbCl}_6)_3 \cdot 15\text{H}_2\text{O}$, in yellowish-green, hygroscopic needles. F. Ephraim and P. Barteczko obtained a yellow **thallous metachloroantimonate**, TlSbCl_6 , by the action of thallous chloride on fused antimony pentachloride. The product decomposes very rapidly into the violet chlorohypoantimonate (*q.v.*). R. F. Weinland and C. Feige obtained **chromium metachloroantimonate**, $\text{Cr}(\text{SbCl}_6)_3 \cdot 13\text{H}_2\text{O}$, in violet-grey, hygroscopic needles. The cold soln. in hydrochloric acid is bluish-violet, and green when hot. They also prepared **chromium orthochloroantimonate**, $\text{CrSbCl}_8 \cdot 10\text{H}_2\text{O}$, in green, hygroscopic plates. The soln. in dil. hydrochloric acid is green, and when the soln. is mixed with tartaric acid, silver nitrate precipitates the whole of the chlorine after some time. P. Pfeifer also prepared the chromium salts, and objects to the view that $\text{CrCl}_3 \cdot \text{SbCl}_5 \cdot 10\text{H}_2\text{O}$ is a derivative of an orthoacid. The soln. obtained with each of the chromium salts by removing the antimony with hydrogen sulphide are not the same. In the one case a violet soln., and in the other, a green soln. is formed. These soln. are identical with those of the compounds $[\text{Cr}_2(\text{OH})_2]_3\text{Cl}_3$ and $[\text{Cr}(\text{OH})_4\text{Cl}_2]\text{Cl} \cdot 2\text{H}_2\text{O}$. The salts of R. F. Weinland and C. Feige should be formulated thus: $[\text{SbCl}_6]_3[\text{Cr}(\text{OH})_2]_6 \cdot 7\text{H}_2\text{O}$

(violet), and $[\text{SbCl}_6][\text{Cr}(\text{OH}_2)_4\text{Cl}_2] \cdot 6\text{H}_2\text{O}$ (green). In the violet salt, the chlorine atoms are in the negative radicle, but in the green salt they are divided between both radicles. P. Pfeifer also believed that the majority of the salts containing quinquevalent antimony can be referred to the co-ordination type $\text{M}[\text{SbCl}_6]$. P. Pfeifer prepared **chromium dichlorodiethylenediaminoantimony pentachloride**, $[\text{Cr}(\text{C}_4\text{H}_8\text{N}_2\text{H}_2)_2\text{Cl}_2]\text{SbCl}_5$, by the action of the pentachloride on the violet cis-compound $[\text{Cr}(\text{C}_4\text{H}_8\text{N}_2\text{H}_2)_2\text{Cl}_2]\text{Cl}$; and from the trans-compound $[\text{Co}(\text{C}_4\text{H}_8\text{N}_2\text{H}_2)_2\text{Cl}_2]\text{Cl}$, he obtained **cobalt dichlorodiethylenediaminoantimony pentachloride**, $[\text{Co}(\text{C}_4\text{H}_8\text{N}_2\text{H}_2)_2\text{Cl}_2]\text{SbCl}_5$. The antimony was removed by hydrogen sulphide and from the respective filtrates derivatives containing two atoms of chlorine were obtained. This shows that the constitution is that just indicated, and agrees with the assumption that the chromium salt is constituted $[\text{Cr}(\text{H}_2\text{O})_4\text{Cl}_2]\text{SbCl}_5$. No **manganese chloroantimonate** was obtained by R. F. Weinland and co-workers. R. F. Weinland and C. Feige prepared **ferric orthochloroantimonate**, $\text{FeSbCl}_8 \cdot 8\text{H}_2\text{O}$, or $[(\text{Cl}_2)\text{Fe}(\text{H}_4\text{O}_2)_4]\text{SbCl}_6$, in yellow, hygroscopic, four-sided, tetragonal tablets with the axial ratio $a : c = 1 : 1.0112$. P. Pfeifer represented the iron salts by $\text{Fe}[\text{SbCl}_8] \cdot 8\text{H}_2\text{O}$ and $[\text{SbCl}_6][\text{Fe}(\text{H}_2\text{O})_4\text{Cl}_2]4\text{H}_2\text{O}$. No **cobalt chloroantimonate** was obtained; but R. F. Weinland and H. Schmid obtained a pale green, crystalline powder of **nickel hexamminometachloroantimonate**, $\text{Ni}(\text{SbCl}_6)_2 \cdot 6\text{NH}_3$.

H. L. Wells⁶ described the deeply coloured **caesium dodecachloroantimonite-antimonate**, $\text{Cs}_4\text{Sb}^{IV}\text{Cl}_{12}$, and argued that in general complex salts containing the same metal in different states of valency are highly coloured, and he suggests that there is a constant exchange of electrons between the atoms of different valency and that this activity of electrons affects the passage of light, producing colours or opacity.

§ 19. Antimony Bromides

A. J. Balard¹ obtained antimony bromide by the direct union of antimony (*q.v.*) and bromine. For the preparation of **antimony tribromide**, SbBr₃, G. S. Sérullas introduced into a retort containing bromine, powdered dry antimony in small portions at a time, agitating the retort after each admixture, and when combustion had ceased, the bromide was distilled from the excess of antimony. The neck of the retort was kept hot to prevent its being blocked by the sublimate. J. Nicklès added an excess of powdered antimony to a cooled soln. of bromine in twice its weight of carbon disulphide, and evaporated the liquid for crystallization. J. P. Cooke used a similar process distilling off first the solvent, and then the tribromide; the product can be purified by recrystallization from carbon disulphide, or by the sublimation in a current of carbon dioxide. A. Raynaud covered a layer of finely-powdered antimony in a flat-bottomed flask with a layer of dry ether, and slowly added five parts of bromine; the mixture was heated with a reflux condenser for 3 hrs. Crystals of *antimony ethyl oxy-pentabromide*, SbBr₅(C₂H₅)₂O, were formed. When the crystals are allowed to stand under a bell-jar for some weeks, or over sulphuric acid, they lose bromine and ether, and form antimony tribromide. The crystals lose ether above 55°, forming *antimony pentabromide*, SbBr₅, and this loses bromine at 78°–88°. R. W. E. MacIvor obtained the tribromide by heating an intimate mixture of antimony sulphate and dry potassium bromide: Sb₂(SO₄)₃+6KBr=3K₂SO₄+2SbBr₃. G. Oddo and U. Giachery prepared the tribromide by distillation from a stoichiometrical mixture of arsenic trioxide, sulphur, and halogen; and A. C. Vournasos, by the action of acetic acid, antimony trioxide, and potassium bromide at 100°.

Analyses by G. S. Sérullas, R. W. E. MacIvor, and J. P. Cooke agree with the

formula SbBr_3 ; and the **vapour density** observed by C. P. Worcester, 12.57, is in agreement with the value 12.43 calculated for SbBr . The colourless, acicular **crystals** obtained by sublimation, and the tabular crystals obtained from the soln. in carbon disulphide were found by J. P. Cooke to belong to the rhombic system and to have the axial ratios $a:b:c=0.817:1:0.869$; C. B. Slawson gave 0.7808:1:1.1645. J. Nicklès also made some observations on the crystals. J. P. Cooke, and W. Herz gave 4.148 for the **specific gravity** at 23° ; H. Kopp gave for sp. gr. of the molten tribromide 3.641 at 90° ; and R. W. E. MacIvor, 3.473 at 96° . F. Ephraïm calculated that a 12.5 per cent. contraction occurs in the formation of the tribromide. J. D. Sullivan discussed its use as a heavy liquid for mineralogical analyses. S. Motylewsky found the drop-weight to be 67 when that of water at 0° is 100. W. Biltz studied the **molecular volume**. I. I. Saslowsky calculated a 1.14 per cent. contraction in the formation of this compound from its elements. F. Schuster calculated for the **internal pressure**, 2013 atm. L. von Pebal and H. Jahn gave 0.0709 for the **specific heat** between 33° and 0° ; 0.0613 between 0° and -21° ; and 0.0640 between -21° and -80° . G. S. Sérullas, and W. Biltz and K. Jeep found the **melting point** to be 94° ; E. K. Rideal, 94.2° ; H. Kopp, N. A. Puschin and S. Löwy, and R. W. E. MacIvor, 90° ; J. Kendall and co-workers, 96.6° ; and J. P. Cooke, and G. B. Bernardis, 93° . The molten compound, added H. Kopp, is brown. S. Tolloczko found the **freezing-point constant** to be 267; and this subject was examined by F. Garelli and V. Bassani. W. Finkelstein found that the lowering of the f.p. of bromine shows that complexes are formed; the soln. is also an electrical conductor—*vide* arsenic tribromide. S. Tolloczko and M. Meyer, and W. Herz gave 9.76 cal. for the latent **heat of fusion** per gram, or 3.51 Cals. per mol. E. K. Rideal obtained for the mol. **heat of vaporization** 3.5 Cals. G. S. Sérullas found the **boiling point** to be 270° ; H. Kopp, 275.4° ; R. W. E. MacIvor, 283° ; J. P. Cooke, and L. Rotinjanz and W. Suchodsky, 280° ; and R. Anschütz and H. Weyer, 275° at 760 mm., and 143° at 11 mm. L. Rotinjanz and W. Suchodsky gave 631.5° for the **critical temperature**, and they gave 0.613 for the ratio T_m/T_c ; M. Prud'homme, and E. van Aubel found the relation between the m.p., b.p., and the critical temp. to be normal. A. Guntz found the **heat of formation** to be $\text{Sb}_{\text{solid}} + 3\text{Br}_{\text{gas}} = \text{SbBr}_{3\text{solid}} + 76.9$ Cals. For the electrolysis of soln. of the tribromide, *vide supra*, explosive antimony. W. Herz gave 2.03×10^{12} for the **vibration frequency**. W. A. Isbekoff studied the **decomposition voltage** of the tribromide, and W. Finkelstein found that in ethyl acetate soln., and in nitrobenzene soln., the decomposition voltage is 0.63 volt.

When antimony tribromide is freshly prepared, J. P. Cooke found it to be colourless. It is hygroscopic, and G. S. Sérullas observed that it is decomposed by **water** with the separation of oxybromide; but, added J. P. Cooke, the oxybromide is not precipitated if tartaric acid be present. When the carbon disulphide

FIG. 44.—Freezing-point Curves of the System: SbBr_3 - Br_2 .

soln. is exposed to air and light, an oxybromide is formed (*q.v.*). W. Biltz and K. Jeep measured the f.p. curve of mixtures of bromine and antimony tribromide. The results are summarized in Fig. 44. P. Walden found the tribromide is soluble in **sulphur monochloride**. C. Löwig found that the tribromide is decomposed by **sulphuric acid**. G. Gore found that antimony bromide is soluble in liquid **ammonia**. V. Thomas observed no reaction when **nitric oxide** is passed into a chloroform soln. of the tribromide, but with **nitrogen peroxide**, white antimony nitratobis-pentoxide, $2\text{Sb}_2\text{O}_5 \cdot \text{N}_2\text{O}_5$, is formed. C. Löwig showed that **nitric acid** has no action in the cold, but when heated bromine is evolved, and antimony nitrate is formed. W. Ramsay and R. W. E. MacIvor obtained antimony phosphide (*q.v.*) by the action of **phosphorus** on a chloroform soln. of the tribromide. P. Walden showed that the tribromide is freely soluble in **phosphorus trichloride and tribromide**. J. W. Retgers

found that antimony tribromide is dissolved by a warm soln. of **arsenic tribromide**, forming a mixture which melts at 47° and has a sp. gr. 3.685. N. A. Puschin and S. Löwy's f.p. curve for mixtures of antimony and arsenic tribromides, Fig. 45, shows that no compound is formed—only a series of solid soln. J. Tarible observed no reaction when antimony tribromide dissolves in **boron tribromide**. J. P. Cooke found that hot absolute **alcohol** converts the tribromide into the oxybromide. According to J. Nicklès, the tribromide is soluble in **carbon disulphide**; and with **ether**, the soln. separates into two layers, the lower viscid layer is a compound with ether. F. Oberhauser studied the reaction with **cyanogen bromide**. A. Naumann found the tribromide is soluble in **acetone**. B. N. Menshutkin measured the solubility of the tribromide in a number of organic liquids. Expressing the results in mols of tribromide per 100 mols of solvent, he found for **benzene** :

N. A. Puschin and S. Löwy measured the f.p. curves of binary mixtures of

antimony tribromide with resorcin, phenol, aniline chloride, α -naphthol, and ethylurethane. E. Kordes discussed the eutectic with triphenylmethane. J. A. Hayes prepared a compound with **pyridine**. Antimony tribromide reacts with a number of other **organic compounds**. Thus, B. N. Menschutkin obtained compounds with the chlorotoluenes, nitrotoluenes, benzaldehyde, benzonitrile, substituted benzenes, xylenes, toluenes, aniline, etc. E. Vanstone studied the action of the tribromide on a number of aromatic compounds; and F. Ephraim and S. Weinberg, on methylamine. For the action of antimony tribromide on organic halides, *vide infra*, antimony triiodide. N. S. Kurnakoff studied the viscosity and f.p. of mixtures of antimony tribromide and triphenylmethane, benzophenone, and acetophenone. W. A. Isbekoff found that the tribromide is soluble in **aluminium bromide**.

A number of compounds with other bromides have been prepared; and R. W. Atkinson made some mixed halides—*vide infra*. R. M. Caven prepared pale yellow hexagonal plates of **ammonium hexadecabromotriantimonite**, $7\text{NH}_4\text{Br}\cdot 3\text{SbBr}_3$, by adding an excess of glacial acetic acid to a conc. aq. soln. of the two halides and the halogen acid. He also obtained **ammonium enneabromodiantimonite**, $3\text{NH}_4\text{Br}\cdot 2\text{SbBr}_3$, in yellow prisms. C. H. Herty prepared yellow rhombic crystals with the composition: $23\text{KBr}\cdot 10\text{SbBr}_3\cdot 27\text{H}_2\text{O}$; which H. J. Wheeler would represent $7\text{KBr}\cdot 3\text{SbBr}_3\cdot n\text{H}_2\text{O}$ —**potassium hexadecabromotriantimonite**. The salt was obtained by evaporating at 35° a soln. containing a mol of antimony tribromide and 3 mols of potassium bromide. F. Ephraim regarded it as $2\text{KBr}\cdot \text{SbBr}_3$. H. J. Wheeler prepared yellow plates or prisms of **rubidium enneabromodiantimonite**, $3\text{RbBr}\cdot 2\text{SbBr}_3$, in a similar way. The hexagonal crystals have the axial ratio $a:c=1:1\cdot 207$. By using a soln. with over six molecular

FIG. 46.—Freezing-point Curve of the Mixtures: $\text{AlBr}_3\text{-SbBr}_3$.

proportions of the alkali bromide in hydrobromic acid, he obtained yellow, six-sided, pseudo-hexagonal crystals of **rubidium hexadecabromotriantimonite**, $7\text{RbBr}\cdot 3\text{SbBr}_3$, or $23\text{RbBr}\cdot 10\text{SbBr}_3$. F. Ephraim regarded it as $2\text{RbBr}\cdot \text{SbBr}_3$. R. Benedikt obtained colourless plates of **calcium pentabromoantimonite**, $\text{CaBr}_2\cdot \text{SbBr}_3\cdot 8\text{H}_2\text{O}$, by the method used for the chloro-salt. The compound dissociates at ordinary temp.; similarly also with **magnesium pentabromoantimonite**, $\text{MgBr}_2\cdot \text{SbBr}_3\cdot 8\text{H}_2\text{O}$. J. Kendall and co-workers observed that there is evidence of the formation of **aluminium hexabromoantimonite**, $\text{AlBr}_3\cdot \text{SbBr}_3$, on the f.p. curve of mixtures of the components, Fig. 46. R. F. Weinland and C. Feige² obtained **vanadium heptabromoantimonite**, $\text{SbBr}_3\cdot \text{VBr}_4\cdot 7\text{H}_2\text{O}$, from a soln. of the component salts. The black, pointed, hygroscopic prisms are decomposed by water.

A compound—**antimony tetrabromide**, SbBr_4 —corresponding with the tetrachloride has not been prepared, but R. F. Weinland and C. Feige obtained **rubidium hexabromohypoantimonate**, $2\text{RbBr}\cdot \text{SbBr}_4$, from a soln. of 4 mols of antimony tribromide and one mol of rubidium bromide in conc. hydrobromic acid. The small, black, six-sided plates lose bromine slowly. H. L. Wells and F. J. Metzger prepared **cæsium hexabromohypoantimonate**, $2\text{CsBr}\cdot \text{SbBr}_4$, by a method similar to that employed for the corresponding chloride. F. Ephraim and S. Weinberg prepared **ammonium hexabromohypoantimonate**, $(\text{NH}_4)_2\text{SbBr}_6$, by adding the requisite quantity of bromine, followed by ammonium bromide, to a soln. of antimony tribromide in conc. hydrobromic acid; it forms black octahedra, stable in air. The free acid was obtained in a state of doubtful purity.

M. Berthelot and P. Petit³ passed stibine into a soln. of potassium bromide containing free bromine, and acidified with hydrochloric acid; under these conditions it was stated that **antimony pentabromide**, SbBr_5 , is formed: $\text{SbH}_3 + 4\text{Br}_2 = \text{SbBr}_5 + 3\text{HBr}$; they also said that the pentabromide is formed when antimony tribromide is dissolved in a hydrochloric acid soln. of potassium bromide. The

pentabromide has not been isolated; but it exists in soln. E. Beckmann showed that the mol. wt. in boiling bromine is normal. As in the case of the pentachloride, a number of complex salts, and **bromoantimonic acids** have been prepared by R. F. Weinland and C. Feige. Of these acids, only the hydrated **metabromoantimonic acid**, $\text{HSbBr}_6 \cdot 3\text{H}_2\text{O}$, is known in the free state. It crystallizes readily from a conc. hydrobromic acid soln. of bromine and antimony tribromide confined in vacuo over sulphuric acid. The black, six-sided, hygroscopic plates rapidly lose bromine when exposed to air, but are more stable in an atm. of bromine. The acid is decomposed by water.

A series of metabromoantimonates as well as a number of derivatives of more complex acids have been prepared. The meta-salts were prepared by R. F. Weinland and C. Feige by dissolving the metal bromide in a soln. of antimony tribromide in fuming hydrobromic acid of sp. gr. 1.49, and adding a large excess of bromine. The soln. is then evaporated over sulphuric acid. Six-sided, black crystals of **ammonium metabromoantimonate**, $\text{NH}_4\text{SbBr}_6 \cdot \text{H}_2\text{O}$, were so obtained; and also black, square, hygroscopic tablets of **lithium metabromoantimonate**, $\text{LiSbBr}_6 \cdot 4\text{H}_2\text{O}$; and stout, six-sided, black tablets of **potassium metabromoantimonate**, $\text{KSbBr}_6 \cdot \text{H}_2\text{O}$. When caesium bromide is treated in a similar way, **caesium tridecabromodiantimonate**, $3\text{CsBr} \cdot 2\text{SbBr}_5 \cdot 2\text{H}_2\text{O}$, was obtained as a black, microcrystalline powder consisting of six-sided, red, transparent plates, which rapidly lose bromine on exposure to air. In a similar way, it was found that **beryllium enneadecabromotriantimonate**, $2\text{BeBr}_2 \cdot 3\text{SbBr}_5 \cdot 18\text{H}_2\text{O}$, furnishes black, glistening prisms which are hygroscopic and very unstable; **aluminium henitricontabromopentantimonate**, $2\text{AlBr}_3 \cdot 5\text{SbBr}_5 \cdot 24\text{H}_2\text{O}$, in black, glistening, stout prisms which are less hygroscopic than the beryllium salt; **ferric metabromoantimonate**, $\text{Fe}(\text{SbBr}_6)_3 \cdot 14\text{H}_2\text{O}$, forms black, irregular, six-sided tablets which are very hygroscopic; and **nickel metabromoantimonate**, $\text{Ni}(\text{SbBr}_6)_2 \cdot 12\text{H}_2\text{O}$, forms black, glistening, irregular, six-sided tablets. Some complexes of metabromoantimonic acid and pyridine have been made by A. Rosenheim and W. Stellmann; and A. Raynaud obtained a compound with ether, $\text{SbBr}_5 \cdot (\text{C}_2\text{H}_5)_2\text{O}$.

§ 20. The Antimony Iodides

R. Brandes¹ found that iodine unites with antimony at ordinary temp., forming **antimony triiodide** SbI_3 ; and if large quantities are used, an explosion may occur. When powdered antimony is added to iodine, the first portions render the iodine fluid; after that the antimony is gradually added until the liquid is saturated. The product is heated in a retort so that the triiodide can be separated from the excess of antimony by distillation. This mode of preparation was also employed by G. S. Sérullas, and J. B. Berthelot. F. M. Jäger and H. J. Doornbosch showed

FIG. 47.—Freezing-point Curves of Antimony and Iodine.

that the f.p. curves of iodine and antimony, Fig. 47, show that the triiodide is the only compound formed. There is no evidence of *antimony tetraiodide*, SbI_4 , or of the pentaiodide. Antimony triiodide, Fig. 47, melts sharply at 170.8° ; it is not appreciably miscible with antimony, but forms two liquid layers with the horizontal branch at 169° . The eutectic with iodine occurs at 80° with 88.2 atm. per cent. of iodine. E. Quercigh made similar observations; the eutectic at 80° is near the composition of that required for the pentaiodide.

Antimony triiodide was prepared by J. Nicklès by warming antimony with a conc. soln. of iodine in carbon disulphide until the colour due to the iodine has vanished; on evaporating the greyish-yellow liquid, the iodide separates out in red plates. A. Perrier and M. le Brument triturated a mixture of alcohol and antimony with twice its weight of iodine, and sublimed the product; E. R. Schneider heated 6 gram-atoms of iodine with a mol of antimony trisulphide—the product is contaminated with some sulphoiodide; R. W. E. MacIvor made the triiodide by heating a mixture of potassium iodide and antimony sulphate; A. Naumann, by adding potassium iodide to a soln. of antimony trichloride in acetone; A. C. Vournasos, by heating to 100° a mixture of antimony trioxide and potassium bromide with an excess of acetic acid; and G. Oddo and U. Giachery, by heating a stoichiometrical mixture of antimony trioxide and sulphur with the halogen. J. P. Cooke purified the triiodide by recrystallization from carbon disulphide; or better, by sublimation at 180° – 200° in a current of carbon dioxide.

Analyses of the salt by R. Brandes, E. R. Schneider, and J. P. Cooke are in agreement with the formula SbI_3 . The **vapour density**, 17.59, observed by C. P. Worcester is in agreement with the value 17.29 calculated for SbI_3 . P. Walden calculated the mol. wt. from the effect on the f.p. of arsenic tribromide, and obtained three times the normal value; and E. Beckmann found the value to be abnormal when the triiodide is dissolved in boiling arsenic trichloride, phosphorus trichloride, and in antimony trichloride. R. W. E. MacIvor observed that when a bar of the melted triiodide is cast in a mould, it forms a dull, reddish, semi-metallic mass

with a radiated fracture and bright metallic lustre. According to J. P. Cooke, the **crystals** of antimony triiodide are trimorphous. (i) The ordinary form of the salt is *trigonal*. The warm sat. soln. in carbon disulphide deposits it as tabular, ruby-red or reddish-brown hexagonal plates; and it is also formed in thin plates when the salt is sublimed above 114° . G. B. Negri's measurements did not agree with those of J. P. Cooke. The sp. gr. is 4.848 at 24° . The birefringence is very strong and negative. (ii) The *rhombic* form of the triiodide appears in greenish-yellow plates with angles 60° and 80° . It is obtained by subliming the salt at about 100° . It is transformed into the trigonal form at 114° , not at 112° . The rhombic crystals are isomorphous with those of antimony tribromide and trichloride. The birefringence is negative. The optic axial angle $2E=36^{\circ}$. (iii) The *monoclinic* form of the triiodide is produced by crystallization from soln. containing free iodine, while most of the crystals obtained by the evaporation of the carbon disulphide soln. are trigonal, a small proportion are monoclinic. The monoclinic prisms or plates are greenish-yellow or lemon-yellow. The dark brown crystals contain free iodine. The axial ratios are $a : b : c = 1.6408 : 1 : 0.6682$, and $\beta = 109^{\circ} 44'$. The (001)-cleavage is distinct. The sp. gr. is 4.768 at 22° . The monoclinic crystals slowly pass into the trigonal form at 125° ; and crystals contaminated with iodine pass into the trigonal form on the water-bath. P. W. Bridgman examined the effect of press. up to 12,000 kgrms. per sq. cm. and at 20° to 12° , but observed no abrupt change in vol. corresponding with a transition point. E. Cohen and H. R. Bruins were likewise unable to detect any signs of a transition temp. at 114° , and said that the effect was *ganz zufällige*. Antimony triiodide prepared by sublimation is said to be a metastable system which may remain unchanged for long periods of time, but the change to the stable system is greatly hastened by traces of the solvent as well as by ether, ethyl acetate, etc.

A. C. Vournasos alleged that in addition to the three forms of antimony triiodide reported by J. P. Cooke, yet a fourth form is obtained by cooling a hot sat. soln. of the red iodide in glycerol. It is thus obtained as an amorphous, yellow powder, m.p. 172° , at which temp. it steadily passes into the red variety, forming hexagonal crystals. This metastable, amorphous form may also be obtained from the red form by warming it on a water-bath with fifteen times its weight of acetic acid and a little potassium acetate. The soln. on cooling deposits the yellow amorphous iodide. It may also be prepared from antimony trioxide and potassium iodide by heating them at 100° with an excess of anhydrous acetic acid.

The stable form of antimony triiodide being the trigonal crystals, the following properties, unless otherwise stated, refer to that variety. C. H. D. Bödeker gave 5.01 for the **specific gravity** at ordinary temp., and H. G. F. Schröder, 4.676 at ordinary temp. referred to water at 0° . J. P. Cooke gave 4.848 at 24° for the trigonal, and 4.768 at 22° for the monoclinic crystals. F. Ephraim calculated that a 13.1 per cent. contraction occurs in the formation of the triiodide. W. Biltz studied the mol. vol. S. Motylewsky found the drop-weight to be 68 when that of water at 0° is 100. G. S. Sérullas said that the crystals melt to a garnet-red liquid, and J. P. Cooke gave 167° for the **melting point**; R. W. E. MacIvor, 164.4° ; E. Quercigh, and G. B. Bernardis, 165° ; and F. M. Jäger and H. J. Doornbosch, 170.8° , Fig. 41. P. W. Bridgman found the m.p. to be 163° at atm. press., and 200.8° at a press. of 1160 kgrms. per sq. cm., and the change of vol. was 0.0240 c.c. per gram. The crystals of the triiodide were found by J. B. Berthemet to volatilize a little above the m.p.; and J. P. Cooke found that the volatilization is perceptible at 100° . Volatilization is rapid and complete at 180° – 200° in a current of carbon dioxide. T. Carnelley and W. C. Williams gave 414° to 427° for the **boiling point**; J. P. Cooke, between 400.4° and 400.9° at 758.5° ; and L. Rotinjanz and W. Suchodsky, 401° . The vapour is orange-red, and, according to R. W. E. MacIvor, the violet tinge is due to a trace of iodine. L. Rotinjanz and W. Suchodsky gave 828° for the **critical temperature**, and they found the ratio T_m/T_c to be quite normal 0.614. A. Guntz gave for the **heat of formation**: $\text{Sb}_{\text{solid}} + 3\text{I}_{\text{gas}} = \text{SbI}_{3\text{solid}} + 45.4$ Cals. The mol. **electrical conductivity**, μ , in arsenic tribromide was found

by P. Walden to be 0.104 for a mol in 100 litres of solvent at 33°. J. W. Williams and R. J. Allgeier studied the dielectric constant of benzene soln. of antimony iodide.

Antimony triiodide was found by R. W. E. MacIvor to suffer no change when distilled in a current of **hydrogen**. J. P. Cooke found that all three modifications rapidly become opaque when exposed to **air** at ordinary temp. owing to the formation of a film of oxyiodide and the escape of iodine. R. W. E. MacIvor found that when the vapour comes in contact with air, an oxyiodide is immediately formed and violet iodine-vapour appears. If the vapour be in contact with **oxygen**, R. W. E. MacIvor said that it burns, forming antimony trioxide. J. P. Cooke found that soln. of the salt in carbon disulphide also furnish the oxyiodide (*q.v.*) when exposed to air and light. G. S. Sérullas observed that **water** decomposes the triiodide with the separation of yellow oxyiodide, and the formation of a red soln. of antimony triiodide in hydriodic acid. L. A. Buchner also studied the action of water on the triiodide. E. Beckmann found that liquid **chlorine** forms an insoluble product; and R. W. E. MacIvor, that gaseous chlorine forms antimony triiodide and iodine chloride; with molten **iodine monochloride**, antimony trichloride and free iodine are produced; and with **bromine**, antimony tribromide and bromine chloride are formed. R. Brandes, and R. W. E. MacIvor showed that cold, fuming **hydrochloric acid** forms a yellow liquid from which water precipitates white oxyiodide; the boiling conc. acid soon converts all the triiodide into trichloride. R. W. E. MacIvor found **hydriodic acid** dissolves the triiodide, forming a yellow liquid. V. Auger mixed carbon disulphide soln. of antimony triiodide and **sulphur** and obtained yellow prisms of **antimony tetracosisulphoiodide**, $\text{SbI}_3 \cdot 3\text{S}_8$, with the m.p. 117°. J. P. Cooke said that when the carbon disulphide soln. is exposed to air and light, an oxyiodide is formed—*vide infra*. L. Ouvrard found that **hydrogen sulphide** converts the triiodide into a sulphoiodide. P. Walden said that the triiodide is soluble in **sulphur monochloride**, in **thionyl chloride**, and in **sulphuryl chloride**. R. W. E. MacIvor said that contrary to the statement of R. Brandes, cold **sulphuric acid**— $\text{H}_2\text{SO}_4 \cdot 12\text{H}_2\text{O}$ —has little or no action on antimony triiodide, but the application of a gentle heat produces iodine and antimony sulphate.

R. Brandes found that aq. **ammonia** converts the triiodide into a yellowish-white powder. G. Gore found that the triiodide reacts with liquid ammonia. V. Thomas showed that **nitrogen peroxide** acts on an ethereal soln. of the triiodide forming antimony nitratobispentoxide. According to R. W. E. MacIvor, **nitric acid** of sp. gr. 1.4–1.5 immediately decomposes the triiodide producing nitrous vapours, free iodine, and antimony oxide; while nitric acid of sp. gr. 1.2 does not act at first, but in a short time heat is developed and the triiodide is decomposed. E. Beckmann found the triiodide to be soluble in **phosphorus trichloride**, and P. Walden, in **phosphorus tribromide** as well as the trichloride; in **phosphoryl**

FIG. 48.—Freezing-point Curves of Mixtures $\text{SbI}_3\text{-PI}_3$.

FIG. 49.—Freezing-point Curves of Mixtures $\text{SbI}_3\text{-AsI}_3$.

chloride; and in **arsenic trichloride**. T. Karantassis studied the reaction with **phosphorus pentachloride** (*q.v.*). Antimony triiodide and **phosphorus triiodide** were found by F. M. Jäger and H. J. Doornbosch to furnish the f.p. curve, Fig. 48. The fusion curve is the typical V-shape with a eutectic at 56°; the f.p. curve with **arsenic triiodide**, Fig. 49, shows that a continuous series of solid soln. is formed

with the solidus and liquidus curves melting at a minimum temp. of about 135° . E. Quercigh also found the triiodides of arsenic and antimony give a similar curve with a minimum at 128° . His study of the ternary system $\text{AsI}_3\text{-SbI}_3\text{-I}_2$ is summarized in Fig. 50. J. W. Retgers found that antimony triiodide can dissolve much arsenic triiodide, and the m.p. falls 31° while the sp. gr. of the mixture is 3.801; and by mixing this product with a soln. of arsenic triiodide in methylene iodide, a heavy liquid of sp. gr. 3.7 at 20° can be prepared. P. Walden, and J. W. Retgers found that antimony triiodide also dissolves in warm **arsenic tribromide**, forming a dark wine-red liquid which soon becomes opaque, the sp. gr. of the sat. soln. is 3.72 at 40° ; it solidifies at 37° . A. M. Wasiléeff studied the eutectic phenomenon with arsenic and antimony triiodides.

FIG. 50. — Freezing-point Curves of the Ternary System: $\text{AsI}_3\text{-SbI}_3\text{-I}_2$.

J. Tarble found that antimony triiodide dissolves in **boron tribromide**. R. W. E. MacIvor found that antimony triiodide is not decomposed when vaporized in **carbon dioxide**. A. C. Vournasos obtained some complex iodycyanides by heating antimony triiodide with **mercuric or cuprous cyanide** in dry xylene—*e.g.* $\text{Hg}[\text{SbI}_3\text{Cy}_2]$; $\text{Hg}_3[\text{Sb}_2\text{I}_6\text{Cy}_6]$; and $\text{Cu}_6[\text{Sb}_2\text{I}_6\text{Cy}_6]$. E. R. Schneider, and J. P. Cooke found that antimony triiodide is slightly soluble in cold **carbon disulphide**, but freely soluble at a higher temp. The soln. is yellow. J. W. Retgers found that 100 parts of **methylene iodide** dissolve 11.3 parts of antimony triiodide at 12° , forming a soln. of sp. gr. 3.453 at 12° ; more is dissolved at a higher temp., and the salt crystallizes out again on cooling. The colour of the soln. is very dark red. R. W. E. MacIvor said that antimony triiodide is nearly insoluble in **chloroform**, and that it does not dissolve in **carbon tetrachloride** or in **turpentine**. J. P. Cooke found it to be insoluble in **petroleum**; and R. W. E. MacIvor obtained a yellow soln. with **benzene**, J. W. Retgers, a red one. On cooling, the boiling soln. of the triiodide in benzene deposits red, tabular crystals of triiodide similar to those deposited from the carbon disulphide soln. A. Naumann observed that the triiodide is soluble in **acetone**. According to R. W. E. MacIvor, when the triiodide is heated with **carbon hexachloride** to 250° , the triiodide dissolves in the molten hexachloride, forming a dark brown soln., and on cooling a lemon-yellow mass is first formed which, on further cooling, quickly changes to a red crystalline mass—no carbon hexiodide is formed. According to J. Nicklès, antimony triiodide is insoluble in **alcohol**, even when heated in a sealed tube at 100° there is no change; similar results were obtained with **ether**. G. S. Sérullas observed that 80 per cent. alcohol partially hydrolyzes the triiodide, forming an oxyiodide. According to J. P. Cooke, and R. W. E. MacIvor, absolute ethyl alcohol partially dissolves the triiodide, forming a brown soln. but the greater portion is converted into the yellow oxyiodide; R. W. E. MacIvor also found that anhydrous ether also partially decomposes the triiodide, forming a yellow oxyiodide, and a dark brown soln. containing undecomposed triiodide. J. P. Cooke said that a soln. of **tartaric acid** dissolves the triiodide without the separation of oxyiodide. A number of compounds of antimony triiodide with **organic compounds** have been prepared: F. Ephraim and S. Weinberg studied the formation of compounds with alkylamines; G. J. Burrows and E. E. Turner, compounds with the ternary and halogenoarsines. R. Brix, and B. Köhnlein showed that in the interchange of halogen with the antimony trihalides and organic halides, antimony unites by preference with iodine rather than with bromine or chlorine, and with bromine rather than with chlorine. A. M. Wasiléeff studied the systems: antimony trichloride with α -nitronaphthalene. and with β -chloronaphthalene.

J. Nicklès, and E. R. Schneider found that antimony triiodide is completely decomposed by a soln. of an **alkali hydroxide** with the separation of antimony trioxide; similarly also with soln. of an **alkali carbonate**. The triiodide forms double salts with the **metal iodides**; and they were prepared by L. Schäffer, and A. Welkow, by dissolving the triiodide in a conc. soln. of the metal iodide, and evaporating the liquid at ordinary temp.; and by J. Nicklès, by treating the metal with a soln. of iodine in alcohol. The black crystals are decomposed by heat with the escape of antimony triiodide; water decomposes the salts with the separation of oxyiodide, but water sat. with the metal iodide does not decompose the salts; conc. sulphuric acid separates the iodine; carbon disulphide extracts the antimony triiodide from the salts; acetic, and hydrochloric acids dissolve the salts, forming yellow soln.—if tartaric acid be present, the soln. is colourless. L. Schäffer reported scarlet-red, four-sided prisms of *ammonium pentadecaiodotetramonite*, $3\text{NH}_4\text{I}\cdot 4\text{SbI}_3\cdot 9\text{H}_2\text{O}$, which are possibly the same as the red, tetragonal prisms of **ammonium metaiodoantimonite**, $\text{NH}_4\text{SbI}_4\cdot 2\text{H}_2\text{O}$, prepared by J. Nicklès, by the action of iodine on antimony in a sat. soln. of ammonium chloride; R. M. Caven reported rectangular, four-sided, dark brown plates of **ammonium enneaiododiantimonite**, $3\text{NH}_4\text{I}\cdot 2\text{SbI}_3\cdot 3\text{H}_2\text{O}$, and L. Schäffer obtained a similar salt in red, tetragonal plates easily soluble in alcohol. L. Schäffer also obtained black, four-sided prisms of **ammonium heptaiodoantimonite**, $4\text{NH}_4\text{I}\cdot \text{SbI}_3\cdot 3\text{H}_2\text{O}$; pale orange-red, four-sided prisms of **sodium enneaiododiantimonite**, $3\text{NaI}\cdot 2\text{SbI}_3\cdot 12\text{H}_2\text{O}$; dark brown, four-sided plates of **potassium enneaiododiantimonite**, $3\text{KI}\cdot 2\text{SbI}_3\cdot 3\text{H}_2\text{O}$; and L. Nicklès, red prisms of **potassium tetraiodoantimonite**, $\text{KI}\cdot \text{SbI}_3\cdot n\text{H}_2\text{O}$. H. J. Wheeler prepared **rubidium enneaiododiantimonite**, $3\text{RbI}\cdot 2\text{SbI}_3$, in deep red, trigonal crystals isomorphous with the corresponding chloride and bromide. The axial ratio is $a : c = 1 : 1.230$, and $\alpha = 89^\circ 46'$; while H. L. Wells and F. J. Metzger obtained brick-red, octahedra, and yellow hexagonal plates of **cesium enneaiododiantimonite**, $3\text{CsI}\cdot 2\text{SbI}_3$. The octahedra were produced from a mixed soln. of the component salts in conc. hydriodic acid and the hexagonal plates by using a less conc. soln. of hydriodic acid. L. Schäffer prepared dark orange-red, rhombic prisms of **barium pentaioodoantimonite**, $\text{BaI}_2\cdot \text{SbI}_3\cdot 9\text{H}_2\text{O}$; A. Welkow obtained prismatic crystals of **beryllium iodoantimonite** which were not analyzed because they could not be separated from the mother-liquor without decomposition; similar results were obtained with **aluminium iodoantimonite**. A. M. Wasiléeff found that with mixtures of stannic iodide and antimony triiodide there is a eutectic at 127° with $\text{SnI}_4 : \text{SbI}_3 = 1 : 0.8728$. A. Mosnier added lead iodide to a boiling sat. soln. of antimony triiodide in fuming hydriodic acid, and on cooling found that black octahedra of **lead enneaiodoantimonite**, $\text{Pb}_3\text{SbI}_9\cdot 12\text{H}_2\text{O}$, were formed. The salt is decomposed by water, and alcohol; and its heat of soln. in 40 parts of water at 15° is -8.5 Cals.; when heated to 45° it is dehydrated, and the heat of soln. is then $+20.6$ Cals. The heat of formation is $(\text{SbI}_3, 3\text{PbI}_2) = 21.4$ Cals.

The reported existence of **antimony pentaiodide**, SbI_5 , is very doubtful. V. van der Espt² stated that he obtained the pentaiodide by heating the elements together in the required proportions, but R. W. E. MacIvor could not confirm this. There is no sign of the formation of such a compound on the f.p. curves of F. M. Jäger and H. J. Doornbosch, and R. Quercigh, Fig. 47. J. H. Pendleton reported that he had made the pentaiodide by fusing antimony with an excess of iodine in an atm. of an inert gas in a sealed tube, and the mixture was kept well fused for an hour or two; the tube was then heated at 130° in a sulphuric acid-bath, one end which was cooled with water serving to collect the surplus iodine which distils off. The residue is a dark-brown crystalline mass, decomposable by water or long exposure to moist air. It melts at $78^\circ\text{--}79^\circ$, but is very unstable, readily undergoing decomposition when exposed to even a moderate increase of temp. Analytical results correspond "pretty closely to the formula SbI_5 ." R. W. E. MacIvor said that the supposed pentaiodide of J. H. Pendleton dissolved in hot carbon disulphide, yielding a soln. possessing the characteristic colour imparted to that liquid by free

iodine, and which, on cooling, deposited crystals of the triiodide melting at 165° . By means of chloroform, in which the triiodide is only slightly soluble, it is possible completely to dissolve out the free iodine from the substance and obtain pure triiodide. On being decomposed by water the material yielded yellow oxyiodide, hydriodic acid, and much free iodine—a result to be expected from such a mixture. R. Hanslian determined the mol. wt. from the f.p. of soln. in iodine.

§ 21. Antimony Oxyhalides

F. A. Flückiger¹ found that **antimony oxyfluoride** is produced as a white precipitate by evaporating a soln. of antimony trifluoride in water without adding hydrofluoric acid; and when hydrofluoric acid is treated with an excess of antimony trioxide. The analysis can be represented $\text{Sb}_3\text{O}_7\text{F}_{10}$. J. C. G. de Marignac obtained a gummy mass by evaporating in vacuo a soln. of antimony pentoxide in hydrofluoric acid, and when heated it gives an oxyfluoride. A definite antimony oxytrifluoride has not been isolated, but some complex salts have been reported. Thus, J. C. G. de Marignac obtained small, deliquescent, hexagonal prisms of **sodium antimony tetrafluoride**, $\text{NaF.SbOF}_3 \cdot \text{H}_2\text{O}$, by concentrating a soln. of antimony pentoxide and sodium carbonate in an excess of hydrofluoric acid. The salt can be crystallized

from water without decomposition. H. L. Wells and F. J. Metzger reported acicular crystals of **cæsius antimony hydroxytetrafluoride**, $\text{CsF} \cdot \text{SbF}(\text{OH})$, to be formed by cooling a warm, conc. soln. of antimony pentafluoride and cæsius fluoride in conc. hydrofluoric acid.

In the sixteenth century, the supposed medical virtues of the white powder obtained by the action of water on *butyrum antimonii* were described by Paracelsus in his *Archidoxies*. Because at that time butter of antimony was prepared from mercuric chloride and antimony sulphide, Paracelsus seems to have assumed that the white powder contained the principle of mercury, and he called it *mercurius vitæ*. He invested this medicament with wondrous powers of rejuvenescence :

Youth and its powers do not fail on account of old age, but these exist equally in the old as in the young. The corruption, however, which grows up with youth is so strengthened that it takes away the powers, whence old age is recognized. . . . The *mercurius vitæ* separates corruption. . . . So powerful is it in man, that, after the corruption shall have been separated from him, the quintessence is again excited, and lives as in youth. . . . The aged life then recovers most effectually its powers as they were before . . . , and corruption cannot demonstrate old age. . . . *Mercurius vitæ* restores the defective and lost powers so that in old women the menses and the blood flow naturally as in young ones ; for it brings back aged women to the same perfection of nature as the younger ones.

Basil Valentine² also observed the precipitation of a white powder when antimony trichloride is treated with water. J. C. Barchusen and H. Boerhaave retained Paracelsus' term *mercurius vitæ* for the white powder. Towards the end of the seventeenth century, Vittorio Algarotto described the *mercurius vitæ* as a medicament and named it *pulvis angelicus* ; but it afterwards came to be called *pulvis Algaroti—powder of Algaroth*. J. R. Glauber called it *flores antimonii vomitivi albi*. J. C. Barchusen explained the formation of the powder by assuming that the water extracted the acid from the antimony trichloride, because, when the water is evaporated, the acid is recovered as *spiritus salis resuscitatus*. He added that the powder contains no mercury ; and the term *mercurius vitæ* is a misnomer. This explanation was accepted by H. Boerhaave.

The hydrolysis of antimony trichloride has been discussed in connection with the chemical action of water on antimony trichloride. It is there shown that J. M. van Bemmelen and co-workers³ believed that the solid phase *antimony oxytetrachloride*, $\text{SbCl}_3 \cdot \text{SbOCl}$, was stable within the limits indicated in Fig. 36. C. Lea and J. K. Wood were unable to confirm the existence of this oxychloride. J. P. Cooke obtained a crystalline product as a result of the action of an acidic soln. of antimony trichloride, and C. Lea and J. K. Wood represent its formula $\text{Sb}_4\text{O}_3(\text{OH})_5\text{Cl}$ —*antimony trioxypentahydroxychloride*—and they also observed acicular crystals of *antimony trioxytrihydroxytrichloride*, $\text{Sb}_4\text{O}_3(\text{OH})_3\text{Cl}_3$. These products are considered to be metastable compounds representing more or less transitory halting stages in the passage to the stable oxychlorides SbOCl , and $\text{Sb}_4\text{O}_5\text{Cl}_2$. The arresting of the incomplete reaction at different stages accounts for the differences in the composition of the products by different investigators at a time when analysis was the main test available. Thus, E. R. Schneider, and A. Sabanejeff reported $\text{Sb}_8\text{OCl}_{22}$, or $\text{SbOCl} \cdot 7\text{SbCl}_3$; J. P. Cooke, and A. Sabanejeff, $\text{Sb}_8\text{O}_{11}\text{Cl}_2$; and W. C. Williams, $10\text{Sb}_4\text{O}_5\text{Cl}_2 \cdot \text{SbCl}_3$ —*vide infra*. The mineral, found by A. Frenzel in cavities in the native antimony of Borneo, and named *sarawakite*, occurs in minute crystals "probably tetragonal." It is colourless, or wine-yellow, or greenish-yellow. It is supposed to be an oxychloride of antimony.

E. M. Péligot showed that **antimony oxychloride**, or **antimonyl chloride**, SbOCl , is produced by the action of cold water on antimony trichloride. A. Sabanejeff allowed a mixture of ten parts of antimony trichloride and seven parts of water to stand for some days to allow the oxychloride to crystallize ; he then washed the dry crystals with ether to remove the adherent antimony trichloride. The conditions of equilibrium are illustrated by Fig. 35. J. M. van Bemmelen showed that this oxychloride is formed at ordinary temp. when a mol of antimony trichloride is

treated with 45 mols of water—*i.e.* about four parts of water to one part of trichloride by weight. If much more than this amount of water is used, the pentoxydichloride is formed, and if less, some oxychloride remains in soln. If the amorphous precipitate first obtained be allowed to stand for some time in contact with its mother-liquor it becomes crystalline provided the liquor be not too dilute. L. Schäffer prepared this salt by heating to 160° a mixture of equimolar parts of antimony trichloride and ethyl alcohol in a sealed tube: $\text{SbCl}_3 + \text{C}_2\text{H}_5\text{OH} = \text{C}_2\text{H}_5\text{Cl} + \text{SbOCl} + \text{HCl}$; if 3 mols of alcohol be employed, the pentoxydichloride is formed. The analyses of the amorphous white powder or white crystals by E. M. Péligot, L. Schäffer, A. Sabanejeff, and J. P. Cooke agree with the formula SbOCl . The mol. wt. is unknown; it is sometimes represented as $\text{Sb}_4\text{O}_4\text{Cl}_4$ by analogy with the pentoxydichloride, $\text{Sb}_4\text{O}_5\text{Cl}_2$, and the trioxide, Sb_4O_6 :

J. P. Cooke found that the crystals belong to the monoclinic system having the axial ratios $a : b : c = 0.8934 : 1 : 0.7577$, and $\beta = 103^\circ 29'$. A. Guntz gave for the heat of formation: $\text{Sb}_{\text{solid}} + \text{O}_{\text{gas}} + \text{Cl}_{\text{gas}} = \text{SbOCl}_{\text{solid}} + 89.7$ Cals. L. Schäffer, A. Sabanejeff, and J. P. Cooke showed that when heated, this oxychloride gives off antimony trichloride, forming the pentoxydichloride. The evolution of the trichloride begins at about 170° and ceases at about 280° when the composition is $\text{Sb}_4\text{O}_5\text{Cl}_2$. At a higher temp., it decomposes into antimony trioxide and trichloride. Hot water decomposes antimony oxychloride into the pentoxydichloride. G. Gore said that the oxychloride is insoluble in liquid ammonia. Antimony oxychloride is insoluble in alcohol and ether (L. Schäffer); but it is soluble in carbon disulphide, chloroform, benzene, and in tartaric and hydrochloric acids (A. Sabanejeff); G. Mazzaron found that antimony oxychloride gives chlorine not chromyl chloride when treated with sulphuric acid and potassium dichromate.

By treating antimony trichloride with 5 to 50 times its weight of cold water, A. Sabanejeff obtained **antimony pentoxydichloride**, $\text{Sb}_4\text{O}_5\text{Cl}_2$. This oxychloride is commonly considered to be powder of Algaroth. If more water is used, the product contains less chlorine. If the amorphous solid be allowed to stand in its mother-liquid it gradually becomes crystalline. The dried product is freed from adhering antimony trichloride by washing. An analogous method was used by F. J. Malaguti, and J. F. W. Johnston. The conditions of equilibrium were studied by J. M. van Bemmelen—Fig. 33—C Lea and J. K. Wood, and H. le Chatelier—*vide* the action of water on antimony trichloride. E. M. Péligot found that boiling water in not too great an excess furnishes the same product; and A. Sabanejeff said that 30 times the weight of cold water gives the same product as 3 times the weight of water at 60°–70°. C. W. E. MacIvor used hot water for the precipitation. C. W. Scheele obtained powder of Algaroth by heating a mixture of antimony oxide (one part), sodium chloride (3.5 parts), sulphuric acid (2.5 parts), and water (2 parts) for 12 hrs. nearly at the b.p.; diluting the soln. with water until precipitation begins; and adding more water to the filtered liquid. C. F. Bucholz used a similar process. Conc. hydrochloric acid can be used in place of sodium chloride and sulphuric acid. J. von Liebig mixed finely powdered antimony sulphide with boiling conc. hydrochloric acid; added water until a precipitate appears which carries down any sulphide present in the liquid; and treated the filtered liquid with more water. J. P. Cooke mixed a soln. of 2 grms. of antimony in 30 c.c. of hydrochloric acid and 5 grms. of tartaric acid and precipitated the oxychloride by water, and allowed it to crystallize by standing for some time. Soln. with 7 to 20 grms. of tartaric acid may be diluted to a litre without turbidity, the oxychloride is precipitated by boiling the soln. V. Merz and W. Weith obtained crystals of an oxychloride, which was

not analyzed, by heating antimony trichloride with 10 times its weight of water, in a sealed tube at 200°-250°. L. Schäffer obtained this oxychloride by heating in a sealed tube at 140°-150°, a mol of antimony trichloride with 3 mols of alcohol: $4\text{SbCl}_3 + 5\text{C}_2\text{H}_5\text{OH} = \text{Sb}_4\text{O}_5\text{Cl}_2 + 5\text{C}_2\text{H}_5\text{Cl} + 5\text{HCl}$. J. P. Cooke also used this process. According to E. R. Schneider, and W. C. Williams, boiling antimony trichloride can dissolve about 0.067 part of its weight of antimony trioxide, and the soln. deposits a crystalline mass, $\text{Sb}_3\text{OCl}_{22}$, which when treated with alcohol forms the pentoxydichloride.

Analyses of the product by E. M. Péligot, R. W. E. MacIvor, A. Duflos, E. R. Schneider, J. P. Cooke, J. M. van Bemmelen and co-workers, L. Schäffer, and A. Sabanejeff agree more or less closely with the formula $\text{Sb}_4\text{O}_5\text{Cl}_2$. J. F. W. Johnston's analyses indicated a little more chlorine—probably owing to inadequate washing—and he represented the formula $2\text{SbCl}_3 \cdot 9\text{Sb}_2\text{O}_3$; P. Grouvelle, R. Phillips, and C. F. Bucholz obtained too little chlorine—possibly owing to too much washing. W. C. Williams obtained a product $10\text{Sb}_4\text{O}_5\text{Cl}_2 \cdot \text{SbCl}_3$ by the action of boiling water on antimony trichloride. The white powder may be amorphous, or it may consist of tabular or prismatic crystals. According to J. P. Cooke, the monoclinic prisms have the axial ratios $a : b : c = 1.234 : 1 : 3.081$, and $\beta = 121^\circ 2'$; and the crystals obtained from a soln. of tartaric acid at ordinary temp. have a sp. gr. 5.014. T. Bergman, and A. Sabanejeff found that the compound could be melted without decomposition, but at a higher temp., antimony trichloride is evolved. J. P. Cooke said that the decomposition begins at 320°, and is completed at a red-heat. M. Lapschin and M. Tichanowitsch observed that it is not decomposed by an electric current at about 500 volts. A. Sabanejeff said that cold water has very little action, but N. E. Henry, A. Duflos, and F. J. Malaguti observed that it loses its chlorine in contact with hot water. H. Debray obtained prismatic crystals of antimony trioxide by heating the oxychloride in a sealed tube at 150°; L. Schäffer said that hydrochloric acid dissolves the oxychloride; P. Grouvelle, that when heated with sulphur, black antimony trisulphide is formed; C. F. Bucholz, that sulphuric acid converts it into antimony sulphate; and nitric acid, into antimony nitrate; A. Sabanejeff, that it is insoluble in alcohol and ether; L. Schäffer, that it is soluble in a soln. of tartaric acid; and T. H. Behrens, that oxalic acid converts it into antimonyl oxalate. The oxychloride is converted by alkali-lye into antimony trioxide.

R. Benedikt prepared **potassium antimonyl pentachloroantimonate**, $2\text{KCl} \cdot \text{SbCl}_3 \cdot \text{SbOCl}$, from a cold soln. of the components without adding hydrochloric acid. The monoclinic prisms are stable in air; they are freely soluble in hydrochloric acid, tartaric acid, and in hot acetic acid; when crystallized from hydrochloric acid, some hexagonal potassium pentachloroantimonite is formed; and the hot acetic acid soln. on cooling, deposits some antimony oxychloride. The salt is insoluble in a cold or hot soln. of potassium chloride; carbon disulphide, alcohol, and ligroin. When heated in a current of carbon disulphide, it leaves a residue of potassium chloride and antimony trioxide.

The oxychlorides so far discussed are supposed to contain tervalent antimony. H. Daubrawa's monohydrated antimony pentachloride (*q.v.*) has been regarded as **antimony oxytrichloride**, SbOCl_3 ; but such a compound has not been made. M. Lapschin and M. Tichanowitsch said that it is a bad electrical conductor. W. C. Williams heated a mol of hydrated antimony pentoxide with 3 mols of antimony pentachloride in a sealed tube at 140°, and obtained two products: (i) **Antimony oxytridechloride**, $\text{Sb}_3\text{OCl}_{13}$, appears in white crystals which melt at 85°, and decompose when heated, giving off chlorine and antimony trichloride, leaving antimony pentoxide as a residue. The compound deliquesces in air, and is decomposed by water. It is soluble in tartaric acid; and insoluble in carbon disulphide. (ii) **Antimony tetroxyheptachloride**, $\text{Sb}_3\text{O}_4\text{Cl}_7$, which appears in small yellow crystals which melt at 97.5°.

The mineral **ochrolite** was found by G. Flirk⁴ in the Harstig mine at Pajsberg, Sweden, and it was named in allusion to its bright sulphur-yellow colour—*εχρος*, bright

yellow; $\lambda\theta os$, a stone. The analysis corresponds with $Pb_4Sb_2O_7 \cdot 2PbCl_2$, or **lead antimony heptoxytetrachloride**, $Pb_4Sb_2O_7Cl_4$, or $Pb_{12}Sb_4O_{15}Cl_8$. The small, thick, tabular, rhombic crystals have the axial ratios $a : b : c = 0.90502 : 1 : 2.01375$. The mineral **nadorite** comes from Djebel-Nador, Constantine, Algiers, and it was described by M. Flajolot. A. Russell described a specimen from Cornwall. Nadorite is smoky-brown or brownish-yellow; and analyses reported by F. Pisani, M. Flajolot, and M. Braun agree with the formula $PbSb_2O_4 \cdot PbCl_2$, or, as P. Groth puts it, $SbO_2(PbCl)$; *i.e.* **lead antimonyl oxychloride**, $Cl.Pb.O.SbO$, a derivative of $HO.SbO$.

G. Cesaro obtained a similar product by fusing a mixture of a gram of lead oxide and 0.778 grm. $SbOCl$. G. Cesaro gave for the axial ratios of the tabular or prismatic, rhombic crystals of nadorite: $a : b : c = 0.7490 : 1 : 1.0310$. Twinning occurs about the (011)-plane; the (100)-cleavage is perfect. The optic axial angle is 145° ; the optical character is negative; the dispersion is strong; the sp. gr. is 7.02; and the hardness is 3.5-4.0.

Two **oxybromides** containing trivalent antimony have been reported, and they are analogous with the two stable oxychlorides. J. P. Cooke found that **antimony oxybromide**, or **antimonyl bromide**, $SbOBr$, or $Sb_4O_4Br_4$, separates out when a soln. of antimony tribromide in carbon disulphide is exposed to air and sunlight. The brown oxychloride is contaminated with decomposition products of the carbon disulphide, otherwise it would be white. The decomposition by heat takes place in two stages as in the case of the corresponding oxyiodide—antimony trioxide being the end-product; and the pentoxydibromide is formed as an intermediate product. J. P. Cooke prepared **antimony pentoxydibromide**, $Sb_4O_5Br_2$, by heating a mixture of absolute alcohol and antimony tribromide in a sealed tube at 160° . A decrease in the proportion of alcohol does not lead to the formation of the oxybromide as in the corresponding case with the trichloride. The same compound is produced when the tribromide is hydrolyzed by cold water. R. W. E. MacIvor removed the adherent tribromide by washing the product with carbon disulphide. G. S. Sérullas said that by repeatedly washing the product with water, all the bromine can be removed. The white powder is either amorphous or crystalline, and, according to J. P. Cooke, the crystals are monoclinic. R. W. E. MacIvor said that at 300° , the compound decomposes into antimony tribromide and trioxide. G. S. Sérullas said that the oxybromide retains water very tenaciously, and is all expelled only when the tribromide is given off. G. Gore found that antimony oxybromide is slightly soluble in liquid ammonia.

Only **oxyiodides** of trivalent antimony are known. J. P. Cooke prepared **antimony oxyiodide**, or **antimonyl iodide**, $SbOI$, or $Sb_4O_4I_4$, by exposing to air and light a soln. of antimony triiodide in carbon disulphide. The soln. is simultaneously discoloured owing to the liberation of some free iodine. The blue and violet rays are the most acute; the red and yellow rays have very little activity. The light from burning magnesium is also active. The amorphous yellow or yellowish-brown powder begins to liberate antimony triiodide at 150° , and at 200° , the evolution ceases; the residue then suffers no further decomposition until a temp. of 350° is attained when its composition corresponds with **antimony pentoxydiiodide**, $Sb_4O_5I_2$. Some of this same iodide is formed along with the oxyiodide, $SbOI$. The pentoxydiiodide produced by the action of absolute alcohol on antimony triiodide has a variable composition. The pentoxydiiodide is also produced as a golden-yellow powder when a soln. of antimony triiodide in hydriodic acid is poured into water. G. S. Sérullas, and J. B. Berthemot found that the composition of the product obtained by the hydrolysis of the triiodide varies with the proportion of water employed, the temp., and the amount of washing to which it is subjected; a protracted washing may remove all or nearly all the iodine. The product holds water very tenaciously so that the compound has begun to give off antimony triiodide at the temp. at which all the water is expelled. The water in which the iodide decomposes acquires a red colour, being a soln. of antimony triiodide in hydriodic acid. The analyses of R. W. E. MacIvor, J. P. Cooke, and H. Halle agree closely with the assigned formula. J. P. Cooke found that the

yellowish-brown pentoxydiiodide may be amorphous, or in colourless monoclinic crystals; it is stable up to 350°, and at a dull red-heat, antimony triiodide is evolved, leaving a residue of cubic and prismatic antimony trioxide. The crystals of the pentoxydiiodide appear in the partially decomposed compound. H. Halle observed very little change in weight between 105° and 250°—then, 0.3622 grm. at 105° became 0.3596 grm. at 250°. R. W. E. MacIvor, and R. Brandes said that the pentoxydiiodide slowly dissolves in a soln. of tartaric acid; and J. B. Berthelot, that zinc or iron precipitates antimony from boiling water in which the pulverulent oxyiodide is suspended; tin acts similarly but more slowly. Alkali and alkaline earth hydroxides decompose the oxyiodide with the separation of antimony trioxide.

A. C. Vournasos said that in the hydrolysis of antimony triiodide by water, there are indications of the intermediate formation of an unstable complex acid, $H_2(SbO_3)$ —*hydroantimonyloxytriiodic acid*. Thus, when equimolar proportions of antimony triiodide and mercuric cyanide are warmed in moist amyl alcohol on a water-bath for 4–6 hrs., **mercury antimonyl oxytriiodide**, $Hg(SbO_3)_3$, m.p. 78°, is produced. The salt can be recrystallized from cold, dil. hydrochloric acid, but is decomposed by conc. acids, and by alkali-lye. Copper acetate under similar conditions furnishes **copper antimonyl triiodide**, $Cu(SbO_3)_3$.

P. Gruhl melted potassium iodide with antimony trioxide; and, when the mass had cooled, separated the upper, greyish-green layer of potassium iodide from the lower, amber-yellow layer. The composition of the product corresponds with **potassium oxydiiodo-hexadecantimonite**, $2KI.K_2O.8Sb_2O_3$. It is insoluble in, and not attacked by cold or hot water; acids and alkali-lyes do not act on the product; aqua regia decomposes it slowly; and tartaric acid dissolves it gradually.

§ 22. The Mixed Antimony Halides

Mixed halides of trivalent antimony have not been prepared. G. B. Bernardis¹ examined the f.p. curves of antimony trichloride and tribromide, Fig. 51; of antimony tribromide and triiodide, Fig. 52; and of antimony trichloride and

FIG. 51.—Freezing-point Curves of the Binary System: SbCl_3 - SbBr_3 .

FIG. 52.—Freezing-point Curves of the Binary System: SbBr_3 - SbI_3 .

FIG. 53.—Freezing-point Curves of the Binary System: SbCl_3 - SbI_3 .

triiodide. Antimony tribromide forms mixed crystals in all proportions with the trichloride and the triiodide with minima respectively at 54° and 82° ; but with the trichloride and triiodide there is a limit with the triiodide up to a conc. of about 45 per cent. SbCl_3 . The eutectic at 41.5° has 82 per cent. SbCl_3 .

A number of mixed halides of quinquivalent antimony have been prepared. F. Swarts² reported **antimony difluorotrichloride**, SbF_2Cl_3 , by the action of antimony trifluoride on antimony pentachloride, in the presence of an excess of chlorine: $2\text{SbF}_3 + \text{SbCl}_5 + 2\text{Cl}_2 = 3\text{SbF}_2\text{Cl}_3$. The crystals are white or pale yellow. The vapour density up to 200° and 760 mm. press. is normal; but at 360° , dissociation is complete. The compound melts to a colourless liquid at 55° . The difluorotrichloride mixes with water with the development of a little heat. The compound attacks glass slowly; it reacts vigorously with ether, benzene, chloroform, and carbon tetrachloride; it carbonizes paper; and with ammonia forms **antimony triaminodifluorotrichloride**, $\text{SbF}_2\text{Cl}_3 \cdot 2\text{NH}_3$.

O. Ruff examined the f.p. curve of mixtures of antimony pentachloride and pentafluoride, and obtained evidence of the existence of six compounds. No signs of the existence of $3\text{SbF}_5 \cdot 2\text{SbCl}_5$ appeared on the fusion curve, Fig. 54. The region of stability of **antimony pentadecafluoropentachloride**, $3\text{SbF}_5 \cdot \text{SbCl}_5$, is shown in the diagram. It is primarily deposited from the vapour in a good vacuum. The region

FIG. 54.—Freezing-point Curve of the Binary Mixture: SbF_5 - SbCl_5 .

of stability of **antimony decafluopentachloride**, $2\text{SbF}_5 \cdot \text{SbCl}_5$, is shown in the diagram; the compound was obtained by extracting with liquid chlorine the solid obtained from fusions with 60 to 66.7 molar per cent. of the pentafluoride. Mol. wt. determinations in sulphuryl chloride soln. are normal with 10 per cent. soln., but in less conc. soln., the compound is dissociated. Its sp. gr. is 3.08 at $20^\circ/0^\circ$; and the mol. vol. 236. **Antimony pentafluopentachloride**, $\text{SbF}_5 \cdot \text{SbCl}_5$, can be isolated from the fusions in the region indicated in the diagram; the same thing applies to **antimony decafluopentadecachloride**, $2\text{SbF}_5 \cdot 3\text{SbCl}_5$. The mol. wt. in sulphuryl chloride is about one-third the theoretical value, even in conc. soln. The sp. gr. is 2.79 at $20^\circ/0^\circ$; and the mol. vol. 473. The crystalline form of **antimony pentafluodecachloride**, $\text{SbF}_5 \cdot 2\text{SbCl}_5$, is different from that of either of its immediate neighbours. The sp. gr. is 2.82 at $20^\circ/0^\circ$; and the mol. vol. is 287. It is possible to isolate **antimony pentafluopentadecachloride**, $\text{SbF}_5 \cdot 3\text{SbCl}_5$, from the fusions; and it is primarily deposited from the vapour in a good vacuum. The mol. wt. in sulphuryl chloride soln. is about one-third the normal value, even in conc. soln. The sp. gr. is 2.73 at $20^\circ/0^\circ$; and the mol. vol. is 406. On fusion, all the compounds are dissociated to a great extent; and there is a considerable decrease in vol. when they are formed from their constituents. The chemical behaviour of these compounds, except in so far as their behaviour towards bromine and a mixture of arsenic trifluoride and bromine is concerned, is similar to what one would expect from a mixture of antimony pentachloride and antimony pentafluoride in the given proportions. When bromine is mixed with twice its weight of $3\text{SbF}_5 \cdot \text{SbCl}_5$, or $2\text{SbF}_5 \cdot \text{SbCl}_5$, there is a slight development of heat, and some of the compound dissolves in the bromine; on mixing with $2\text{SbF}_5 \cdot 3\text{SbCl}_5$, $\text{SbF}_5 \cdot 2\text{SbCl}_5$, or $\text{SbF}_5 \cdot 3\text{SbCl}_5$, however, there is a considerable absorption of heat, and the mixture becomes liquid. The mixture of arsenic trifluoride and bromine does not give arsenic pentafluoride with any of the above compounds. In the formation of these compounds, the negative affinity of the antimony pentafluoride mol. is considered to lie between those of elementary fluorine and chlorine, whereas the affinity of the antimony pentachloride mol. is more negative than that of the iodine mol., and about as strong as that of the bromine mol. In the light of Werner's theory, the maximum co-ordination number of the antimony pentahalogenides is 8.

O. Ruff obtained **antimony pentafluobromide**, $\text{SbF}_5 \cdot \text{Br}$, by the union of bromine with antimony pentafluoride at ordinary temp. The product is a dark brown, viscid mass. The vap. press. shows that the bromine is probably combined with the pentafluoride; any bromine in excess can be removed by warming it in a current of carbon dioxide; there is a slight dissociation of the warm pentafluobromide, and this is complete near the m.p. of antimony pentafluoride. O. Ruff also found that iodine reacts with antimony pentafluoride with the development of heat, and the formation either of a bluish green liquid or of a dark brown or bluish-green solid, according to the proportion of pentafluoride employed. When iodine is heated to 160° – 220° with an excess of the pentafluoride, **antimony decafluoiodide**, $(\text{SbF}_5)_2 \cdot \text{I}$, is formed as a dark bluish-green crystalline mass which melts at 110° – 115° , and does not lose iodine at 240° . When heated for a long time in a current of carbon dioxide, practically no iodine is given off, but antimony pentafluoride distils over. Water decomposes the decafluoiodide with a hissing noise, and the separation of iodine. If antimony pentafluoride be mixed with an excess of iodine, and the temp. be raised above the b.p. of iodine, **antimony pentafluoiodide**, $\text{SbF}_5 \cdot \text{I}$, is obtained when the excess of iodine is volatilized. The dark brown compound is decomposed above 260° with the evolution of iodine: its m.p. is a little below 80° . It is decomposed by water more slowly than is the case with antimony decafluoiodide.

According to R. W. Atkinson, tetragonal crystals of **potassium trichlorotribromantimonite**, $\text{K}_3\text{SbCl}_3\text{Br}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, crystallize from a soln. of a mol of antimony trichloride and 3 mols of potassium bromide, or from a soln. of a mol of antimony tribromide and 3 mols of potassium chloride. If a theory of molecular compounds

be true, then by mixing one eq. of antimony trichloride with 3 eq. of potassium bromide, and also one eq. of antimony tribromide with 3 eq. of potassium chloride, two different isomeric salts should be obtained, *viz.* $\text{SbCl}_3 \cdot 3\text{BKr}$, and $\text{SbBr}_3 \cdot 3\text{KCl}$. R. W. Atkinson found the two products are identical, and hence inferred that in the act of soln. the elements must be so distributed that the same compound is obtained from whichever pair of salts a start is made. The formula of the stable salt is supposed to be:

because the affinity of chlorine for potassium is greater than that of bromine for antimony, and this is thought to explain why R. W. Atkinson could prepare but one compound by the action of potassium chloride on antimony tribromide or of potassium bromide on antimony trichloride. C. H. Herty said that these substances are in all probability not true individuals, but isomorphous mixtures of the double chloride and double bromide. This view is in harmony with the observation that, after heating the supposed substance, $\text{SbCl}_3 \cdot \text{Br}_3 \cdot \text{K}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, until a constant weight is obtained, the residue contains an appreciable quantity of antimony, and that therefore the determination of the halogens in it by R. W. Atkinson affords no satisfactory evidence of the nature of the substance. According to R. W. Atkinson, the salt effloresces over calcium chloride, and loses its water readily when the temp. is raised a little. When heated to 100° , the salt darkens in colour, and at a higher temp., 200° – 300° , it loses equimolar parts of antimony trichloride and tribromide, and the residue is free from antimony. The salt deliquesces in air; and the yellow aq. soln., when sat., has a sp. gr. 1.9, and contains 120.5 grms. of salt per 100 c.c. The hydrochloric acid soln. of the salt quickly deposits crystals of potassium chloride. R. W. Atkinson also obtained pale yellow, octahedral crystals of **potassium trichlorobromoantimonite**, $\text{KBrSbCl}_3 \cdot \text{H}_2\text{O}$, from a soln. of 2 mols of antimony trichloride, and 3 mols of potassium bromide; and pale yellow rhombic crystals of **potassium hexachlorotribromodiantimonite**, $3\text{KBr} \cdot 2\text{SbCl}_3 \cdot 2\text{H}_2\text{O}$, from a soln. containing rather a less proportion of antimony trichloride than that employed in preparing the trichlorotribromantimonite. C. H. Herty regards both salts as solid soln., not chemical individuals. A. C. Vournasos prepared the stable mixed halides **potassium tribromotriiodoantimonite**, $\text{K}_3[\text{SbI}_3\text{Br}_3]$, as well as **sodium triiodotricyanoantimonite**, $\text{Na}_3[\text{SbI}_3\text{Cy}_3]$.

G. B. Bernardis' f.p. curve of mixtures of antimony trichloride and triiodide is shown in Fig. 53. O. Ruff measured the f.p. curves of mixtures of iodine monochloride and antimony pentachloride; and the results are summarized in Fig. 55. The compounds, **antimony heptachlorodiiodide**, $\text{SbCl}_5 \cdot 2\text{ICl}$, and **antimony octochlorotriiodide**, $\text{SbCl}_5 \cdot 3\text{ICl}$, may be isolated by sublimation from a mixture of antimony pentachloride (10 grms.) and iodine (4.3 or 8.6 grms.) under 15 mm. press., from a bath at 30° – 35° . They form bluish-black crystals, stout prisms or needles, m.p. 62° – 63° , which fume in the air, and dissolve readily in carbon tetrachloride or chloroform, but sparingly in antimony pentachloride. In the soln. they are strongly dissociated. A. C. Vournasos obtained a complex acid—**hydroantimonato-bromotriiodic acid**, HSbI_3Br —by the action of dry gaseous hydrogen bromide on antimony triiodide in a non-aq. medium such as glacial acetic acid. It cannot be isolated in a solid state by the evaporation of the acetic acid soln., as, owing to dissociation, only a residue of the triiodide remains. The salts of this acid are,

FIG. 55.—Freezing-point Curves of Mixtures of Antimony Pentachloride and Iodine Monochloride.

however, obtained in crystalline form by triturating and finally warming equimolecular proportions of antimony triiodide and a bromide with a suitable non-aq. medium, acetic acid, xylene, etc. The compounds form coloured crystals, which are rapidly decomposed by water or ethyl alcohol, giving antimonious oxide, hydriodic acid, and the metallic bromide. **Sodium antimonatotriiodobromide**, SbBrI_3Na , prepared in xylene, forms small, orange-yellow crystals. **Potassium antimonatotriiodobromide**, SbBrI_3K , is similar in colour, but the **ammonium antimonatotriiodobromide**, $\text{NH}_4\text{SbI}_3\text{Br}$, and **lithium antimonatotriiodobromide**, LiSbI_3Br , are reddish-yellow. **Zinc antimonatotriiodobromide**, $\text{ZnSbI}_3\text{Br}_2$, forms brown, tabular crystals, which are fairly stable and only slowly decomposed by water.

§ 23. Antimony Sulphides

The affinity of antimony for sulphur was discussed by K. Jelinek and J. Zakowsky.¹ M. Faraday suggested the possibility of the existence of *antimony subsulphide*, or **antimony disulphide**, Sb_2S_2 —analogous to realgar, As_2S_2 —but J. J. Berzelius could find no evidence in support of this assumption. B. Unger found that by treating antimony trisulphide with a soln. of sodium hydroxide or sulphide with the exclusion of air, he obtained a mixture of sulphantimonite and sulphantimonate and antimonate. The oxidation product is ascribed to the reduction of the antimony trisulphide to disulphide, but he was unable to isolate the disulphide—acids precipitate the trisulphide from the soln.—and the existence of the disulphide as a chemical individual has not been confirmed.

J. J. Berzelius showed that molten antimony trisulphide can dissolve antimony, which separates out on cooling. H. Pélabon found that fused mixtures of antimony and antimony trisulphide form one or two liquid phases according to the ratio, R , of the antimony sulphide to the total mass of the mixture. When R is less than 0.015, the liquid is homogeneous, and consists of soln. of the trisulphide in antimony, the solidification temps. of which decrease, as R increases, from 632° , the f.p. of antimony to 615° , that of a sat. soln. of antimony trisulphide in antimony. For values of R between 0.015 and 0.25, the liquid product of fusion consists of two phases, of which the less dense is a soln. of antimony in the trisulphide, and the more dense a soln. of the trisulphide in antimony; the solidification temps., 515° and 615° , of these two liquids remain sensibly the same for all values of R between the limits stated above. Finally, when R is greater than 0.25, the fused mixture is a homogeneous soln. of antimony in the trisulphide, and the solidification temp. increases with R from 515° to 555° , the f.p. of the trisulphide. These immiscible soln. are represented by the curves on the right of Fig. 56. P. Chrétien and J. M. Guinchant said that the formation of the two liquid phases with fused mixtures of antimony and antimony trisulphide is conditioned by the lower

FIG. 56.—Freezing-point Curves of Antimony and Sulphur.

sp. gr. and the higher coeff. of expansion of the trisulphide. The sp. gr. of the soln. of antimony in the trisulphide, and of trisulphide in antimony are:

Trisulphide layer	13°	64°	698°	1116°	1156°
Antimony layer	4.63	3.85	—	3.82	—
	6.75	—	6.55	—	6.45

and the percentage composition of the soln. of antimony in the trisulphide at different temp. is:

	539°	640°	702°	750°	825°	960°	1036°	1108°	1130°	1180°
Antimony .	11.28	14.34	16.00	17.96	19.01	20.6	21.0	21.8	21.3	21.1

They represented that the quantity, w , of antimony dissolved per 100 grams of the mixture at θ° by $w=20.33+0.0333(\theta-810)$ for temp. below 810° , and $w=20.33+3.003(\theta-810)$ for temp. above 810° . F. M. Jäger and H. S. van Klooster fused mixtures of antimony and sulphur, and observed only one maximum on the f.p. curve at 546° —Fig. 55. The eutectics are at 530° and 519° respectively with 61.3 and 55 at. per cent. of sulphur. On both sides of these limits two liquid layers are formed—at 530° for mixtures of sulphur and antimony trisulphide, and at 615° for mixtures of antimony and its trisulphide. There are no signs of the existence of either antimony disulphide or antimony pentasulphide on the f.p. curve. The failure of the f.p. curves to indicate the existence of the pentasulphide shows the indecisive character of this negative evidence as an *experimentum crucis* in establishing the individuality of a supposed compound.

The history of **antimony trisulphide**, Sb_2S_3 , is intimately associated with the history of antimony (*q.v.*). The miners' term for grey mineral sulphide was *Spiessglas* or *Spiessglanz*—*le verre d'antimoine*, *antimony glass*, or *antimony glance*—and this term was employed by Basil Valentine,² and G. Agricola. After antimony itself had been separated from the *antimonium sulphure mineralisatum*, the mineral came to be called—by J. G. Wallerius, L. A. Emmerling, and A. G. Werner—*graues Spiessglanzerz*, and elemental antimony *Spiessglas*. Basil Valentine, and J. Kunckel knew that the mineral contained sulphur; H. Boerhaave regarded it as a metal sulphide; and, towards the end of the eighteenth century, T. Bergman analyzed the mineral. In allusion to the crystalline form, F. Mohs called the mineral *prismatoidal antimony glance*, a term abbreviated by C. C. von Leonhard to *Antimonglanz*; and by W. Haidinger, to *antimonite*. F. S. Beudant designated it *stibine*, a term altered by J. D. Dana to **stibnite**.

In addition to the analyses made by T. Bergman, analyses of the natural or artificial trisulphide were later on reported by R. Brandes, J. Davy, and J. L. Proust; and still later by A. d'Achiardi, J. J. Berzelius, H. Credner, I. Domeyko, K. Friedrich, M. Garot, F. M. Jäger, W. Koort, J. Loczka, E. Luzzatto, W. van der Marck, M. M. P. Muir, E. Müller, G. de Angelis d'Ossat, E. Priwoznik, C. F. Rammelsberg, E. Reichardt, F. Sandberger, E. R. Schneider, O. Stutzer, T. Thomson, A. R. C. Selwyn and G. H. F. Ulrich, L. N. Vauquelin, C. E. Waite, H. W. F. Wackenroder, W. Witting, and V. Zani. These all agree with the formula Sb_2S_3 . Similar results were obtained in the analyses of the amorphous sulphide by J. P. Cooke, L. F. Nilson, E. R. Schneider, and P. Chrétien and J. M. Guinchant. The presence of arsenic was noted as early as 1617 by A. Libavius, and A. Sala.

Basil Valentine³ obtained red antimony trisulphide by subliming the spießglance with Armenian salt (ammonium chloride and sulphide); and J. R. Glauber, and N. Lemery alluded to the dissolution of spießglance in alkaline soln. and its reprecipitation as a red sulphide. According to N. Lemery, a Carthusian monk, Frère Simon, first emphasized the medicinal properties of the red sulphide which was called *poudre des Chartreux*, *pulvis Carthusianorum*, or *Carthusian powder*; and also *alkermes minerale*, or **mineral kermes**—in allusion to the resemblance of the colour to that called *kermes*, or *vegetable kermes*, derived from the *coccus ilicis*.

In 1720, this medical preparation was so much esteemed that the French government bought S. de la Ligerie's recipe for its preparation. This involved boiling spießglance with a soln. of potassium carbonate; the red powder separated from the cooling liquor. G. F. Stabel, and E. P. Meuder used potash-lye in a similar way. C. J. Geoffroy fused the spießglance with alkali carbonate, and boiled the product with water. Many other methods of preparation were devised. C. J. Geoffroy considered mineral kermes to be a compound of alkali with antimony sulphide, and P. J. Macquer also considered the alkali to be an essential constituent, but this A. Baumé denied. It was then considered to be *oxyde d'antimoine sulfuré rouge*. This is not very different from the ideas of T. Bergman, and C. L. Berthollet, and A. F. de Fourcroy. In 1821, J. J. Berzelius showed that mineral kermes is hydrated antimony trisulphide; and soon afterwards, H. Rose, and J. N. von Fuchs showed that it differs from spießglance only in its state of aggregation. Later, confirmatory analyses were made by E. Matieu-Plessy, J. Akerman, N. Teclu, and H. Baubigny. L. Gmelin has given a detailed account of mineral kermes. According to J. Bougault, kermes mineral owes its therapeutic action to the antimony oxide formed by the acids of the stomach on the contained antimony trisulphide and sodium pyroantimonate.

The preparation of antimony trisulphide.—The extraction of antimony trisulphide as *antimonium crudum* has been indicated in a special section. The crystals of antimony trisulphide occurring in the preparation of crude antimony have been described by J. A. Krenner,⁴ C. C. von Leonhard, C. W. C. Fuchs, and P. P. Heberdey. The preparation of crystalline antimony trisulphide is comparatively easy. The black sulphide can be made by the direct union of the two elements; when melted together, the combination is attended by a feeble incandescence. The region of stability is indicated in Fig. 51. J. von Liebig made the trisulphide by gradually adding to a red-hot crucible a mixture of 13 parts of antimony and 5 parts of sulphur, and fusing the mixture. W. Spring found that union occurs when an intimate mixture of the two elements is strongly compressed; C. Geitner, when a mixture is heated with water to 200° in a sealed tube; C. Geitner, and J. Uhl, when antimony is heated with gaseous or an aq. soln. of sulphur dioxide; and, according to C. Heumann and P. Köchlin, presumably, when sulphuryl chloride is passed over heated antimony—some antimony trichloride is formed at the same time.

P. Jannasch and W. Remmler made the crystalline sulphide by melting antimony trioxide with an excess of sulphur—the reaction is hastened if a trace of iodine be present. B. Unger obtained it by heating a mixture of an antimonate with an excess of sulphur; J. Durocher, and H. Arctowsky, by the action of hydrogen sulphide on the vapour of antimony trichloride, or, according to A. Carnot, on other antimony compounds; J. T. Norton, by heating a mixture of antimony chloride and sodium thiosulphate in a sealed tube at 140°–200°; and E. Weinschenk, by heating potassium antimonyl tartrate with an aq. or tartaric acid soln. of ammonium thiocyanate, or by heating it with potassium thiocyanate. N. H. Warren said that at a low temp. the amorphous sulphide is formed, and at a higher temp., the crystalline sulphide. According to H. Rose, and T. Paul, crystalline antimony trisulphide is formed when antimony pentasulphide is heated to 200°–300° in a current of carbon dioxide. B. Brauner said that the pentasulphide forms the trisulphide in the presence of a soln. of hydrogen sulphide in dil. hydrochloric acid exposed to sunlight; and the trisulphide, by the action of hydrogen sulphide on the pentasulphide suspended in dil. hydrochloric acid at 98°, or in the presence of chromium trichloride. H. de Sénarmont obtained the crystalline trisulphide by heating the pentasulphide in a soln. of sodium hydrocarbonate in a sealed tube at 250°. G. Tocco showed that alternating current electrolysis of sodium thiosulphate soln. with antimony electrodes yields the sulphides and thio-salts of this metal in proportions varying with the conditions. The proportion of the sulphide reaches 100 per cent. when a 20

per cent. thiosulphate soln. is electrolyzed at 50°–60° with a current density of 51 amps. per sq. dm. As a rule, the formation of sulphides is favoured by a high current density, limited by the value at which mechanical disintegration of the electrode begins, by a high concentration of the thiosulphate, and by a temp. of about 50°. The addition of alkali sulphide or carbonate hinders the formation of sulphide and enhances that of sulpho-salt. The current efficiency is 0.669 per cent.—*vide infra*, sodium sulphantimonite.

Amorphous antimony trisulphide was reported by J. N. von Fuchs, and H. Rose to be formed by rapidly cooling the molten compound—say by cooling the sulphide, melted in a narrow, thin-walled, glass tube, by ice-cold water. The shorter the time of fusion, and the longer the time of cooling, the greater the proportion of crystalline sulphide associated with the amorphous. A. Ditte obtained the black, crystalline sulphide by pouring the molten sulphide into cold water. H. Rose said that if a rapid current of carbon dioxide be passed over the molten trisulphide, a red sublimate of amorphous sulphide is formed a little distance away. P. Chrétien and J. M. Guinchant passed a current of nitrogen over artificial antimony trisulphide at 850°, and cooled the tube in the immediate vicinity by cold water. The sublimed trisulphide is amorphous, any excess sulphur can be removed by carbon disulphide at the b.p., and then in a sealed tube at 110°. J. von Liebig obtained the amorphous trisulphide by adding a dil. soln. of a strong acid to a soln. of an alkali or alkaline earth sulphantimonite. The amorphous trisulphide is formed when the so-called kermes (*q.v.*) is treated with tartaric or acetic acid. L. Brunet obtained the impure sulphide by the action of the sulphur dioxide fumes from roasting furnaces on sulphantimonites of the alkalis or alkaline earths. G. Vortmann obtained the amorphous trisulphide by the action of sodium thiosulphate on a soln. of an antimonious salt: $2\text{SbCl}_3 + 9\text{Na}_2\text{S}_2\text{O}_3 = \text{Sb}_2\text{S}_3 + 3\text{Na}_2\text{S}_4\text{O}_6 + 3\text{Na}_2\text{SO}_3 + 6\text{NaCl}$; a trace of sulphuric acid is formed at the same time. The colour—orange to dark red—of the product depends on the temp. and on the conc. of the soln. The amorphous trisulphide is also formed when stibine (*q.v.*) acts on sulphur or hydrogen sulphide.

O. Bosek found that the trisulphide, along with some pentasulphide, is formed when hydrogen sulphide acts slowly on a warm, hydrochloric acid soln. of antimony pentoxide, so that the long-continued passage of the gas favours the formation of the trisulphide. So does low acid conc., and a temp. not exceeding say 95°. L. M. Currie obtained similar results. As indicated in connection with some analytical reactions of antimony, antimony trisulphide is formed when hydrogen sulphide is passed into a soln. of an antimonious salt. H. Rose passed hydrogen sulphide through a soln. of antimony chloride and tartaric acid in hydrochloric acid, until the warm soln. is sat. The precipitate was washed with warm water. A. Duflos said that the soln. is not completely decomposed if the tartaric acid be omitted owing to the formation of a sulphochloride which is not all decomposed under these conditions; and, added J. P. Cooke, for a soln. of 2 grms. of antimony in 30 c.c. of conc. hydrochloric acid, 15 grms. of tartaric acid are necessary to prevent the formation of the sulphochloride. F. Schmidt said that if the precipitation is made from potassium antimony tartrate, the tartrate can be removed from the precipitate by washing with water containing potassium carbonate. R. Finkener precipitated the sulphide from an ammoniacal soln. of antimony trichloride and tartaric acid. S. P. Sharples added that when the precipitation is made from boiling soln., the trisulphide is granular and easily washed.

According to L. A. Youtz, antimony trisulphide precipitated from a soln. containing free hydrochloric acid is never pure, but is always contaminated with more or less relatively volatile antimony oxychloride, which cannot be removed even by redissolving the precipitate in ammonium sulphide and reprecipitating with acetic acid. Antimony trisulphide precipitated from a soln. free from chlorides does not suffer loss on prolonged heating at 250° in a current of carbon dioxide.

TABLE III.—THE SOLUBILITY OF ANTIMONY TRISULPHIDE IN HYDROCHLORIC ACID.

Conc. of free acid per cent. HCl	100 grms. of solution contain in grms.			100 c.c. of supernatant gas.

FIG. 57.—Solubility of Antimony Trisulphide in Hydrochloric Acid.

As previously indicated, the formation of antimony trisulphide, by the action of hydrogen sulphide on a hydrochloric acid soln. of antimony trichloride, is a reversible one, $2\text{SbCl}_3 + 3\text{H}_2\text{S} \rightleftharpoons \text{Sb}_2\text{S}_3 + 6\text{HCl}$. J. Lang found that when an excess of antimony trisulphide is allowed to remain in contact with hydrochloric acid of different conc. for 4 months, at 15° – 18° , the amounts of antimony trichloride passing into soln. are those indicated in Table III. Fig. 57 depicts the amount of antimony which escapes precipitation as trisulphide in the presence of hydrochloric acid of different concentrations. On the other hand, when a soln. of antimony trichloride in hydrochloric acid, is treated with 0.250 grm. of hydrogen sulphide per 100 parts of liquid at 20° – 24° :

Initial	{ SbCl ₃ .	0.004	0.047	0.609	1.230	1.940	3.220 grms.
	{ HCl .	18.362	20.458	22.046	22.660	22.905	23.203 "
Final	HCl .	18.4	20.5	22.2	23.0	23.4	24.0 "

at 53° the results were :

Initial	{ SbCl ₃ .	0.006	0.278	3.350	11.276	21.550 grms.
	{ HCl .	16.870	19.077	20.480	20.760	19.088 "
Final	HCl .	16.9	19.2	21.2	23.4	26.1 "

and at 97° :

Initial	{ SbCl ₃ .	trace	0.102	4.602	8.220 grms.
	{ HCl .	8.850	9.031	10.890	11.151 "
Final	HCl .	8.86	9.04	11.42	12.2 "

J. Lang found that hydrochloric acid of all concentrations acts on antimony trisulphide. In the presence of an excess of the trisulphide, the action continues until the conc. of the hydrochloric acid diminishes to a certain point, this point depending on the proportion of hydrogen sulphide present in the soln. The equilibrium will then be disturbed if the press. on the hydrogen sulphide over the soln. be increased; this causes a reversal of the reaction, which is shown by the separation of antimony trisulphide. On the other hand, if the hydrogen sulphide be removed from the soln. as it is formed, the action of the hydrochloric acid will continue until all the antimony trisulphide is dissolved. M. Berthelot, and A. Ditte discussed the phenomena from the point of view of the principle of maximum work.

H. Rose converted the red amorphous sulphide into the black crystalline form by heating it to 200° in a current of an indifferent gas. If the temp. be 180° – 190° , the red amorphous form reappears on cooling. J. P. Cooke said that at 210° – 220° ,

the conversion of red amorphous sulphide into the black crystalline form starts in one place, and extends throughout the whole mass; and the black amorphous sulphide becomes crystalline at 265° in vacuo. G. Tammann made some observations on this subject. V. Zani found that the orange-red precipitate changes into the greyish-black form at about 217°, and heat is evolved during the change. Stibnite differs from the greyish-black form only in sp. gr. A. Mourlot found the transformation occurs when the amorphous sulphide is melted; W. Spring, when it is subjected to great pressures; A. Carnot, when it is heated in a current of hydrogen sulphide; E. Schürmann, when it is heated in a sealed tube with water vapour at 200°; and H. de Sénarmont, when it is heated with water at 200°, or a soln. of sodium hydrocarbonate or potassium sulphide. H. Rose observed that no transformation occurs in water at 100°. The transformation was also found by J. L. Proust, H. Rose, and A. Ditte to occur when the amorphous sulphide is treated with dil. acids, particularly hydrochloric acid. J. Lang said that the change occurs slowly in the presence of hydrochloric acid, and this the more rapidly, the more conc. the acid. For example, at 15°–16°, the transformation occupies the following periods in hydrochloric acid of the concentration named:

HCl	20–23	18	16	15	14	13	1 per cent.
Time for transformation	8	13	21	26	33	40	150 days.

H. Rose said that the boiling acid, of such a concentration, dissolves only a little sulphide, converting amorphous antimony trisulphide in 15–120 mins. into the crystalline sulphide—the precipitated sulphide rather more quickly than that prepared in the dry way. Hydrobromic acid was found by A. Ditte to act like hydrochloric acid. A. Ditte, and H. Rose also showed that sulphuric acid affects the conversion more slowly than does hydrochloric acid. Tartaric acid, and acids which have not the power to dissolve the trisulphide, were found by H. Rose to have no perceptible action on the transformation. S. Wilson and C. R. McCrosky observed no appreciable transformation during two months' action of 7*N*-H₃PO₄, 7*N*-H₂SO₄, glacial and normal acetic acid, and a sat. soln. of hydrochloric acid in ether—at 18°–22°. With 12*N*-HCl, 7*N*-HCl, and *N*-HCl, they found the times necessary for complete transformation were respectively 0·5 day, one day, and 10·5 days. The action was attributed to a dissolution of the red variety and a reprecipitation as the less soluble black variety. With 20 per cent. aq. hydrochloric acid, complete conversion at 26·5° required forty-four hrs.; at 30°, twenty-nine hrs.; 35°, sixteen hrs.; 40°, nine hrs.; 68·5°, sixty-two mins.; and 75°, thirty-two mins. A 20 per cent. soln. of hydrobromic acid gave no change after 20 hrs. at 75°. F. de Bacho found that there is no material difference in the loss in weight when the red trisulphide is heated in carbon dioxide at temp. from 150° to 300°, the change to the black modification taking place at 212°, whilst in a current of hydrogen sulphide the change occurs at 207°. By adding ammonium chloride to the red sulphide, the temp. of the change in carbon dioxide is lowered (for example, to 170°), whilst the presence of antimony chloride reduces the temp. still further. Thus in the case of a mixture of equal parts of antimony trisulphide and trichloride, the black coloration appeared at 125°. Metallic silver also has a favourable influence on the transformation. The action of ammonium chloride in boiling soln. also promotes the formation of the black sulphide to an extent depending on the conc. of the soln., whilst the rapidity of the transformation stands in relationship to the degree of hydrolysis of the ammonium chloride and consequent acidity of the soln. The presence of antimony trichloride facilitates this conversion, which is accelerated by the presence of hydrochloric acid, antimony trisulphide, and potassium nitrate at high concentrations. Conc. soln. of electrolytes, such as sodium chloride, ammonium sulphate, or potassium nitrate alone have no effect on the transformation, which is therefore not merely the result of molecular condensation. The conversion always takes place when the conditions permit of immediate contact between the red antimony trisulphide and antimony

trichloride, whether added as such or formed in the sol'n. It is probable that the following reaction takes place : $2\text{Sb}_2\text{S}_3 + 2\text{SbCl}_3 \rightarrow 6\text{Sb} + 3\text{S}_2\text{Cl}_2$. It is also probable that the trace of free antimony thus formed, or that produced by dissociation of the red trisulphide when heated, forms in the colloidal condition a solid soln. with the antimony trisulphide. C. A. Mitchell saturated with hydrogen sulphide a soln. of antimony trioxide in dil. hydrochloric acid, and passed carbon dioxide through the boiling hot liquid to obtain the crystalline trisulphide.

The physical properties of antimony trisulphide.—Amorphous antimony trisulphide has various colours ; it may appear dark lead-grey or reddish-brown, and in thin layers hyacinth-red (J. N. von Fuchs) without showing under the microscope any sign of crystalline structure (H. Rose⁵ and N. Teclu). It may be violet (P. Chrétien and J. M. Guinchant) ; dark red, fiery red, rose, carmine-red, orange-red (B. Unger, N. Teclu, J. Lang, and E. Kopp). As shown by J. Akerman, and M. Pettenkofer, the colour depends on the mode of preparation. The different colours are probably related with the size of the grain as in the analogous case of ferric oxide noted by L. Wöhler and C. Condrea. V. Zani found that the compositions of orange-red precipitated sulphide ; of the greyish-black sulphide obtained by heating the orange-red sulphide ; and of stibnite—all correspond with Sb_2S_3 . L. M. Currie showed that the amorphous trisulphide is yellow if in a fine state of subdivision ; if the grain size is larger, the colour is crimson. Maroon colours are mixtures of the yellow-and-black crystalline sulphide. Yellow trisulphide can be obtained by electrical disintegration. Pigments precipitated in the presence of sulphides or hydrosulphides darken through varying shades of yellow, brown, and black. The difference between brown and maroon pigments is due to an adsorbed film of hydrogen sulphide on the former which prevents the growth of the particles. F. Kirchhof suggested that the colour of red antimony sulphide may be due to the closed ring structure :

Antimonium crudum, and the crystalline antimony trisulphide prepared by melting the constituent elements together, form dark grey masses with a metallic appearance. The artificial **crystals** may appear as greyish-black needles. The mineral *mine d'antimoine grise ou sulfureuse* was shown by J. B. L. Romé de l'Isle to have crystals belonging to the rhombic system. The mineral occurs in lead-grey, steel-grey masses, in coarse or fine granules, and sometimes as an impalpable grey powder. The crystals under ordinary conditions are opaque, but O. Mügge found that in sunlight very thin plates were transparent and coloured yellowish-red or deep red, and P. Drude found the transmitted light has a greater wave-length than the Li-light. The crystals commonly occur in confused aggregates or radiating groups of acicular crystals. A few measurements were reported by R. J. Haiüy, J. J. Bernhardt, and F. Mohs. The subject was examined in some detail by J. A. Krenner in his monograph : *Crystallographische Studien über den Antimonit*. E. S. Dana gave for the axial ratios of the rhombic crystals $a : b : c = 0.99257 : 1 : 1.01788$. The prismatic crystals often have acute terminations, and the vertical planes may be striated or deeply furrowed longitudinally. The crystals may also be curved, bent in knee-shaped forms, or twisted about an axial plane. The twinning or trilling of the crystals was described by J. A. Krenner, H. Schneiderhöhn, and H. Buttgenbach. The **cleavage** on the (010)-face is perfect, and that face is often bent transversely and striated. The (100)- and (110)-cleavages are imperfect. O. Mügge also detected cleavages on the (001)- and (101)-faces. The **gliding plane**, and the **percussion figures** were studied by O. Mügge, G. Seligmann, M. Kuhara, F. B. Peck, and A. S. Eakle ; and the corrosion figures by H. Schneiderhöhn. Observations on the crystals were also reported by A. Schrauf, P. Gravino, P. Groth, E. Quercigh, M. de Angelis, W. Koort, T. Haege, H. von Foullon, A. Schmidt,

O. Neff, A. Lévy, E. Rethwisch, V. Goldschmidt, H. Hessenberg, E. Artini, J. R. Blum, A. Sadebeck, and L. Bombicci. H. Schneiderhöhn studied the microstructure of polished surfaces etched with potash-lye. J. A. Krenner said that the crystals are isomorphous with those of bismuthinite, and guanajuatite. F. Rinne also discussed its isomorphism with antimony trioxide. The **X-radiogram** of stibnite was examined by H. Haga and F. M. Jäger, and P. F. Kerr. C. Gottfried found that the edge of the elementary rhomb has sides $a=11.39$ A., $b=11.48$ A., and $c=3.89$ A.; each elementary cell has 4 mols. of Sb_2S_3 ; and the calculated axial ratios are $a : b : c = 0.992 : 1 : 0.338$. Similar results were obtained by Z. Ooe.

The so-called amorphous antimony trisulphide was found by H. Rose⁶ to retain 0.2–0.6 per cent. of water when dried over sulphuric acid, or at 100° , and this is driven off at 200° as the amorphous passes into the grey sulphide. Confirmatory observations were made by G. C. Wittstein, and W. P. Dexter. According to A. Ditte, the precipitated trisulphide retains water eq. to $Sb_2S_3 \cdot 2H_2O$ when dried over sulphuric acid in vacuo for many days. J. P. Cooke said that some of the loss that occurs when the trisulphide is heated is due to the volatilization of adsorbed antimony trichloride. J. P. Cooke, L. F. Nilson, J. Akerman, and E. Matheuplessy found that the precipitate dried at 100° is free from water. V. Zani said that the losses in weight obtained by heating the orange-red precipitated sulphide to 100° , are not due to the loss of water, but to secondary reactions involving the absorption of oxygen, the loss of sulphur dioxide, and the eventual production of antimony.

The **specific gravity** of the amorphous trisulphide prepared by fusion was found by J. N. von Fuchs to be 4.15; and that of a sample not all amorphous was found by H. Rose to be 4.467. P. Chrétien and J. M. Guinchant gave 4.278 for the sp. gr. of the violet form at 0° ; 4.120 for that of the red form at 0° ; V. Zani, 4.1205, for the orange-red, precipitated sulphide; J. P. Cooke, 4.323 at 23° for the red form dried at 180° ; H. Rose, 4.421 at 16° for the precipitated trisulphide dried at 200° ; and V. Zani, 4.2906 for the greyish-black form obtained by heating the orange-red trisulphide. The sp. gr. of the crystalline trisulphide prepared from its elements was found by H. Rose to be 4.614 at 16° when in lumps, and 4.641 when powdered; A. Ditte gave 4.89; E. Quercigh, 4.651; P. Chrétien and J. M. Guinchant, 4.659 at 0° ; 4.63 at 13° ; 3.84 at 643° ; and 3.82 at 1116° . The expansion during fusion amounts to about 17 per cent. For the crystalline trisulphide obtained by heating the amorphous form, C. J. B. Karsten gave 4.752; H. Rose, 4.753–4.806 at 16° ; J. P. Cooke, 4.29 at 27° ; and P. Chrétien and J. M. Guinchant, 4.652 at 0° . For the crystalline trisulphide obtained by heating the amorphous form in dil. hydrochloric acid, H. Rose gave 4.670 at 16° ; and A. Ditte, 5.01. For the crystalline form derived from the pentasulphide, H. Rose gave 4.57. The high values reported by A. Ditte, and C. J. B. Karsten were attributed by P. Chrétien and J. M. Guinchant to the use of an impure sulphide. For the sp. gr. of stibnite, F. W. Clarke gave 4.52–4.75; H. Schröder, 4.624; V. Zani, 4.6353; and F. E. Neumann, 4.603. F. de Bacho found a gradual increase in sp. gr. on heating the red trisulphide, but no sudden rise occurred in passing from the red to the black form. The **hardness** of the mineral is 2.0–2.5. E. Madelung and R. Fuchs gave for the **compressibility**, 1.94×10^{12} dynes per sq. cm.

H. de Sénarmont measured the relative values of the **thermal conductivities** in the directions of the axes, and found for the ratio $c : b = 1.8$, for $c : a = 1.4$, and for $a : b = 1.3$; and for the isothermal ellipsoid in the directions $c : a : b = 1.8 : 1.3 : 1.4$. F. B. Peck also made observations on this subject. F. E. Neuman gave for the **specific heat** of stibnite, 0.0877–0.0907; H. V. Regnault, 0.08403 for the artificial crystals; and A. de la Rive and F. Marcet, 0.1286. A. S. Russell gave for the crystalline sulphide prepared from the fused elements 0.0850 from 4.0° to 45.7° ; 0.0800, from 0° to -73.2° ; and 0.0627, from -83.2° to -188.4° . P. Chrétien and J. M. Guinchant gave 0.0816 for the mean sp. ht. between 20° and

500°; 0.220 for the sp. ht. of the solid at 500°, and 0.263 for the sp. ht. of the liquid at 582°. N. Teclu observed that when the amorphous trisulphide is heated to 100° it becomes brown or grey, but the original colour returns on cooling. As indicated above, at temp. not far from 200°, the orange-red trisulphide becomes permanently greyish-black. R. Cusack found the **melting point** of stibnite to be between 513° and 523°; L. H. Borgström, 546°–551°; and for artificial trisulphide, H. Pélabon gave 550°; Y. Takahashi, 494°; E. Quercigh, 548°; K. Konno, 549°; P. Chrétien and J. M. Guinchant, 540°; and F. M. Jäger and H. S. van Klooster, 546°—*vide* Fig. 50. K. Friedrich said that stibnite from Ichinokawa, Japan, does not decrepitate when heated; if the fine-grained material is heated in oxygen, it sinters together at 370°; in a current of air, at 440°; and at 510°, the whole mass melts. A lump of the stibnite began to melt at 540°. F. Krafft and L. Merz observed that when the trisulphide is heated in vacuo at 530°, it distils with great rapidity, and it can thus be quantitatively separated from bismuthinite, which distils at 740°. If air be excluded, antimony trisulphide can be distilled without decomposition. C. Zengelis showed that antimony trisulphide can vaporize at ordinary temp. J. Joly gave 380° for the sublimation temp. of stibnite. P. Chrétien and J. M. Guinchant gave 1180° for the **boiling point**. H. Pélabon found the **freezing-point constant** to be 788°–797°; and he found the latent **heat of fusion** to be 17.5 Cals., when the calculated value is 16.7 Cals. According to A. Mourlot, by raising the temp. of stibnite high enough for a few minutes in an electric arc furnace it can be completely decomposed into antimony, etc. P. Chrétien and J. M. Guinchant said that the trisulphide is usually dissociated at 600°. P. Chrétien and J. M. Guinchant found the **heat of formation** of antimony trisulphide from octahedral sulphur and antimony to be (2Sb,3S)=38.2 Cals. for the black variety, 33.9 Cals. for the violet; and for the moist orange-red, 34.0 Cals., and for the dried, 32.6 Cals. They therefore gave for the **heat of transformation**: violet to black, 4.3 Cals.; dry, precipitated, orange-red to black, 5.6 Cals.; and moist, precipitated, orange-red to black, 4.2 Cals. K. Jellinek and J. Zakowsky calculated for the mol. ht. of formation, 31.3 Cals. M. Berthelot measured the **heat of solution** of the amorphous orange-red sulphide in a soln. of sodium sulphide at 12°, and found it to be 666 cal., when that of the crystalline form is 631 cal.; the **heat of crystallization**, within the limits of experimental error, is therefore 35 cal.

P. Drude found the **indices of refraction**, μ_1 , and μ_2 , for sodium light to be 5.17 and 4.49; and for the **coefficients of absorption**, k_1 , and k_2 , he gave 0.143 and 0.177. E. C. Müller found for the light of wave-length λ :

λ	C-ray	610 $\mu\mu$	D-ray	E-ray	510 $\mu\mu$	F-ray	460 $\mu\mu$	G-ray
μ_1	4.69	4.87	5.12	5.47	5.48	5.53	5.17	4.65
μ_2	0.0537	0.104	0.124	0.234	0.305	0.404	0.531	0.681
k_1	4.47	4.26	4.37	4.52	4.51	4.49	4.41	4.28
k_2	0.120	0.177	0.187	0.252	0.286	0.344	0.413	0.485
$\mu_1 - \mu_2$	0.22	0.61	0.75	0.95	0.97	1.04	0.76	0.37

A. Hutchinson obtained the indices of refraction $\alpha=3.194$, $\beta=4.046$, and $\gamma=4.303$. Stibnite has the highest known index of refraction and **birefringence**, $\mu_1 - \mu_2$. K. Asagoe and N. Kumagai studied the reflecting power; W. W. Coblenz and C. W. Hughes, the ultra-violet reflecting power; W. W. Coblenz, and I. B. Crandall, the ultra-red reflecting power; and I. B. Crandall, and E. P. T. Tyndall, the optical properties of stibnite. A. de Gramont examined the **spark spectrum** of stibnite. C. Doelter found that **radium rays** make stibnite rather more violet-grey, and somewhat darker; the amorphous form is not crystallized by exposure to these rays. O. Stelling studied the **X-ray absorption spectrum** for the K-series. The mineral does not phosphoresce in the **cathode rays**; and the sol is browned but not precipitated by **ultra-violet rays**. A. Hutchinson found the mineral is **diathermal** in that it is not opaque to **ultra-red rays**. If the plane of the symmetry of a crystal coincides with the plane of oscillation of the nicol's prism, no heat is

transmitted through the crystal, but when the plane of symmetry is rotated 45° , a maximum transmission is obtained. E. T. Wherry classed stibnite as a poor **radiodetector**. W. W. Coblenz studied the **photoelectric effect** with stibnite, and found that the passage of an alternating current has no permanent effect on the photoelectric sensitivity. J. O. Perrine observed no ultra-violet fluorescence when stibnite is exposed to X-rays for 5 hrs. The maximum effect occurs at 0.77μ . H. F. Vieweg studied the frictional electricity.

According to H. Rose, amorphous antimony trisulphide is a very bad **electrical conductor**; and F. Beijerinck said that the crystalline mineral is a very bad conductor at 240° . C. Doelter, G. Cesaro, and H. Bäckström and K. Angström obtained similar results. J. Königsberger and K. Schilling, and F. M. Jäger found rhombic antimony sulphide is a very bad conductor of electricity in darkness at room temp. while the sulphide which has been fused is a good conductor. The sp. resistance of the rhombic native crystals is about 10^8 ohms at ordinary temp., but this decreases with a rise of temp. F. M. Jäger found the **electrical resistance** of a centimetre rod of Japanese stibnite to be 500×10^6 to $20,000 \times 10^6$ ohms. C. Tubandt and M. Haedicke found that antimony trisulphide is an insulator below its m.p. The electrical conductivity of crystals of stibnite is photosensitive since it is very much augmented by exposure to light. The effect is not due to a rise of temp. With white-light, the conductivity was raised 200–210 per cent.; in red-light, 194–205 per cent.; in yellow-light, 150–153 per cent.; in green-light, 116–118 per cent.; and in blue-light, 175–176 per cent. The green rays for which the index of refraction and birefringence attain their greatest value, have least effect on the electrical conductivity. When the mineral is finely powdered, the effect is suppressed, showing that the effect is due to the microscopic structure of the mineral. This property of stibnite is important; light sensitive cells can be obtained with a much larger potential difference than with selenium, and the recovery of the cell occupies less time. The subject was also investigated by B. Glatzel, T. W. Case, and C. Ries. J. Olie and H. R. Kruyt found that impure stibnite was not photoelectric. Artificial stibnite prepared by heating the constituents in vacuo at 600° is photosensitive; and the maximum sensitiveness, corresponding with that of Japanese stibnite, is attained with a mixture equivalent to Sb_2S_3 . The rapid change in the photoelectric sensitiveness when the mixture deviates slightly from Sb_2S_3 , is probably due to the formation of mixed crystals. Small quantities of impurities are of considerable importance—even impurities derived from the glass in which the sulphur is heated have an effect. For the electrical conductivity of mixtures of antimony and antimony trisulphide, *vide supra*, antimony. Unlike F. M. Jäger, J. Olie and H. R. Kruyt found that the stibnite can be melted and solidified without appreciably changing the effect. The conductivity of a surface of stibnite strewn with lycopodium shows that the favoured zone is elliptical. This subject was studied by H. de Sénarmont, and E. Jannettaz. K. Fischbeck found that there is a 60 per cent. reduction of powdered antimony trisulphide on a platinum electrode in contact with 2 per cent. sulphuric acid. E. E. Fairbanks found the **dielectric constant** is less than 81.

The chemical properties of antimony trisulphide.—H. Rose,⁷ and P. Berthier showed that when antimony trisulphide is heated to near its m.p., it is reduced to the metal by **hydrogen**; E. R. Schneider observed no reduction at 320° , but found that it occurred near 360° , and at this temp., antimony is transformed into the trisulphide by hydrogen sulphide. The equilibrium conditions in the reaction $\text{Sb}_2\text{S}_3 + 3\text{H}_2 \rightleftharpoons 2\text{Sb} + 3\text{H}_2\text{S}$ were studied by H. Pélabon—*vide supra*, antimony. H. Pélabon gave for the ratio $v_{\text{H}_2\text{S}}/v_{\text{H}_2}$, 0.754 at 440° ; 0.945 at 510° ; 1.07 at 555° ; 1.27 at 610° ; and 1.32 at 625° ; and K. Jelinek and J. Zakowsky calculated for the vap. press., p , of the sulphur at 440° , $\log p = -6.93$; at 515° , -5.88 ; at 565° , -5.58 ; and at 610° , -4.92 . When the trisulphide is heated in **air**, the crystalline form burns with a blue flame, before it melts, forming sulphur dioxide and a mixture of the tri- and tetra-oxides (*q.v.*); J. von Liebig said that the amorphous

form glows when brought in contact with a red-hot substance. L. A. Buchner found that powdered, black antimony trisulphide slowly oxidizes when exposed to air; a soln. of potassium tartrate will extract the trioxide from the exposed trisulphide. W. Haidinger observed the passage of stibnite to valentinite, and antimony ochre; while A. S. Eakle reported the formation of sénarmontite, sulphur, and gypsum; H. Laspeyres observed pseudomorphs of antimony ochre after stibnite; and J. R. Blum reported pseudomorphs of several other minerals after stibnite. P. L. Geiger and L. Hesse said that when the moist, amorphous sulphide is exposed to air it is gradually converted into the trioxide; while E. Pollacci said that antimony sulphide oxidizes rapidly in moist air. F. Carmichael observed 0.07 per cent. oxidation occurred by exposing the powdered mineral to the action of aerated water for 13 days. P. Jannasch found that stibnite is readily decomposed when heated in **oxygen**. According to W. R. Schoeller, antimony is produced when stibnite is heated alone in a current of air, and subsequently at 950° in a current of carbon dioxide. K. Friedrich found that the oxidation of antimony trisulphide: $2\text{Sb}_2\text{S}_3 + 9\text{O}_2 = 2\text{Sb}_2\text{O}_3 + 6\text{SO}_2$, begins at about 290° with a grain-size of 0.10 mm., and at 340° , with a grain-size 0.20 mm. H. Saito found that oxidation begins at about 290° , and above 500° , the oxidation of the trioxide: $\text{Sb}_2\text{O}_3 + \frac{1}{2}\text{O}_2 = \text{Sb}_2\text{O}_4$, begins; it is rapid at 520° , and ceases at 560° . A. Mailfert said that **ozone** transforms stibnite into antimony sulphate. E. H. Riesenfeld and W. Haase found that a colloidal soln. of the trisulphide is oxidized by ozone to antimonic acid. G. Tammann and H. Bredemeier studied the surface oxidation of antimony sulphide. O. Weigel inferred from his conductivity measurements that a litre of **water** dissolves 5.2×10^{-6} mol of the precipitated trisulphide per litre at 18° . A. Ditte said that the formula of the precipitated, amorphous trisulphide when dried in vacuo over sulphuric acid is $\text{Sb}_2\text{S}_3 \cdot 2\text{H}_2\text{O}$, but this is probably a chance result, since there is no evidence of the formation of definite *hydrates of antimony trisulphide*; E. M. Plessy gave $\text{Sb}_2\text{S}_3 \cdot \text{H}_2\text{O}$. As shown by P. L. Geiger and L. Hesse, and by A. Vogel, boiling water slowly decomposes the precipitated trisulphide, forming hydrogen sulphide and a little antimony trioxide which passes into soln. P. de Clermont and J. Frommel said that the freshly precipitated sulphide is more readily decomposed than that which has been dried at 125° . By boiling the trisulphide with water under reduced press., decomposition can be observed at 95° . E. Lesser, M. Rousseau, W. Elbers also observed the reaction with hot water. According to J. Lang, stibnite is also readily decomposed by boiling water, and a little soluble sulphantimonite is formed by the action of alkali dissolved from the glass. C. Doelter showed that powdered stibnite reacts with water when the mixture is heated in a sealed tube for some weeks. The presence of carbon dioxide, or of sodium or hydrogen sulphide, accelerates the reaction. H. V. Regnault found that when steam is passed over red-hot antimony trisulphide, hydrogen sulphide and dioxided antimony oxysulphide are formed. L. J. Thénard found that **hydrogen dioxide** converts antimony trisulphide into sulphate, and, added L. Zambelli and E. Luzzato, if the dioxide be in excess, at 40° , antimony pentoxide is formed. J. Clark observed that an ammoniacal soln. of hydrogen dioxide converts the trisulphide completely into ammonium metantimonite; and F. Raschig, T. Poleck, and W. Hampe, that **sodium dioxide** converts the trisulphide into sodium metantimonite.

H. Moissan⁸ found that, at ordinary temp., **fluorine** converts antimony trisulphide into the trifluoride, and the reaction is accompanied by a blue flame. H. Rose observed that **chlorine** does not act on the powdered crystalline trisulphide in the cold, but when heated, antimony trichloride is formed. P. Jannasch and W. Remmler showed that the trisulphide is completely decomposed by **bromine**; and, in the presence of water, E. H. Bartley said that hydrated antimony pentoxide is formed. J. Lemberg found that a soln. of bromine in potash-lye converts the trisulphide into soluble potassium antimonate. H. C. Bolton found that **iodine** in the presence of water completely decomposes stibnite. H. Rose, C. Tookey,

and L. L. de Koninck and A. Lecrenier observed that when a current of **hydrogen chloride** is passed over the heated trisulphide, hydrogen sulphide and antimony trichloride are formed; and J. Kelley and E. F. Smith also noticed that antimony trisulphide is completely volatilized when heated in a current of hydrogen chloride or **hydrogen bromide**. Conc. **hydrochloric acid** was found by H. Rose to act similarly. H. N. Warren found that the native sulphide is more quickly attacked than the precipitated sulphide. W. R. Lang and C. M. Carson found that the trisulphide is soluble in a mixture of 50 parts of water and 18 parts of hydrochloric acid, of sp. gr. 1.16, even when completely saturated with hydrogen sulphide. Consequently, hydrogen sulphide does not precipitate antimony trisulphide from conc. hydrochloric acid soln.—*vide supra*, Fig. 54. The work of J. Lang, M. Berthelot, and A. Ditte on this subject has been previously discussed; and the application of the reaction for the analytical separation of antimony trisulphide from the less soluble arsenic trisulphide has been discussed by F. Field, E. Lesser, M. Schleier, L. Loviton, H. Köhler, A. Stromeier, F. Neher, etc.—*vide* arsenic trichloride. E. R. Schneider observed that amorphous trisulphide becomes crystalline in the presence of **hydrobromic acid**—*vide supra* for the conversion of amorphous into the crystalline trisulphide. According to R. Böttger, a mixture of **potassium chlorate** and antimony trisulphide is explosive, and it can be detonated by the electric spark.

The relations between antimony trisulphide and **sulphur** are indicated in Fig. 56. S. E. Linder and H. Picton⁹ thought that colloidal antimony trisulphide is united with **hydrogen sulphide**, and M. Berthelot added that if a soln. of an antimony compound is added in very small drops with continual agitation to a sat. soln. of hydrogen sulphide, the precipitate which forms is redissolved. This fact points to the formation of a hydrosulphide or unstable *hydrosulphantimonious acid*, which, however, can exist only in contact with water in presence of a large excess of hydrogen sulphide. A. Baudrimont, and H. Feigl found that sulphur monochloride dissolves antimony trisulphide, forming sulphur and antimony trichloride. A. E. Becquerel, and A. V. L. Verneuil found that antimony trisulphide modifies the phosphorescence of **calcium and strontium sulphides**. According to H. Prinz, the reaction with heated **thionyl chloride** can be represented: $6\text{SOCl}_2 + 2\text{Sb}_2\text{S}_3 = 4\text{SbCl}_3 + 9\text{S} + 3\text{SO}_2$, and O. Ruff showed that antimony trisulphide is dissolved by **sulphuryl chloride**, forming antimony trichloride with the separation of sulphur, but in the presence of aluminium chloride, sulphur dichloride is produced. P. Berthier said that an aq. soln. of **sulphur dioxide** is without action on the trisulphide, but A. Gueront found that a little amorphous trisulphide is dissolved with the separation of sulphur, and the formation of hydrogen sulphide. R. Bunsen found that a boiling soln. of **potassium hydrosulphite** and sulphur dioxide completely dissolves the trisulphide, but L. F. Nilson said that in one experiment 71 per cent. remained undissolved; arsenic trisulphide, however, was completely soluble under the same conditions. Antimony trisulphide remains quite undissolved in the presence of a large quantity of thiosulphate formed by boiling its soln. in potassium sulphide, after adding excess of sulphurous acid, but the thiosulphate precipitates a large quantity of arsenic trisulphide. If the proportion of thiosulphate is lessened, so as to ensure complete soln. of the arsenic, then antimony is also dissolved. According to H. Rose, boiling conc. **sulphuric acid** slowly dissolves the trisulphide producing a soln. of antimony sulphate, and sulphur dioxide gas, and a fused mass of sulphur. C. Hensgen obtained the sulphate in this way. H. Rose found that dil. sulphuric acid converts the amorphous into the crystalline trisulphide—*vide supra*. M. Websky found that when the trisulphide is fused with **potassium hydrosulphate**, a basic sulphate remains suspended in the fused mass; it is insoluble in water. If the fusion be continued for a long time, a clear liquid is obtained and potassium pyroantimonite, soluble in water, is produced, as well as a little antimonate.

According to G. Gore,¹⁰ red, orange, and black antimony trisulphides are insoluble

in liquid **ammonia**, and E. G. Franklin and C. A. Kraus also confirmed the observation with the black trisulphide. M. Carot found that 0.005 part of crystalline antimony trisulphide dissolves in 100 parts of aq. ammonia, forming a yellow soln. from which hydrochloric acid separates a red precipitate; 0.167 part of the amorphous sulphide is dissolved by aq. ammonia. L. Garnier also found that amorphous, freshly precipitated trisulphide is readily soluble in aq. ammonia, and H. Capitaine observed that when the soln. stands exposed to air, the trisulphide is again precipitated. P. de Clermont observed that a boiling soln. of **ammonium chloride** converts the trisulphide into antimony trichloride and ammonium sulphide. F. Ephraim found that when **sodamide** is heated with the trisulphide a vigorous reaction occurs, and antimony and sodium sulphantimonite are produced. H. Rose, and R. Bunsen found that conc. **nitric acid** transforms the trisulphide partly into sulphate and partly with nitrate with the separation of sulphur; with fuming nitric acid of sp. gr. 1.52, on a water-bath, sulphuric acid and antimony pentoxide are formed. A hot mixture of dil. sulphuric and nitric acids gradually produces a mixture of antimony sulphate and sulphur; a mixture of hydrochloric and nitric acids forms antimony trichloride and sulphur; aqua regia forms hydrated antimonious acid; and similarly also with a mixture of hydrochloric acid and potassium chlorate. C. R. Fresenius found that when the trisulphide is heated with a mixture of ammonium chloride and nitrate (5 : 1), the trisulphide is completely transformed into trichloride. A mixture of **potassium nitrate** and antimony trisulphide detonates at a red-heat yielding potassium sulphantimonate and antimony nitrate. H. Rose observed that when the trisulphide is heated with **phosphine**, hydrogen sulphide and a mixture of phosphorus and antimony are formed. E. Baudrimont found that **phosphorus chlorides** react with the trisulphide, forming antimony trichloride and phosphorus sulphide as well as some antimony sulphophosphide. For the behaviour of the trisulphide with **antimony**, *vide supra*, Fig. 56. H. Pélabon studied the effect of antimony on the trisulphide in an atm. of hydrogen. For the action of **antimony trioxide**, and of **antimony tetroxide**, *vide supra*. W. R. Schoeller showed that at 965°, a mixture of trisulphide and trioxide (1 : 2) furnishes antimony. J. Fiedler showed that a mixture of the sulphide and oxide loses oxygen in sunlight. E. R. Schneider observed the formation of antimony sulphochloride when the trisulphide is heated with **antimony trichloride**, and likewise sulphoiodide with **antimony triiodide**. 100 parts of the trichloride dissolve 6.67–7.14 parts of the trisulphide.

O. Materne¹¹ observed that antimony trisulphide, unlike arsenic trisulphide, is only slightly soluble in a hot two per cent. soln. of **borax**, and rather more soluble in a cold soln. L. Kahlenberg and W. J. Trautmann found that **silicon**, at comparatively low temp., does not act on antimony trisulphide, but at very high temp. a reaction occurs.

P. Berthier found that antimony trisulphide is quickly reduced by **carbon** to antimony, forming carbon disulphide when it is heated with carbon; and A. P. Hernandez, discussing the possibility of reducing the proportion of reducing agent for a given yield, represented the reaction with carbon in the presence of potassium nitrate: $\text{Sb}_2\text{S}_3 + 8\text{KNO}_3 + 6\text{C} = 2\text{Sb} + 3\text{K}_2\text{SO}_4 + \text{K}_2\text{CO}_3 + 4\text{CO}_2 + \text{CO} + 4\text{N}_2$. F. Göbel found that the trisulphide is partly reduced when it is heated in a current of **carbon monoxide**. N. D. Costeanu observed no chemical action with **carbon dioxide** at temp. up to 1100°. H. C. Bolton found that the trisulphide is insoluble in **formic and acetic acids**. A. C. Vournasos observed that at 400° **sodium formate** reduces antimony trisulphide to antimony and hydrogen sulphide. According to F. W. Clarke, the amorphous sulphide is decomposed when boiled for a long time with **oxalic acid**, and the antimony which is dissolved is precipitated from the soln. by hydrogen sulphide, while the soln. of stannic sulphide is not precipitated in the presence of an excess of oxalic acid. Hence the two sulphides can be separated by the reaction. The analytical process was discussed by F. W. Clarke, E. P. Dewey, A. Carnot, J. Clark, and E. Lesser. H. C. Bolton also observed that

antimony trisulphide is soluble in a hot soln. of oxalic acid; and H. C. Bolton, and H. Gordon, in a hot soln. of **tartaric acid**. H. Rose said that the trisulphide is only slightly attacked when boiled with a soln. of tartaric acid or potassium tartrate. H. C. Bolton found that the trisulphide is soluble in cold or hot soln. of **citric acid**, and that it is very easily soluble in citric or oxalic acid in the presence of potassium nitrate, nitrite, or chlorate. The trisulphide is slightly soluble in **malic, benzoic, picric, and pyrogallic acids**. According to J. von Liebig, antimony trisulphide is reduced to antimony when fused with **potassium cyanide**, and potassium thiocyanate is produced. H. Rose also showed that some antimony trisulphide escapes reduction owing to the formation of a sulphantimonite. If the mixture be heated in a current of hydrogen, C. R. Fresenius observed the formation of an antimony mirror, but not so with a current of carbon dioxide. A. Levul reduced the trisulphide by heating it with **potassium ferrocyanide**. R. Zsigmondy found that glass is coloured yellow by antimony trisulphide.

When antimony trisulphide is heated to redness in the presence of many **metals**—sodium, potassium, copper, tin, iron, etc.—antimony is formed. This unites with the excess of metal, forming an antimonide (*q.v.*), and the metal sulphide unites with the antimony trisulphide, forming a sulphantimonite. According to G. Marchal,¹² the displacement of antimony from antimonious sulphide (stibnite) by copper always resulted in the formation of cuprous sulphide whatever the proportion of copper employed. The reaction, scarcely perceptible at 500°, occurs readily at 600°–700°, and at that temp. is complete in about 8 hrs., the antimony volatilizing whilst almost pure cuprous sulphide remains. When insufficient copper is used for the complete formation of cuprous sulphide, no cupric sulphide is formed, but instead the compound $3\text{Cu}_2\text{S}\cdot\text{Sb}_2\text{S}_3$, which is only slowly decomposed above 700°, antimony sulphide subliming without decomposition, leaving finally a residue of cuprous sulphide only. C. Pertusi found that when antimony trisulphide is suspended in water and mixed with five times its weight of powdered magnesium, it reacts like arsenic trisulphide (*q.v.*). N. Parravano and P. Agostini studied the action of aluminium. Many **metal oxides** mixed with carbon act similarly because the carbon reduces the oxide to the metal. R. Bunsen found that **mercuric oxide** transforms the trisulphide into antimony pentoxide. J. J. Berzelius found that when an excess of **alkali hydroxide or carbonate** is heated with antimony trisulphide, antimony pentoxide and an alkali sulphide are formed; the antimony pentoxide forms either an oxysulphantimonate or an antimonate with the undecomposed alkali and the trisulphide, while the alkali sulphide forms a sulphantimonite. The reaction with an excess of carbonate is symbolized: $5\text{Sb}_2\text{S}_3 + 7\text{K}_2\text{CO}_3 = 7\text{CO}_2 + 3\text{K}_4\text{Sb}_2\text{S}_5 + \text{K}_2\text{Sb}_4\text{O}_7$; and with an excess of trisulphide, $4\text{Sb}_2\text{S}_3 + 3\text{K}_2\text{CO}_3 = 6\text{KSbS}_2 + \text{Sb}_2\text{O}_3 + 3\text{CO}_2$. Some antimony may be produced by the reaction: $2\text{K}_2\text{Sb}_4\text{O}_7 = 2\text{Sb} + 3\text{Sb}_2\text{O}_4 + 2\text{K}_2\text{O}$; or, according to H. Rose, by the reaction: $5\text{K}_4\text{Sb}_2\text{S}_5 = 4\text{Sb} + 6\text{K}_3\text{SbS}_4 + \text{K}_2\text{S}$. J. von Liebig found that the amorphous trisulphide dissolves in cold alkali-lye, forming potassium antimonite and sulphantimonite; and, according to B. Unger, some sulphantimonate is formed at the same time. When the crystalline trisulphide is boiled with alkali-lye, the alkali sulphide and antimony oxide first produced are converted into antimonites and sulphantimonites. The pyrosulphantimonite can dissolve more trisulphide $\text{K}_4\text{Sb}_2\text{S}_5 + \text{Sb}_2\text{S}_3 = 4\text{KSbS}_2$; but when the soln. is cooled, the pyrosulphantimonite is reformed, and the trisulphide is deposited as *mineral kermes*. O. Materne observed that a boiling soln. containing 5 per cent. Na_2CO_3 dissolves antimony trisulphide, but deposits it as orange-brown trisulphide on cooling. Acids, or ammonium chloride, precipitate the orange trisulphide from the soln., but the last trace is deposited only in the presence of hydrogen sulphide. A. Terreil said that a soln. of potassium carbonate does not act on antimony trisulphide; and that fused potassium carbonate furnishes more mineral kermes than sodium carbonate. J. Lemberg said that a hot or cold soln. containing $\text{KOH} : 4\text{H}_2\text{O}$ covers stibnite with a red mixture of antimony trioxide and trisulphide. In etching

stibnite with alkali-lye, H. Schneiderhöhn found that the (001)-face is the most quickly attacked, the (100)-face less quickly; and the (010)-face is attacked the most slowly. H. Weppen said that soln. of the **alkaline earth hydroxides** form sulphantimonites when boiled with antimony trisulphide; and A. Terreil found that while a soln. of calcium hydroxide reacts with antimony trisulphide, a soln. of strontium or barium hydroxide has no action. J. Lemberg said that baryta-water colours the surface of stibnite with a red mixture of antimony trioxide and trisulphide.

E. Schürmann found that a soln. of **copper sulphate** decomposes the trisulphide completely; soln. of **zinc and cadmium sulphates**, and of **stannous chloride** have no action; and a soln. of **mercuric chloride** completely decomposes the trisulphide. A. Vogel noticed that **mercurous chloride** gradually forms antimony trichloride and mercuric sulphide; and P. L. Geither said that with freshly precipitated mercurous chloride and antimony trisulphide, moist or dry, the decomposition is rapid. At 100°, mercuric chloride is blackened by the dry trisulphide. A. Lindner found that a conc., feebly acidic soln. of **ferric chloride** completely decomposes antimony trisulphide with the separation of sulphur.

Colloidal antimony trisulphide.—According to H. O. Schulze,¹³ colloidal antimony trisulphide is probably the primary product of the action of hydrogen sulphide on antimonious salts; and the crystalline trisulphide is produced by the action of acids or salts on the amorphous variety. Assuming that the amorphous antimony trisulphide, previously described, is really non-crystalline, in modern terminology it would be called a **hydrogel of antimony trisulphide**. As in the corresponding case of arsenic trisulphide, colloidal soln. or the **hydrosol** of antimony trisulphide can be obtained by the action of hydrogen sulphide on a dil. soln. of antimonious salts. Thus, H. Capitaine saturated with hydrogen sulphide an aq. soln. of antimony trioxide. The small solubility of the trioxide in water renders it possible to obtain only a very dil. colloidal soln. by this means, but, added H. O. Schulze, a more conc. soln. can be obtained by repeating the addition of more trioxide, and hydrogen sulphide a number of times. H. O. Schulze treated soln. containing not more than 0.5 per cent. of potassium antimonyl tartrate with hydrogen sulphide; soln. containing 1.6–1.7 per cent. of the salt are completely precipitated by hydrogen sulphide. He also obtained the colloidal soln. by passing hydrogen sulphide into a soln. of antimony trioxide (4.4 grms. per litre) and tartaric acid (12.9 grms. per litre). H. Picton poured the aq. soln. of antimony trioxide into hydrogen sulphide-water, and removed the excess of hydrogen sulphide by a current of air. According to A. Ditte, if a few drops of a soln. of potassium sulphide be added to water holding amorphous antimony trisulphide in suspension, a brownish-red gelatinous mass is formed which forms a yellow soln. with potash-lye. The soln. is coloured dark red by water, and it soon congeals to an orange-red or brownish-red jelly. If the water containing the trisulphide in suspension be treated with enough potassium sulphide to dissolve most of the antimony trisulphide, and the liquid be then diluted with 10–12 vols. of water, the soln. is coloured red, and it quickly congeals. A. Ditte showed that potassium sulphide can transform antimony trisulphide into a colloid, which subsequently produces complex sulphides (*q.v.*). S. Ghosh and N. R. Dhar found that antimony sulphide and its complex salts are peptized to the colloidal form by alkali-lye, yellow ammonium sulphide, and sodium arsenite. M. S. Wolvekamp obtained colloidal soln. with the trisulphide associated with a protein. F. V. von Hahn made the trisulphide by cathode charging, and by the arc process; and S. Utzino, and H. Neugebauer, by extremely fine grinding. The soln. with particles in the finest state of subdivision are not the most stable.

According to H. O. Schulze, the antimony is present in colloidal soln. wholly as trisulphide. S. E. Linder and H. Picton thought that the trisulphide is actually united to some hydrogen sulphide. The colour of the colloidal soln. depends on the state of subdivision of the colloid. It may vary from red to yellow. If the liquid

be contained in a litre flask, a soln. with 0.0025 per cent. of Sb_2S_3 appears raspberry-red; with 0.00166 per cent., to 0.0010 per cent. yellowish-red; 0.0001 per cent. wine-yellow; 0.0000 per cent. light wine-yellow; and one with 0.00001 per cent. Sb_2S_3 can be recognized only in thick layers. W. Biltz and W. Geibel has described the ultra-microscopic appearance of the soln. The clear dil. soln. shows intensely coloured, minute spheres of light. A dil. colloidal soln. of the trisulphide appears slightly fluorescent. H. Zsigmondy and C. Carius discussed the grain-size of the hydrosol. H. Picton said that the soln. keeps well, but has a tendency to deposit small quantities of the trisulphide. It is not coagulated by boiling. In a beam of light concentrated by a lens—Tyndall's effect—the track of the beam was marked by a beautiful, soft, red glow, the light of which, on examination with a Nicol's prism, was found to be completely polarized. The soln., therefore, has no true fluorescence, but consists of excessively minute particles in suspension. The most dil. soln. gave similar results. On dialyzing the colloidal soln. prepared from the tartrate, the liquid appeared to become more strongly fluorescent as dialysis proceeded, and in about 10 days, the particles in suspension were of microscopic dimensions. On further dialysis, by which means all the tartrate present was eliminated, the antimony began to precipitate, and in the course of a few weeks was completely thrown down. This is interesting, as showing the progress of a gradual condensation occurring among the minute particles. There was no sudden or irregular change, but, apparently, a regular increase of size among all the particles, forcibly reminiscent of molecular condensation. The presence of the tartrate thus hinders the precipitation of the colloid. The dialyzed soln., said H. O. Schulze, is tasteless, and dries to a brown film resembling lacquer, and containing water. N. R. Dhar and A. C. Chatterji studied the adsorption of sols and ions by antimony sulphide. H. O. Schulze found that a colloidal soln. of antimony trisulphide is less readily converted spontaneously into the insoluble form than is colloidal arsenic trisulphide. No sign of diffusion of the colloidal antimony trisulphide was observed by H. Picton, the trisulphide in suspension was separated by filtration through porous earthenware; the soln. passed through well-washed filter-paper. The liquid gave a continuous spectrum. R. Wintgen found that the refractive index and sp. gr. are linear functions of the conc. of the soln. N. Lubavin, and A. Sabanéeff found that when the frozen soln. is thawed, the trisulphide is coagulated. H. Picton observed no temp. change during the coagulation of the soln. S. S. Bhatnagar and co-workers studied the action of light. A. Sabanéeff observed no perceptible lowering of the f.p. of water by the colloidal trisulphide. H. O. Schulze found that the maximum dilutions of soln. of acids and salts which cause the precipitation of antimony trisulphide are as follow:

HCl, 1:270; H_2SO_4 , 1:140; $H_2C_2O_4$, 1:45; K_2SO_4 , 1:65; $(NH_4)_2SO_4$, 1:130; $MgSO_4$, 1:1720; $MnSO_4$, 1:2060; $NaCl$, 1:135; $BaCl_2$, 1:2050; $MgCl_2$, 1:5800; $CoCl_2$, 1:2500; KNO_3 , 1:75; $FeCl_3$, 1:2500; $Ba(NO_3)_2$, 1:1250; $K_2Al_2(SO_4)_4$, 1:35,000; $(NH_4)_2Fe_2(SO_4)_4$, 1:800; $K_2Cr_2(SO_4)_4$, 1:40,000; $KSbOC_4H_4O_6$, 1:18.

A few drops of a conc. soln. of tartaric acid with a conc. colloidal soln. of antimony trisulphide give a clear mixture, which then becomes turbid, particularly when warmed. Cane sugar, boric acid, and glacial acetic acid behave like tartaric acid. No precipitation occurs when to the hot or cold soln. is added carbon dioxide, arsenic trioxide, alcohol, chloral hydrate, or salicylic acid—*vide* colloidal arsenic trioxide. The subject was studied by K. C. Sen and co-workers, Wo. Ostwald, S. Ghosh and N. R. Dhar, A. Ivanitzkaja and L. Orlova, L. Schiloff, and S. Wosnessensky. S. S. Bhatnagar and co-workers studied the effect of the size of the colloidal particles on the coagulation by salts; adsorbed sucrose, glucose, or gelatin loses its optical activity, and this is taken to agree with a chemical explanation of the mechanism of protective action with colloids; K. Jablczynsk and co-workers studied the velocity of coagulation of the sol. P. B. Ganguly and N. R. Dhar found the colloid is coagulated by exposure to tropical sunlight.

N. R. Dhar and A. C. Chatterji did not succeed in making antimony trisulphide coagulate rhythmically. M. Prasad and co-workers studied the adsorption of sugars by antimony sulphide; and S. S. Bhatnager and co-workers, the protective action of soaps, and the photochemical reaction with gold and silver sols.

§ 24. The Sulphoantimonites

Antimony trisulphide can play the part of an acid anhydride, forming a series of complex salts with the basic sulphides, and the products can be regarded as derivatives of a series of hypothetical **sulphoantimonious acids**, which, by analogy with the corresponding sulpharsenious acids (*q.v.*), can be tabulated:

Orthosulphoantimonious acid	H_3SbS_3
Metasulphoantimonious acid	HSbS_2
Pyrosulphoantimonious acid	$\text{H}_4\text{Sb}_2\text{S}_5$
Orthosulphotetrantimonious acid (<i>i.e.</i> $\text{H}_{12}\text{Sb}_4\text{S}_{12}$ less $3\text{H}_2\text{S}$)	$\text{H}_6\text{Sb}_4\text{S}_9$
Metasulphotetrantimonious acid (<i>i.e.</i> $\text{H}_{12}\text{Sb}_4\text{S}_{12}$ less $5\text{H}_2\text{S}$)	$\text{H}_2\text{Sb}_4\text{S}_7$
Orthosulphoctoantimonious acid (<i>i.e.</i> $\text{H}_{24}\text{Sb}_8\text{S}_{24}$ less $7\text{H}_2\text{S}$)	$\text{H}_{10}\text{Sb}_8\text{S}_{17}$
Metasulphoctoantimonious acid (<i>i.e.</i> $\text{H}_{24}\text{Sb}_8\text{S}_{24}$ less $11\text{H}_2\text{S}$)	$\text{H}_2\text{Sb}_8\text{S}_{13}$

Some of the acids furnish basic salts, some of which can be regarded as combinations of orthosulphoantimonites with $n\text{M}_2\text{S}$. Some mineral sulphoantimonites belong to this family—*e.g.*, silver, cuprous, mercurous, lead, and ferrous sulphoantimonites. Arsenic replaces antimony isomorphously in many of these minerals. J. J. Berzelius¹ made the sulphoantimonites by fusing together the component sulphides; by treating antimony trisulphide with a soluble sulphide; and by treating a soluble sulphoantimonite with a salt of the heavy metals. Modifications of the process were employed by A. Ditte, I. Pouget, V. Stanek, and B. Unger. H. Sommerlad obtained the salts by melting together antimony trisulphide and the chlorides of copper, silver or lead. B. Unger obtained some sulphoantimonites

by the action of the hydroxides of the alkalis or alkaline earths, or of the alkali carbonates on antimony trisulphide; and M. Berthelot, by the action of alkali sulphides on antimony trisulphide. A. Duflos reduced antimonates to antimonites by means of antimony.

The alkali sulphoantimonites are yellow, red, or brown; they melt easily, and without decomposition if air be excluded. The sulphoantimonites of the heavy metals are usually black and rarely red. The artificial salts are usually amorphous. Some of the heavy metal salts give off antimony trisulphide when heated out of contact with air. When the sulphoantimonites are heated in air, sulphur dioxide, and the metal oxides are formed. The alkali salts are hygroscopic, and some are decomposed by the absorbed moisture. The heavy metal salts are stable in air. The alkali and alkaline earth salts are usually soluble in water—they are not decomposed by water if alkali sulphides be present in excess. The aq. soln. are usually brown. The aq. soln. may be decomposed by the carbon dioxide of the air with the separation of antimony trisulphide; and they may be oxidized to sulphantimonates. The salts are decomposed by acids as well as by carbon dioxide, and oxalic and acetic acids. Many of these salts are decomposed by nitric acid with the formation of sulphur and antimony oxide. W. Hampe decomposed some of the native sulphoantimonites with a mixture of nitric and tartaric acids; and H. C. Bolton, with a mixture of citric acid with potassium nitrate, nitrite, or chlorate. H. Rose, and T. Poleck oxidized the sulphoantimonites with chlorine; P. Jannasch and T. Poleck, with bromine; H. C. Bolton, with iodine and water; T. Poleck, with sodium dioxide; R. Bunsen, C. Doelter, and A. Terreil, with soln. of alkali sulphides; and E. F. Smith, by electrolyzing a molten mixture of the sulphoantimonite and potassium hydroxide. I. Pouget found that the sulphoantimonites reduce cupric salts to cuprous salts, and mercurous salts to mercury. The reduction of cupric oxide to cuprous sulphide and the formation of sulphoantimonates was studied by E. Berglund, C. Serons, K. Heumann, and H. Rose.

G. Kohl treated an excess of antimony trisulphide with a boiling soln. of ammonium hydrosulphide; and added alcohol to the soln. The pale yellow mass of rhombohedral crystals is precipitated. G. Kohl supposed the salt to be a sulphoantimonite; V. Stanek, a sulphoantimonate. If alcohol be added to a soln. of a mol of antimony trisulphide and a conc. soln. of 3 mols of ammonium sulphide, I. Pouget found that a white, crystalline precipitate of **ammonium orthosulphoantimonite**, $(\text{NH}_4)_3\text{SbS}_3$, is formed. It is less stable than the corresponding salts of the alkalis. It is soluble in water, and the soln. loses ammonium sulphide on exposure to air. If the soln. be crystallized without the addition of alcohol, **ammonium metasulphoantimonite**, $\text{NH}_4\text{SbS}_2 \cdot 2\text{H}_2\text{O}$, is formed. V. Stanek obtained the same salt by treating pulverulent stibnite with a freshly prepared soln. of ammonium sulphide. Small yellow crystals are soon formed. In 12 hrs., the crystals are drained from the mother-liquor, washed with water, then with alcohol and ether, and dried between bibulous paper. The yellow, four-sided needles or plates are fluorescent; they become brownish-red on exposure to air; they are insoluble in water; they lose 22.13 per cent. in weight at 105° , forming, according to V. Stanek, and I. Pouget, **ammonium metasulphotetrantimonite**, $(\text{NH}_4)_2\text{Sb}_4\text{S}_7$. V. Stanek also made this salt by heating a mixture of antimony trisulphide and ammonium hydrosulphide in a sealed tube at 150° ; and also by heating ammonium orthosulphoantimonate and antimony pentasulphide in a sealed tube: $\text{Sb}_2\text{S}_5 + 2(\text{NH}_4)_3\text{SbS}_4 = 2(\text{NH}_4)_2\text{S}_3 + (\text{NH}_4)_2\text{Sb}_4\text{S}_7$. I. Pouget treated a mol of antimony trisulphide with 3 mols of a dil. soln. of 3 mols of ammonium sulphide (0.15 mol of the salt per litre). The yellow, acicular crystals are stable in air; they are not decomposed at 200° , but break down at a higher temp. They are insoluble in boiling water.

I. Pouget did not succeed in making *lithium pyrosulphoantimonite*, $\text{Li}_4\text{Sb}_2\text{S}_5$ and *lithium metasulphoantimonite*, LiSbS_2 ; but he obtained **lithium orthosulphoantimonite**, $\text{Li}_3\text{SbS}_3 \cdot 3\text{H}_2\text{O}$, by evaporating a soln. containing 3 mols of lithium sulphide and one mol of antimony trisulphide. The small, white, deliquescent crystals are

freely soluble in water. The properties of the salt are like those of the other alkali orthosulphoantimonites. If a hot soln. of lithium sulphide be sat. with antimony trisulphide, a dark red, gelatinous precipitate of **lithium metasulphotetrantimonite**, $\text{Li}_2\text{Sb}_4\text{S}_7 \cdot 3\text{H}_2\text{O}$, is formed; it could not be crystallized.

G. Kohl obtained a liver-brown mass by melting a mixture of a mol of antimony trisulphide, 9 mols of sodium sulphide, and 0.20–0.25 gram-atom of antimony. When the aq. extract were evaporated, deliquescent prisms of an impure sodium sulphoantimonite were formed. P. Berthier melted 15 parts of antimony trisulphide and 10 parts of anhydrous sodium sulphate in a closed carbon crucible at a white-heat. Along with a little reduced antimony there is produced a reddish-brown mass which deliquesces in air, and with water furnishes a brown soln. and a precipitate of antimony trisulphide. J. J. Berzelius, B. Unger, and C. Doelter obtained impure sulphoantimonites by dissolving antimony trisulphide in soln. of sodium sulphide. C. Tocco prepared sodium sulphoantimonite by the electrolysis of soln. of sodium thiosulphate—*vide supra*, antimony trisulphide. The proportion of the sulphide reaches 100 per cent. when a 20 per cent. sodium thiosulphate soln. is electrolyzed at $50^\circ\text{--}60^\circ$, with a current density of 51 amps. per sq. dm. As a rule the formation of sulphides is favoured by a high current density, limited by the value at which mechanical disintegration of the electrode begins, by a high conc. of the thiosulphate, and by a temp. of about 50° . The addition of alkali sulphide or carbonate hinders the formation of sulphide and enhances that of sulpho-salt. The current efficiency is 9.41 per cent. I. Pouget prepared **sodium orthosulphoantimonite**, $\text{Na}_3\text{SbS}_3 \cdot 9\text{H}_2\text{O}$, by concentrating in an atm. of hydrogen a soln. of a mol of antimony trisulphide and 3 mols of sodium sulphide. The pale yellow, acicular crystals lose all their water when heated in a current of hydrogen at 150° , and furnish a red powder. The salt retains its water in vacuo over sulphuric acid, and both the solid and aq. soln. are readily oxidized to sulphoantimonate. According to M. Berthelot, the heat of formation is $\text{SbCl}_3 + 3\text{Na}_2\text{S}_{\text{soln.}} = \text{Na}_3\text{SbS}_3 + 3\text{NaCl} + 62$ to 69 Cals., according to the conc. of the soln. of sodium sulphide. Most of the heat is developed with the first two mols of sodium sulphide, the third mol develops only 2.26 Cals. When a mol of sodium orthosulphoantimonite is treated with 3 mols of hydrochloric acid 18.12–18.59 Cals. are evolved. E. Giebe and A. Schiebe studied the piezoelectric properties of the crystals. I. Pouget obtained **potassium orthosulphoantimonite**, K_3SbS_3 , in a similar way. The small white crystals are dried on a porous tile in vacuo. The crystals are very deliquescent; they are soluble in water; and readily oxidize in air. I. Pouget, and A. Ditte made **potassium pyrosulphoantimonite**, $\text{K}_4\text{Sb}_2\text{S}_7$, by evaporating in the cold a conc. soln. of antimony trisulphide and potassium sulphide (2 mols). The soln. behaves like that of the metasulphoantimonite. J. J. Berzelius obtained a product with the same composition, but mixed with some antimonite by fusing antimony trisulphide with potassium carbonate. A. Ditte made **potassium metasulphoantimonite**, KSbS_2 , in red, transparent crystals by melting a mixture of antimony trisulphide, potassium carbonate, and sulphur, and allowing a soln. of the product, in a small proportion of water, to crystallize. I. Pouget obtained this salt by the method employed for the sodium salt; J. J. Berzelius obtained this salt in dark brown crystals resembling graphite, and contaminated with some antimonite, by fusing a mixture of 6 parts of antimony trisulphide and 3 parts of potassium carbonate; and W. Müller, by heating potassium metantimonite in a current of carbon disulphide. I. Pouget said the small red crystals are unchanged in air; they are insoluble in cold water; and decomposed by hot water. If the mother-liquor remaining after the separation of the sulphoantimonate from a partially oxidized soln. of orthosulphoantimonite be evaporated, it furnishes crystals of **sodium orthosulphotetrantimonite**, $\text{Na}_6\text{Sb}_4\text{S}_9$. I. Pouget evaporated a soln. of a mol of antimony trisulphide and 2 mols of sodium sulphide, and obtained a mixture of **sodium metasulphoantimonite**, NaSbS_2 and orthosulphoantimonite. The former salt separates as the first crop of crystals.

B. Unger made the same salt by adding alcohol to a soln. of antimony trisulphide in an excess of sodium sulphide; washing away the excess of sodium sulphide by alcohol; and evaporating an aq. soln. of the product on a water-bath when pale yellow crystals of sodium orthosulphoantimonite, and dark brown metasilphoantimonite are formed. According to I. Pouget, if a dil. soln. of a mol of antimony trisulphide and 2 mols of sodium sulphide be evaporated in vacuo, besides yellow, tetrahedral crystals of orthosulphoantimonate, there are produced small red crystals of **sodium metasilphotetrantimonite**, $\text{Na}_2\text{Sb}_4\text{S}_7 \cdot 2\text{H}_2\text{O}$, which can be purified by levigation. A hot sat. soln. of antimony trisulphide in one of sodium sulphide deposits a brown gelatinous precipitate, and the mother-liquor contains the metasilphotetrantimonite; and when a soln. of a mol of antimony trisulphide and 2 mols of sodium sulphide is treated with much water, a red gelatinous precipitate of the metasilphotetrantimonite is formed. A. Ditte prepared **potassium metasilphotetrantimonite**, $\text{K}_2\text{Sb}_4\text{S}_7 \cdot 3\text{H}_2\text{O}$, by evaporating a soln. of antimony trisulphide in a less conc. soln. of potassium sulphide than that used for the metasilphoantimonite; and I. Pouget, by diluting a conc. soln. or cooling a hot sat. soln. of the pyrosulphoantimonite. The small, pale red, prismatic crystals, or red amorphous powder are superficially discoloured by light. If a soln. of sodium orthosulphoantimonite be treated with hydrogen sulphide, I. Pouget found that a red precipitate of **sodium hydrometasilphotetrantimonite**, $\text{NaHSb}_4\text{S}_7 \cdot 2\text{H}_2\text{O}$, is formed. This should be washed in an atm. of hydrogen sulphide and dried on a porous tile. It furnishes a garnet-red powder. I. Pouget obtained **potassium hydrometasilphotetrantimonite**, KHSb_4S_7 , in a similar manner.

According to H. Pélabon,² the m.p. of antimony trisulphide is lowered from 555° to 498° , by the addition of 4 mols of cuprous sulphide to one mol of antimony trisulphide, and any further additions of cuprous sulphide raise the m.p. The 2:1 mixture has two m.p., and these are indications of the formation of a compound $2\text{Cu}_2\text{S} \cdot 3\text{Sb}_2\text{S}_3$. N. Parravano and P. de Cesaris examined the f.p. curve of

mixtures of cuprous and antimonious sulphides more closely, and the results are represented in Fig. 58. Two maxima appear on the curve; the one at 542° corresponds with cuprous metasilphoantimonite, $\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$, or CuSbS_2 ; and the other at 607° corresponds with cuprous orthosulphoantimonite, $3\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$, or Cu_3SbS_3 . There are two arrests in the f.p. curve of the ortho-salt, one at 607° and the other at the eutectic temp. The more the mixtures differ in composition from the eutectics the lower are the temp. at which the eutectic arrests occur. This is attributed to the low thermal conductivity of the fused masses. M. Chikashige and Y. Yamanchi considered that the first maximum occurs at 520° , corresponding with $4\text{Cu}_2\text{S} \cdot 5\text{Sb}_2\text{S}_3$, and the second at 571° , corresponding with the orthosulphoantimonite. They place the eutectics at 463° with 7 per cent. Cu_2S ; at 514° , with 37 per cent. Cu_2S ; and 571° , with 68 per cent. of Cu_2S . No solid soln. are formed. W. Guertler and K. L. Meissner showed that sulphur cannot exist in equilibrium with copper antimonide and that a reaction occurs with the formation of cuprous sulphide: $2\text{Cu}_3\text{Sb} + \text{S} = 2\text{Cu}_2\text{S} + \text{Cu}_2\text{Sb}$; $\text{Cu}_2\text{Sb} + \text{S} = \text{Cu}_2\text{S} + \text{Sb}$. Cuprous sulphide melted with either antimony or the antimonides yields stable mixtures, but no ternary compounds are formed. Copper and antimony trisulphides react according to the equations: $12\text{Cu} + \text{Sb}_2\text{S}_3 = 3\text{Cu}_2\text{S} + 2\text{Cu}_3\text{Sb}$; $10\text{Cu} + \text{Sb}_2\text{S}_3 = 3\text{Cu}_2\text{S} + 2\text{Cu}_2\text{Sb}$; $6\text{Cu} + \text{Sb}_2\text{S}_3 = 3\text{Cu}_2\text{S} + 2\text{Sb}$. The rectangle $\text{Cu}-\text{Sb}-\text{Sb}_2\text{S}_3-\text{Cu}_2\text{S}$ is subdivided into six triangles by the five quasi-binary intersections, $\text{Cu}_2\text{S}-\text{Cu}_3\text{Sb}$; $\text{Cu}_2\text{S}-\text{Cu}_2\text{Sb}$; $\text{Cu}_2\text{S}-\text{Sb}$; $\text{Cu}_3\text{SbS}_3-\text{Sb}$; and CuSbS_2-Sb . Two independent mixture gaps occur

FIG. 58.—Freezing-point Curves of the Binary Mixtures: $\text{Sb}_2\text{S}_3-\text{Cu}_2\text{S}$.

in the system, which are probably dependent on similar gaps in the binary systems Cu—Cu₂S and Sb—Sb₂S₃. For **tetrahedrite**, see tennantite—**S.** 51, 31.

The mineral **stylotypite** was named by F. von Kobell; he obtained it from Copiapo, Chili. It was named in allusion to its columnar form—from *στυλος*, column; and *τύπος*, form. Analyses by F. von Kobell, and S. Stevanovic correspond approximately with (Cu₂,Ag₂,Fe,Zn)₃{(AsSb,Bi)S₃}₂; and E. T. Wherry and W. F. Foshag represent the idealized mineral as **cuprous orthosulphoantimonite**, Cu₃SbS₃. N. Parravano and P. de Cesaris obtained the compound by fusing its component sulphides in an atm. of hydrogen—Fig. 57. H. Sommerlad synthesized it by melting a mol of antimony trisulphide with 3 mols of either cuprous chloride or cuprous sulphide; and I. Pouget, by the action of water on potassium cuprous orthosulphoantimonite. F. von Kobell supposed the crystals of the iron-black mineral belong to the rhombic system, and to exhibit cruciform twinning. S. Stevanovic showed that the crystals are more probably monoclinic with the axial ratios $a : b : c = 1.9202 : 1 : 1.0355$, and $\beta = c. 90^\circ$. P. Groth, and S. Stevanovic supposed the mineral to be isomorphous with xanthoconite, and pyrostilpnite. The sp. gr. ranges from F. von Kobell's 4.79 to S. Stevanovic's 5.18, and J. J. Saslawsky made some calculations on the contraction which occurs in the formation of the compound from its elements. H. Sommerlad gave 5.13–5.182 for the artificial orthosulphoantimonite. The hardness of the mineral is 3. The m.p. by N. Parravano and P. de Cesaris is 607°; and by M. Chikashige and Y. Yamanchi, 571°. The mineral is soluble in nitric acid; and potash-lye extracts antimony trisulphide.

W. T. Page described a *fahlerz* from Colorado which appears to be related to stylotypite; and A. Raimondi, a plumbiferous mineral from Cinquimarca, which is also related to stylotypite when due allowance is made for admixed quartz. A. Raimondi called *durfeldtite*—after R. Dürfeldt. S. Stevanovic said that similar remarks can be made respecting a mineral from Joachimsthal which he called *falkenhaynite*—after J. Falkenhayn. F. Sandberger supposed falkenhaynite to be related to amonite or tetrahedrite. The antimonic varieties of *fahlerz*, represented in the limiting case by *tetrahedrite*, have been discussed in connection with tennantite, the limiting case at the arsenical end of the series.

J. C. L. Zincken discovered a mineral at Wolfsberg, Harz, which he called *Kupferantimonglanz*. The crystals were examined by G. Rose, they were analyzed by H. Rose, and the resemblance to zinckenite and miargyrite was noted. J. J. N. Huot called it *rosite*; E. F. Glocker, **chalcostibite**, or rather *Chalkostibit*; and J. Nicol, *wolfsbergite*. E. Cumenge described a mineral from Guejar, Andalusia, which he called *guejarite*, and to which he ascribed the formula Cu₂Sb₄S₇. These crystals were examined by C. Friedel. L. J. Spencer showed that guejarite and chalcostibite are probably the same mineral species, and this was confirmed by S. L. Penfield, and A. Frenzel. Analyses were made by H. Rose, T. Richter, P. N. Tschirwinsky, E. Cumenge, and A. Frenzel; the results agree with the formula Cu₂S.Sb₂S₃, or **cuprous metasulphoantimonite**, CuSbS₂—or possibly with 4Cu₂S.5Sb₂S₃. H. Sommerlad obtained this salt by heating a mixture of 3 mols of cuprous chloride, and 2 mols of antimony trisulphide. The reaction begins at about 130°, and proceeds slowly at 300°. It was also made by H. Sommerlad, and N. Parravano and P. de Cesaris, by melting together the constituent sulphides. The lead-grey or iron-grey mineral occurs granular, massive, and in small aggregated prisms belonging to the rhombic system, with the axial ratios, according to S. L. Penfield, $a : b : c = 0.5312 : 1 : 0.63955$. L. J. Spencer described the twinning of the crystals. The cleavage on the (001)-face is perfect, and that on the (100)- and (010)-faces imperfect. The crystals were examined by G. Rose, P. Groth, H. Laspeyres, L. J. Spencer, G. A. Kennigott, and P. N. Tschirwinsky. L. J. Spencer discussed the isomorphous zinckenite, etc. For the isomorphous family of which chalcostibite is a member, *vide infra*, zinckenite. The sp. gr. of the mineral given by J. C. L. Zincken was 4.748; and S. L. Penfield gave 4.959. H. Sommerlad found for the artificial compound a sp. gr. 4.885–4.979. The hardness is 3–4. N. Parravano and P. de Cesaris found the m.p. to be 542°, Fig. 58; and M. Chika-

shige and Y. Yamanchi, about 520°. A. de Gramont examined the spark spectrum. T. W. Case found chalcostibite is a poor conductor, and light has no measurable effect. The mineral is decomposed by nitric acid with the separation of sulphur; aq. ammonia has no action; and soln. of the alkali hydroxides or sulphides extract antimony trisulphide.

According to C. F. Rammelsberg, when cupric sulphoantimonate is heated in a retort, **cuprous orthosulphotetrantimonite**, $\text{Cu}_6\text{Sb}_4\text{S}_9$, or $3\text{Cu}_2\text{S} \cdot 2\text{Sb}_2\text{S}_3$, is formed; and H. Sommerlad found that by melting 6 mols of cuprous chloride and 7 mols of antimony trisulphide in a retort chemical action begins at about 180°, and at 300°, **cuprous metasulphotetrantimonite**, $\text{Cu}_2\text{Sb}_4\text{S}_7$, is formed as a grey mass with a scaly fracture and sp. gr. 4.814. It resembles the metasulphoantimonite in its chemical reactions. The mineral *guejarite* was at first thought to have this composition, but was later shown to be chalcostibite (*q.v.*).

According to I. Pouget, if a dil. soln. of potassium orthosulphoantimonite be treated with sufficient cupric salt, a black precipitate of **cupric orthosulphoantimonite**, $\text{Cu}_3(\text{SbS}_3)_2$, is formed; and if a conc. soln. of the potassium salt is used, a black precipitate of **potassium cuprous orthosulphoantimonite**, KCu_2SbS_3 , is formed. The black precipitate gradually becomes yellow and crystalline. It should be dried in an atm. of hydrogen. If the precipitate be dried below 100°, it is trihydrated, $\text{KCu}_2\text{SbS}_3 \cdot 3\text{H}_2\text{O}$, and anhydrous if dried over that temp. Water decomposes it, forming cuprous orthosulphoantimonite.

The m.p. curves of mixtures of silver and antimonious sulphides were examined by H. Pélabon,³ who found two maxima corresponding with $\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$, and $3\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$; and three eutectics at 438°, 440°, and 454°, corresponding respectively with 17.5, 52.7, and 79 per cent. of silver sulphide. P. Chrétien and J. M. Guinchant found that 4.936, 10.34, 15.1, and 20.6 grms. of silver sulphide in 100 grms. of antimony trisulphide lowered the m.p. respectively 18°, 35°, 53°, and 78°. F. M. Jäger and H. S. van Klooster's observations are summarized in Fig. 59. The f.p. curve has two maxima, corresponding with $3\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$ and $\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$ respectively. The first of these, identical with the mineral pyrargyrite, has m.p. 483°. The second maximum corresponds with miargyrite, m.p. 509°. Eutectic points occur at 81, 64.5, and 28.2 mol. per cent. Ag_2S , and 463°, 455°, and 449° respectively. The minerals bolivianite, stephanite, pyrostilpnite, polybasite, and polyargyrite can only have been formed from soln., as they are not represented in the equilibrium diagram. K. Konno found one maximum corresponding with $\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$ and two eutectics—at 462° and 22 per cent. Ag_2S , and 464° and 72 per cent. Ag_2S . This compound does not form solid soln. with either component.

The history of the mineral **pyrargyrite** has been indicated in connection with proustite. Some early analyses were reported in connection with proustite; and later analyses have been reported by C. G. A. von Weissenbach, J. Loczka, C. Castro, P. A. von Bonsdorff, R. Böttger, T. Petersen, F. Field, A. Streng, I. Domeyko, F. Wöhler, E. Rethwisch, H. A. Miers, and H. Traube. The results show that the idealized mineral is **silver orthosulphoantimonite**, Ag_3SbS_3 . The antimony is replaced by more or less arsenic, and finally merges into proustite, Ag_3AsS_3 . Indeed, F. M. Jäger and N. S. van Klooster found that proustite and pyrargyrite form an unbroken series of solid soln. The f.p. curve, Fig. 60, has a flat minimum at 473.5°. Silver orthosulphoantimonite was obtained by J. Margottet by heating a mixture of silver, antimony, and sulphur; by C. F. Rammelsberg, by heating silver sulphoantimonite in a retort; by J. Fournet, F. Wöhler, and F. M. Jäger and H. S. van

Fig. 59.—Freezing-point Curves of the Binary System: $\text{Ag}_2\text{S}-\text{Sb}_2\text{S}_3$.

Klooster, by heating a mixture of the component sulphides in stoichiometrical proportions—Fig. 59; by H. Sommerlad, by heating a mixture of silver chloride and antimony trisulphide in the proportions: $3\text{AgCl} + \text{Sb}_2\text{S}_3 = \text{Ag}_3\text{SbS}_3 + \text{SbCl}_3$ —

FIG. 60.—Melting-point Curve of Mixtures of Ag_3AsS_3 and Ag_3SbS_3 .

the reaction begins at 140° , but the temp. is raised to distil off the trichloride—F. Ducatte, and J. Rondet always found the product contaminated with halides; H. de Sénarmont, by heating a mixture of silver sulphate, and sodium sulphoantimonite and hydrocarbonate to 275° , or by heating a mixture of silver sulphoantimonate and sodium hydrocarbonate to 325° ; J. Durocher, by heating a mixture of silver and antimonious chlorides in a current of hydrogen sulphide—C. Doelter said that miargyrite is formed at low temp., and pyrargyrite at high ones. C. Doelter obtained this salt by the action of hydrogen sulphide on a soln. of silver chloride and potassium antimonate, or on a mixture of silver chloride, antimony trioxide, and sodium carbonate in a sealed tube for a long time between 80° and 150° ; by I. Pouget, as a black, amorphous precipitate, by adding silver nitrate to an excess of a dil. soln. of potassium orthosulphoantimonite 0.1 mol per litre—if the silver nitrate be in excess, the black precipitate is a mixture of several silver sulphoantimonites; and F. M. Jäger and H. S. van Klooster, by heating for 50 hrs. a mixture of antimony trichloride, silver sulphide, a conc. soln. of sodium sulphide, and sodium hydrocarbonate. All the trichloride is transformed into pyrargyrite, but without the sodium hydrocarbonate some antimony sulphide remains in soln. The compound is not produced in acidic soln.

The **colour** of the artificial products is usually dark red and the material is crystalline; the mineral may be black, dark grey, or deep red. Pyrargyrite may be massive and compact; or it may occur in prismatic and hemimorphic **crystals** belonging to the trigonal system. H. A. Miers gave for the axial ratio of the trigonal pyramid $a : c = 1 : 0.7880$. For a monoclinic form, *vide infra*, pyrostilpnite. The **twining** of the crystals of pyrargyrite is common about the $(11\bar{2}0)$ - and $(10\bar{1}4)$ -planes; less common about the $(10\bar{1}1)$ -plane; and rare about the $(01\bar{1}2)$ -plane. The **cleavage** on the $(10\bar{1}1)$ -face is distinct, and that on the $(01\bar{1}2)$ -face imperfect. The crystals were also examined by M. J. Schuster, H. Traube, V. Goldschmidt, O. Mügge, C. Busz, E. Rethwisch, W. Haidinger, R. J. Häuy, F. Mohs, A. Lévy, Q. Sella, O. Luedecke, A. Frenzel, F. Sandberger, M. Fenoglio, and E. A. Schenck. H. Schneiderhöhn examined polished sections of the mineral; and L. G. Raviez, the etching of polished surfaces with potash-lye. For the **specific gravity** of pyrargyrite, R. Böttger gave 5.89; T. Petersen, 5.90; A. Streng, 5.68; E. Rethwisch, 5.716–5.871; H. A. Miers, 5.77–5.86; H. Traube, 5.76; and J. Loczko, 5.852. The sp. gr. of the artificial product by H. Sommerlad is 5.49–5.76; and F. M. Jäger and H. S. van Klooster, 5.75–5.79. The **hardness** is 2–3. O. Mügge examined the effect of **pressure** on the crystals. H. Fizeau found the coeff. of **thermal expansion** to be 0.0691 at 40° when parallel to the chief axis, and 0.02012 at 40° when vertical thereto. A. Sella gave for the **specific heat**, 0.0755. F. M. Jäger and H. S. van Klooster found the **melting point** to be 483° —Fig. 59. A. des Cloizeaux reported the **indices of refraction** to be $\omega = 3.084$, and $\epsilon = 2.881$ at 19° for Li-light. The **birefringence** is strong and negative. W. W. Coblenz and J. F. Eckford studied the photoelectric sensitivity. At 22° there is a wide, unsymmetrical maximum in the ultra-violet with a weak, ill-defined maximum in the region of 0.63. It also differs from that of the constituent sulphides, but resembles that of proustite (silver arsenic sulphide). At -165° , pyrargyrite reacts electrically to all wave-lengths from the extreme ultra-violet to 1.5, but the greatest reaction is localized in the band at 0.63. A. de Gramont examined the **spark spectrum**, and said that its **electrical conductivity** is smaller than that of argentite

or dyscrasite. C. Tubandt and M. Haedicke found that the pure salt is an insulator. M. von Laue, T. W. Case, and E. Giebe and A. Scheibe studied the piezoelectric properties of the crystals; and P. H. Geiger, the **photoelectric effect**. H. E. McKinstry found that the surface of the mineral is roughened by exposure to the light of an electric arc. E. E. Fairbanks found the **dielectric constant** to be less than 81.

Pyrrargyrite is decomposed by **hydrochloric acid** with the separation of sulphur and antimony trioxide; it is also decomposed by **nitric acid**; it is soluble in a mixture of tartaric and nitric acids, and is decomposed by **chlorine**; it is blackened by a warm soln. of **alkali hydroxide**, and L. G. Raviez found that a hot soln. of **alkali carbonate** extracts a trace of antimony trisulphide, while a hot dil. soln. of **alkali sulphide** dissolves out the antimony trisulphide, and leaves black silver sulphide behind. C. A. Burghardt found that when melted with **ammonium nitrate**, and extracted with water, it yields a soln. of silver sulphate, and a residue of mixed antimony tri- and penta-oxides. H. B. North and C. B. Conover observed that the mineral is attacked by **thionyl chloride** at 150°. The weathering of pyrrargyrite has been studied by W. Maucher, and A. Hofmann and F. Slavik; the transformation of the mineral into argentite and silver, by the leaching out of the antimony trisulphide, has been frequently observed—by J. R. Blum, A. Breithaupt, etc.

A. Breithaupt⁴ described monoclinic crystals of a rare mineral from Kurprinz, near Freiberg, which he called *Feuerblende*; it contained silver and antimonious sulphides. J. D. Dana translated A. Breithaupt's term into *fire blende*, or **pyrostilpnite**—from $\pi\upsilon\rho$, fire; and $\sigma\tau\iota\lambda\eta\nu\acute{o}\varsigma$, shining; M. Adam called it *pyrochrolite*; and A. Breithaupt later called it *pyrochrotite*. The analysis reported by O. Luedecke showed that the mineral, like pyrrargyrite, is silver orthosulphoantimonite, Ag_3SbS_3 . G. Cesaro wrote the formula $(\text{Ag}_2\text{S}_2)(\text{SbS}_2)_2$. C. Doelter synthesized crystals of this mineral along with those of pyrrargyrite. G. A. Kennigott supposed the hyacinth-red, slender, prismatic, or tabular crystals are rhombic; but A. Breithaupt, F. A. Roemer, W. H. Miller, and A. Streng showed that they are monoclinic, and O. Luedecke gave for the axial ratios $a : b : c = 0.35465 : 1 : 0.17819$, and $\beta = 90^\circ$. H. A. Miers calculated the values for another orientation of the crystals and gave $a : b : c = 1.9465 : 1 : 1.0973$, and $\beta = 90^\circ$ for pyrostilpnite; and $1.9187 : 1 : 1.0152$, and $\beta = 88^\circ 47'$ for xanthoconite, Ag_3AsS_4 , so that the two minerals are isomorphous. Twinning occurs about the (100)-plane; the (010)-cleavage is perfect. W. H. Miller gave 4.3 for the sp. gr., but this value is probably too small. J. J. Saslawsky calculated the contraction which occurs when the mineral is formed from its elements. The hardness is over 2. The general chemical properties are like those of pyrrargyrite.

F. Mohs⁵ described *hemiprismatic ruby blende* as a mineral obtained from Bräunsdorf, Freiberg; H. Rose called it **miargyrite**—from $\mu\acute{\epsilon}\iota\omega\nu$, less; and $\acute{\alpha}\rho\gamma\upsilon\rho\omicron\varsigma$, silver—in allusion to its containing less silver than kindred ores. A. Breithaupt called a sample from Clausthal, *hypargyrite*; and W. Haidinger, a sample from Felsőbanya, *kennigotite*. Analyses were reported by H. Rose, R. Helmhacker, I. Domeyko, L. Sipőcz, A. Weisbach, J. Rumpf, L. J. Spencer, and H. Sommerlad. C. F. Rammelsberg calculated the formula $\text{Ag}_2\text{S.Sb}_2\text{S}_3$, or **silver metasulphoantimonite**, AgSbS_2 , i.e. $\text{S}=\text{Sb}-\text{ASg}$ —*vide* arsenomiargyrite. H. Sommerlad made this salt by melting together a mixture of silver chloride and antimony trisulphide: $3\text{AgCl} + 2\text{Sb}_2\text{S}_3 = 3\text{AgSbS}_2 + \text{SbCl}_3$; and C. Doelter, a mixture of silver chloride, and antimony trichloride and trioxide in a current of hydrogen sulphide. If the temp. exceeds 300°, some pyrrargyrite is formed. F. M. Jäger and H. S. van Klooster obtained it by melting together the constituent sulphides—Fig. 59. C. Doelter, and C. Vrba discussed the formation of the mineral in nature.

The iron-grey or steel-grey mineral in thin splinters appears blood-red. It occurs massive, and also in thick tabular or prismatic crystals. Some of the flakes may show striations. According to W. J. Lewis, the crystals are monoclinic, with

the axial ratios $a : b : c = 2.99449 : 1 : 2.90951$ and $\beta = 81^\circ 22' 35''$. The (010)-cleavage shows in traces. Observations on the crystals were also made by C. F. Naumann, P. Groth, G. vom Rath, A. Weisbach, W. H. Miller, O. Mügge, E. V. Shannon, and A. S. Eakle. L. J. Spencer compared monoclinic miargyrite, AgSbS_2 , with monoclinic andorite, $\text{PbAg}(\text{SbS}_2)_3$; and with monoclinic zinckenite, $\text{Pb}(\text{SbS}_2)_2$; and V. Goldschmidt, L. Tokody, and A. S. Eakle discussed the possible isomorphism of miargyrite and lorandite. L. Sipöcz gave 6.06 for the sp. gr.; J. Rumpf, 5.08; L. J. Spencer, 5.20; and G. A. Kenngott, 6.06 for a variety containing lead. For the artificial compound C. Doelter gave 5.28; H. Sommerlad, 5.20; and F. M. Jäger and H. S. van Klooster, 5.36. J. J. Saslawsky studied the contraction which occurs during the formation of the mineral. The hardness is 2.0–2.5. G. vom Rath, and O. Mügge discussed the effect of press. H. Pélabon gave 503° for the m.p.; and F. M. Jäger and H. S. van Klooster, 507° —*vide* Fig. 59. H. E. McKinstry observed that the mineral is not changed when it is exposed to the light of an electric arc. T. W. Case observed the resistance to be less than a megohm, and insolation has no perceptible influence; and C. Tubandt and M. Haedicke, that the pure salt is an insulator. E. E. Fairbanks gave 81 for the dielectric constant (water 81). The mineral is decomposed by nitric acid with the separation of sulphur and antimony oxide.

An iron-black or blackish-grey silver sulphantimonite occurs at Wolfach, Baden, in cubic crystals which are usually in the form of distorted and indistinct octahedra. T. Petersen⁶ called it **polyargyrite**—from πολύς , many; and ἀργυρος , silver—in allusion to the high proportion of silver present. T. Petersen's analysis corresponds with $12\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$, or **silver enneasulphodiorthosulphoantimonite**, $9\text{Ag}_2\text{S} \cdot 2\text{Ag}_3\text{SbS}_3$. G. Cesaro supposed that silver formed a bivalent radicle Ag_2 , or $-\text{Ag} \cdot \text{Ag}-$, and copper, Cu_2 , or $-\text{Cu} \cdot \text{Cu}-$. He represented the constitution of polyargyrite $\text{S}=\text{Sb}-\text{S}(\text{Ag}_2-\text{S})_{12}-\text{Sb}=\text{S}$. H. Sommerlad obtained it by melting the components together in stoichiometrical proportions; but he did not obtain it by heating silver chloride with antimony trisulphide. T. Petersen gave 6.974 for the sp. gr. of the mineral, and H. Sommerlad, 6.50 for the artificial product. J. J. Saslawsky calculated the contraction which occurs during the formation of the compound. The hardness is 2–3. The chemical properties are like those of pyrargyrite. H. E. McKinstry found that the mineral is not altered by exposure to the light of an electric arc. F. Sandberger discussed its formation in nature. There is no sign of it in the f.p. curve, Fig. 59.

In 1546, G. Agricola⁷ referred to a black silver ore, *argentum rude nigrum*; and a couple of centuries later, J. G. Wallerius described a *Schwarzertz* or *Schwarzgulden*; I. S. R. I. Eques a Born, *argentum mineralisatum nigrum fragile*, or the *Roschgewachs* of the Hungarian miners; M. H. Klaproth, and A. G. Werner, *Sprödglasserz*—*brittle silver ore*; C. C. von Leonhard, *Schwarzgultigerz*; R. Jameson, and F. Mohs, *prismatischer Melanglanz*; E. F. Glocker, *melanargyrite*; R. J. Haüy, *argent noir*, or *argent antimoiné sulfuré noir*; F. S. Beudant, *psaturose*—from ψαθυρός or ψαδαρός , fragile; and W. Haidinger, **stephanite**—after Stephan von Oerterreich. A. Breithaupt, and C. F. Naumann showed that F. Mohs' prismatic melanoglanze covers only a part of the brittle silver ore of A. G. Werner; the other part is hexagonal, and A. Breithaupt called it *Eugenglanz*—from εὐγενής , rare. H. Rose called the form **polybasite**—from πολύς , many; and βάσις , base—in allusion to the many metallic bases present.

Analyses of polybasite were reported by M. H. Klaproth, H. Rose, C. A. Joy, F. Tonner, G. A. Kenngott, W. J. Taylor, I. Domeyko, F. A. Genth, G. T. Prior, and H. Ungemach. The complexity of the mineral makes the formula somewhat speculative. H. Rose gave $9\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$, or rather $9(\text{Cu}, \text{Ag})_2\text{S}(\text{Sb}, \text{As})_2\text{S}_3$, *i.e.* in the limiting case, **silver trisulpho-orthosulphoantimonite**, $3\text{Ag}_2\text{S} \cdot \text{Ag}_3\text{SbS}_3$. C. F. Rammelsberg, and F. R. van Horn, however, gave this formula, $8\text{Ag}_2\text{S} \cdot \text{Sb}_2\text{S}_3$, or rather $\text{Ag}_{16}\text{Sb}_2\text{S}_{11}$; G. Boländer found the ratio $\text{R}_2\text{S} : \text{R}_2\text{S}_3$ varied from 7.22 : 1 to 10 : 1, and he considered the mineral to be a mixture of $\text{R}_2\text{S} \cdot \text{As}_2\text{S}_3$ with a pre-

ponderating proportion of $7\text{R}_2\text{S.Sb}_2\text{S}_3$. S. L. Penfield gave Ag_9SbS_6 analogous with the formula Ag_9AsS_6 for pearcite; and G. Cesaro, $9\text{Ag}_2\text{S.Sb}_2\text{S}_3$, or $\text{S}=\text{Sb}-\text{S}-(\text{Ag}_2\text{S})_9-\text{Sb}=\text{S}$ —*vide supra*, pyrostilpnite. The subject was also discussed by E. H. Kraus and J. P. Goldsberry, and W. F. Foshag. H. Sommerlad obtained polybasite—free from copper—by heating a mixture of silver chloride and antimony trisulphide in the molar proportions 1 : 24.5. The product was extracted with a soln. of sodium thiosulphate to remove silver chloride, and the dried residue melted in a current of hydrogen sulphide. There is no sign of the compound on the f.p. curve, Fig. 59. Polybasite is an iron-black mineral which in thin splinters appears cherry-red. J. L. C. Schröder van der Kolk wrote on this subject. While H. and G. Rose considered that the tabular prisms with bevelled edges belong to the hexagonal, A. des Cloizeaux showed that it is rhombic, and probably isomorphous with stephanite. This was supported by H. A. Miers, who gave for the axial ratios $a : b : c = 0.5793 : 1 : 0.91305$, and S. L. Penfield showed that it is more probably monoclinic with the axial ratios $a : b : c = 1.7309 : 1 : 1.5796$, and $\beta = 90^\circ 0'$. The twinning is supposed to be like that of mica; the (001)-cleavage is imperfect. A. des Cloizeaux gave for the optical axial angle $2E = 88^\circ 15'$, for white light. For the sp. gr., H. Rose gave 6.214; C. A. Joy, and F. A. Genth, 6.009; G. A. Kenngott, 6.03; and G. T. Prior, 6.33. For the artificial mineral, H. Sommerlad gave 6.352. J. J. Saslawsky estimated the contraction which occurs during the formation of polybasite from its constituents. The hardness is 2–3. J. Joly found that sublimation occurs at 430° . A. de Gramont examined the spark spectrum. H. E. McKinstry observed that the surface of the mineral is roughened by exposure to the light of an electric arc. T. W. Case found that polybasite has a resistance less than a megohm, and light decreases the resistance. E. E. Fairbanks found the dielectric constant of polybasite to be less than 81, and of stephanite, greater than 81. O. Mügge made some observations on the weathering of polybasite.

Analyses of stephanite were made in the early days by R. Brandes, B. Kerl, and H. Rose, and later ones have been reported by A. Frenzel, C. Vrba, J. D. Dana, I. Domeyko, G. T. Prior, W. E. Ford, and T. L. Walker. C. F. Rammelsberg calculated the formula $5\text{Ag}_2\text{S.Sb}_2\text{S}_3$, or $\text{Ag}_2\text{S.Ag}_3\text{SbS}_3$, **silver orthosulphoantimonite**. G. T. Prior, and P. Groth and K. Mieleitner used C. F. Rammelsberg's formula. R. F. Weinland regarded stephanite as a complex salt $[\text{SbS}_4]\text{Ag}_5$; and G. Cesaro gave $\text{S}=\text{Sb}-\text{S}-(\text{Ag}_2-\text{S})_5-\text{Sb}-\text{S}$. W. F. Foshag also discussed this subject. C. Doelter made the mineral by heating silver chloride and antimony trioxide in the molar proportions 10 : 1 with a soln. of sodium carbonate in an atm. of hydrogen sulphide, in a sealed tube at 80° – 150° for some weeks. H. Sommerlad heated silver chloride and antimony trisulphide in the molar proportion 15 : 4 at 200° . L. G. Ravicz obtained a product with a composition between that of polybasite and that of stephanite, by adding an excess of silver sulphate to a soln. of antimony trisulphide and alkali sulphide. No sign of stephanite appears on the f.p. diagram, Fig. 59. The iron-black mineral occurs massive, and disseminated; it also occurs in short prisms or in elongated, and tabular forms. The crystals of stephanite were at first supposed by J. F. von der Null to be hexagonal, but W. Haidinger, and F. Mohs showed that the crystals belong to the rhombic system. F. H. Schröder gave for the axial ratios $a : b : c = 0.62911 : 1 : 0.68526$, and C. Vrba, $0.629129 : 1 : 0.685135$. The hemimorphism of the crystals was established by O. Luedecke, H. A. Miers, and G. d'Achiardi. It shows itself by a want of symmetry in the striations on the $-(110)$ -face parallel to the edge (110) : (371). Oft-repeated twinning occurs about the $-(110)$ -plane giving a pseudo-hexagonal form to the crystals; twinning also occurs about the (130)-, (110)-, or (010)-plane. The crystals were also examined by V. R. von Zepharovich, A. Reuss, F. Slavik, V. Nejd, E. Artini, G. vom Rath, C. Morton, L. J. Spencer, A. Frenzel, P. Groth, W. J. Lewis, F. Sandberger. H. Rose gave for the sp. gr., 6.275; B. Kerl, 6.15; A. Frenzel, 6.28; C. Vrba, 6.271; and G. T. Prior, 6.24–6.26. H. Sommerlad gave 6.173 for the artificial crystals. J. J. Saslawsky estimated the contraction which occurs during the formation of

the mineral from its components. The hardness is 2-3. A. de Gramont examined the spark spectrum. T. W. Case said that the resistance is less than a megohm, and it is lessened by insolation. P. H. Geiger studied the photoelectric effect. The weathering of stephanite was studied by V. R. von Zepharovich, A. Reuss, E. Döll, and J. R. Blum.

A. Breithaupt⁸ described an *antimonial silver sulphide* occurring as a leaden-grey mineral from Bolivia, and he called it *bolivian*, i.e. **bolivianite**. The tufts of acicular prisms resemble stibnite. The composition approaches $\text{Ag}_3\text{S}\cdot 6\text{Sb}_2\text{S}_3$. The sp. gr. is 4.820-4.828, and the hardness 2.5. Further details are wanting.

According to I. Pouget,⁹ when a conc. soln. of potassium orthosulphoantimonite is treated with silver nitrate, the black precipitate rapidly becomes yellow and crystalline owing to the formation of **potassium silver orthosulphoantimonite**, KAg_2SbS_3 ; and in a similar manner, **sodium silver orthosulphoantimonite**, $\text{NaAg}_2\text{SbS}_3$; **lithium silver orthosulphoantimonite**, $\text{LiAg}_2\text{SbS}_3$; and **ammonium silver orthosulphoantimonite**, $\text{NH}_4\text{Ag}_2\text{SbS}_3$, are formed. All these salts are yellow, and decomposed into silver orthosulphoantimonite when treated with water. I. Pouget obtained a brown precipitate of **gold sulphoantimonite** on adding a soln. of gold chloride to a conc. soln. of potassium sulphoantimonite. The precipitate dissolves when the liquid is agitated. When heated, the liquid deposits gold.

J. S. F. Pagenstecher¹⁰ heated to a high temp. a mixture of antimony trisulphide, barium sulphate, and carbon, and obtained a reddish-brown, sintered mass of indefinite composition. With hot water, a yellow powder separates out. I. Pouget was unable to prepare *calcium orthosulphoantimonite*, $\text{Ca}_3(\text{SbO}_3)_2$, he obtained **strontium orthosulphoantimonite**, $\text{Sr}_3(\text{SbS}_3)_2\cdot 10\text{H}_2\text{O}$, from a hot soln. of a mol of antimony trisulphide and 3 mols of strontium hydrosulphide. The brown liquid, on cooling, furnishes white scales. He obtained **barium orthosulphoantimonite**, $\text{Ba}_3(\text{SbS}_3)_2\cdot 8\text{H}_2\text{O}$, in a similar way. These salts are deliquescent, and are decomposed by water, forming orthosulphotetramtimonite. The salts are oxidized by air; and dissolve in a soln. of the alkaline earth sulphide. I. Pouget prepared **calcium pyrosulphoantimonite**, $\text{Ca}_2\text{Sb}_2\text{S}_5\cdot 15\text{H}_2\text{O}$, by evaporating in vacuo, in an atm. of hydrogen, a hot soln. of antimony trisulphide and calcium sulphide. The colourless, triclinic crystals dissolve in water without decomposition; they readily oxidize in air; and when dry become black on exposure to light. If the soln. be evaporated by heat, small red crystals of **calcium hydroxymetasulphoantimonite**, $\text{HO}\cdot\text{Ca}\cdot\text{SbS}_2$, are formed. They are insoluble in water, dissolve without residue in conc. hydrochloric acid; and when heated to redness in a current of hydrogen sulphide they lose water and hydrogen sulphide. The mother-liquor, remaining after the separation of this salt, yields the pyrosulphoantimonite. I. Pouget said that if strontium sulphide be used instead of the hydrosulphide employed in the preparation of strontium orthosulphoantimonite, or if the mother-liquor from that salt be evaporated in vacuo, **strontium pyrosulphoantimonite**, $\text{Sr}_2\text{Sb}_2\text{S}_5\cdot 15\text{H}_2\text{O}$, is formed in small, yellow, triclinic crystals which easily change to a brown colour. The salt is soluble in water without decomposition, but it easily oxidizes, forming pyrosulphoantimonite. If in the preparation of barium orthosulphoantimonite the barium sulphide be not in excess, greyish-green crystals of **barium pyrosulphoantimonite**, $\text{Ba}_2\text{Sb}_2\text{S}_5\cdot 8\text{H}_2\text{O}$, are formed. The crystals become yellow on exposure to air. The salt is almost insoluble in a soln. of barium sulphide. The mother-liquor furnishes crystals of the orthosulphoantimonite. If a soln. of barium orthosulphotetramtimonite be boiled for a long time with much water, amorphous, brown **barium metasulphoantimonite**, $\text{Ba}(\text{SbS}_2)_2\cdot 4\frac{1}{2}\text{H}_2\text{O}$, is produced. A salt of the composition $\text{Ba}_5\text{Sb}_4\text{S}_{11}\cdot 16\text{H}_2\text{O}$ is formed when an excess of barium sulphide is employed in the method used for the preparation of the pyrosulphoantimonite. The product may be a basic salt: $\text{Ba}_3\text{Sb}_4\text{S}_9\cdot 2\text{BaS}\cdot 16\text{H}_2\text{O}$ —**barium disulphorthosulphotetramtimonite**; or a mixture of $\text{Ba}_3(\text{SbS}_3)_2\cdot 8\text{H}_2\text{O}$ and $\text{Ba}_2\text{Sb}_2\text{S}_5\cdot 8\text{H}_2\text{O}$; if it be treated with much water, yellowish-green **barium orthosulphotetramtimonite**, $\text{Ba}_3\text{Sb}_4\text{S}_9\cdot 10\text{H}_2\text{O}$, is formed. It dries to a brown, amorphous mass.

I. Pouget prepared **zinc orthosulphoantimonite**, $Zn_3(SbS_3)_2$, by adding a salt of zinc to a dil. soln. of potassium orthosulphoantimonite; with a conc. soln., crystalline **potassium zinc orthosulphoantimonite**, $KZnSbS_3$, is formed. I. Pouget also prepared **cadmium orthosulphoantimonite**, $Cd_3(SbS_3)_2$, in a similar way.

According to H. Pélabon,¹¹ the f.p. curve for mixtures of antimony and mercuric sulphides consists of two simple branches melting at a eutectic point at 455° . The eutectic mixture contains 34 per cent. of mercuric sulphide. On account of the volatilization of the mercuric sulphide, it was not possible to study the behaviour of mixtures containing more than 68 per cent. of it. The mol. lowering of the f.p. was calculated to be 788 for mercuric sulphide, and 797 for cuprous sulphide. I. Pouget found that the precipitates with both mercurous and mercuric salts in dil. or conc. soln. of potassium sulphoantimonite are rapidly reduced. M. Barcena described a lead-grey mineral which he called **livingstonite**—after D. Livingstone—and obtained from Huitzucó, Mexico. F. Sandberger, A. Hilger, and W. T. Page also described specimens from other localities. Analyses by M. Barcena, F. P. Venable, and W. T. Page correspond with $HgS \cdot 2Sb_2S_3$, or, in harmony with the views of P. Groth, with **mercuric metasulphotetranantimonite**, $HgSb_4S_7$. P. Groth and K. Mieleitner gave this formula with the possibility that it might be a mercurous salt, $Hg_2S \cdot 4Sb_2S_3$, or $Hg_2Sb_8S_{13}$. L. Baker called it an acid sulphoantimonite, $HgS \cdot 2Sb_2S_3$, but represented it graphically with quinquevalent antimony. G. Cesaro represented it graphically with trivalent antimony :

E. T. Wherry and W. F. Foshag used L. Baker's formula, but were doubtful about its homogeneity. W. M. Davy and C. M. Farnham made some observations on the mineral. He obtained a crystalline mass of a similar composition by melting a mixture of mercuric sulphide and antimony trisulphide in an atm. of carbon dioxide. H. Sommerlad obtained only mixtures of mercuric sulphide and antimony trisulphide by heating mercurous or mercuric chloride and antimony trisulphide at 100° – 150° . Livingstonite occurs either massive, or in groups of slender, prismatic crystals. The sp. gr. is 4.81, and the hardness, 2. J. J. Saslawsky calculated the contraction which occurs during the formation of the mineral from its components. The mineral was found by J. Joly to sublime at 440° . J. Joly gave 430° for the sublimation temp. E. S. Lassen found the mineral is pleochroic; that its double refraction is strong; and its optical character positive.

According to L. F. Hawley¹² thallos sulphide forms mixed precipitates or solid soln. with either antimony trisulphide or antimony pentasulphide analogous to those with arsenic trisulphide; but not **thallos sulphoantimonite** or sulphoantimonate. The two series of solid soln., respectively with antimony tri- and pentasulphides, are so much alike that they are described in the same words. Each series is homogeneous and complete. These solid soln. vary in colour from black when high in thallos sulphide through red to orange when high in the antimony sulphide. Dil. acids readily dissolve some of the thallos sulphide, the solid soln. becoming richer in the antimony sulphides and hence more resistant towards acids, so that only warm conc. acids will completely remove the thallium sulphide. In the same way dil. alkaline sulphides partially dissolve the antimony sulphides, but only hot conc. alkaline sulphides will completely remove the antimony sulphides. These solid soln. are stable in the air except when high in thallos sulphide; then they are readily oxidized especially when not completely dry. Most of these solid soln. of intermediate composition if heated to about 100° in the air or even in the soln. in which they are prepared sinter and become black and vitreous without change in composition.

N. Parravano and P. de Cesaris¹³ investigated the m.p. of the stannous sulphide

and antimony trisulphide system in an atm. of nitrogen. The results are summarized in Fig. 61; there is probably formed **stannous metasulphoantimonite**, $\text{SnS} \cdot \text{Sb}_2\text{S}_3$, or $\text{Sn}(\text{SbS}_2)_2$. Antimony trisulphide does not furnish solid soln., or does so with only small conc. of stannous sulphide; but the stannous sulphide forms solid soln. with up to 15 per cent. of antimony trisulphide. W. Guertler,¹⁴ and H. Schack made a partial study of the ternary system Pb-Sb-S. K. Wagemann investigated the f.p. curve of lead sulphide and antimony trisulphide, and

FIG. 61.—Freezing-point Curves of the Binary System: $\text{SnS}-\text{Sb}_2\text{S}_3$.

FIG. 62.—Freezing-point Curves of the Binary System: $\text{PbS}-\text{Sb}_2\text{S}_3$.

found only one compound, $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$, with a eutectic between lead pyrosulphoantimonite and the antimony trisulphide. Solid soln. were formed. F. M. Jäger and H. S. van Klooster examined the curve in more detail, and found breaks corresponding with $5\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$ at 609° , and $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$ at 570° . The latter compound has a transition temp. at 523° . D. Iitsuka, Fig. 62, observed (i) a maximum at 672° corresponding with $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$; (ii) the formation of a compound $3\text{PbS} \cdot 2\text{Sb}_2\text{S}_3$ at 610° with a transition temp. at 510° ; (iii) the formation of $\text{PbS} \cdot \text{Sb}_2\text{S}_3$; and (iv) the formation of $5\text{PbS} \cdot 2\text{Sb}_2\text{S}_3$ at 590° and a transition temp. at 468° .

C. L. Boulanger described a *plomb antimonié sulfuré* which he obtained from Molières, France. J. F. L. Hausmann called it **boulangerite**. A. Breithaupt obtained a variety from Nerchinsk, Siberia, which he called *embrithite*—from $\epsilon\mu\beta\rho\theta\eta\varsigma$, heavy—and another variety from the same locality which he called *plumbostib*, or *plumbostibite*. Analyses were reported by C. L. Boulanger, M. C. J. Thaulow, J. F. L. Hausmann, W. Brüel, L. G. Eakins, V. R. von Zepharovich, E. Bechi, R. W. Helmhacker, F. A. Genth, G. vom Rath, M. Websky, A. Frenzel, T. Haegé, C. Guillemain, E. V. Shannon, H. Sjögren, and H. Sommerlad. The formulæ calculated by C. F. Rammelsberg from the analyses were $5\text{PbS} \cdot \text{Sb}_2\text{S}_3$, $3\text{PbS} \cdot \text{Sb}_2\text{S}_3$, and $10\text{PbS} \cdot 3\text{Sb}_2\text{S}_3$. E. V. Shannon gave $5\text{PbS} \cdot \text{Sb}_2\text{S}_3$, and $7\text{PbS} \cdot 3\text{Sb}_2\text{S}_3$. Most of the older analyses correspond with $5\text{PbS} \cdot 2\text{Sb}_2\text{S}_3$, or *lead henasulphotetrantimonite*, $\text{Pb}_5\text{Sb}_4\text{S}_{11}$, and some of the more recent analyses with $3\text{PbS} \cdot \text{Sb}_2\text{S}_3$, or $\text{Pb}_3\text{Sb}_2\text{S}_6$, **lead orthosulphoantimonite**. Some of the minerals analyzed by M. Websky, and E. V. Shannon approximate to $\text{Pb}_3(\text{SbS}_3)_2$, and were called *epiboulangerite*. M. Websky represented epiboulangerite as $12\text{PbS} \cdot \text{Sb}_2\text{S}_3 \cdot \text{Sb}_2\text{S}_5$, or $\text{Pb}_3(\text{SbS}_3)_2 \cdot 3\text{Pb}_3(\text{SbS}_4)_2$, *lead orthosulphodiantimonohehexantimonate*. Idealized boulangerite has not been definitely recognized; it is most commonly regarded as boulangerite, $\text{Pb}_5\text{Sb}_4\text{S}_{11}$, or as epiboulangerite, $\text{Pb}_3(\text{SbS}_3)_2$, and, according to C. Guillemain, contaminated with more or less lead sulphide; and epiboulangerite has not been accepted as a definite mineral species. C. F. Rammelsberg prepared what he regarded as boulangerite by heating to redness lead orthosulphoantimonate out of contact with air; H. Sommerlad, by treating a soln. of sodium orthosulphoantimonate with lead acetate, washing and drying at 100° the reddish-brown

precipitate, and heating the product a little in a covered crucible; H. Sommerlad, by melting 3 mols of lead chloride into two of antimony trisulphide and repeating the treatment with more trisulphide—F. L. Ducatte, and J. Rondet do not consider that this process gives the desired product. I. Pouget obtained lead orthosulphoantimonite by adding a lead salt soln. to a dil. soln. of potassium orthosulphoantimonite—if a conc. soln. be used, a potassium lead orthosulphoantimonite is formed. There is no sign of the ortho-salt on F. M. Jäger and H. S. van Klooster's or D. Iitsuka's f.p. curves, Fig. 62; but D. Iitsuka observed that the compound $5\text{PbS}\cdot 2\text{Sb}_2\text{S}_3$, which he regards as artificial boulangerite, is formed by the action of plumosite on lead sulphide at 590° . This compound exists in two modifications with a transition temp. at 468° , and it forms a eutectic with 78 per cent. of lead sulphide at 557° . W. Guertler and H. Schack said that antimony trisulphide forms a eutectic with 10 per cent. of lead sulphide, which melts at 485° . There is a region of immiscibility in the series between 52 and 68 per cent. of lead sulphide. In the system Pb-Sb-S, two ternary compounds can exist in the molten state, $3\text{PbS}\cdot \text{Sb}_2\text{S}_3$ and $2\text{PbS}\cdot 3\text{Sb}_2\text{S}_3$. The former corresponds with boulangerite. F. Zambonini made observations on the formation of the Pb-Sb-S minerals in nature.

Boulangerite is described as a lead-grey mineral which occurs granular and compact, and also in plumose masses with a crystalline fracture. J. L. C. Schröder van der Kolk made some observations on the colour. H. Sjögren showed that the rhombic, bipyramidal crystals have these axial ratios $a : b : c = 0.5527 : 1 : 0.7478$, and are isomorphous with diaphorite, $(\text{Pb}, \text{Ag})_5\text{Sb}_4\text{S}_{11}$. W. Brüel gave 5-690 for the sp. gr.; C. F. Rammelsberg, 5-831; V. R. von Zepharovich, 5-690-6-08; R. W. Helmhacker, 5-520; G. vom Rath, 5-935; F. Zambonini, 6-01; M. Websky, 5-835-6-309; A. Frenzel, 6-120-6-320; H. Sjögren, 6-185 at 16.5° ; and E. V. Shannon, 6-274-6-407. H. Sommerlad's artificial preparations had a sp. gr. between 5-860 and 5-907. H. Sommerlad gave 5-871 for the sp. gr. of the synthetic product. J. J. Saslawsky made some observations on the contraction which occurs during the formation of the mineral from its components. The hardness is 2-3. W. W. Coblenz studied the photoelectric sensitivity of a mineral approximating Pb_3SbS_3 . T. W. Case found that boulangerite and epiboulangerite are poor conductors, but in light the former conducts better than in darkness, while light has no effect on the latter. E. E. Fairbanks gave 36 for the dielectric constant (water 81). S. B. Christy found the potential of the mineral in N-KCy to be -0.50 volt, and in 0.1N- to 0.01N-soln., -0.55 volt. M. C. J. Thaulow showed that the mineral is decomposed but not all dissolved by nitric acid; and is soluble in hydrochloric acid with the development of hydrogen sulphide. A. Terreil said that boulangerite is not decomposed by a 10 per cent. soln. of sodium sulphide.

E. V. Shannon found a mineral which he called *mullanite*, near Mullan, Idaho, and also accompanying epiboulangerite in the Iron Mountain, Montana. Mullanite is indistinguishable from epiboulangerite except that the latter gives a greyish-black streak, the former, a brownish-black streak. The mineral occurs in fine, matted, wool-like masses of dark grey fibres, and as a compact, steel-grey, fibrous material. The needles are usually flattened and are deeply striated longitudinally; they are terminated by the basal plane, and are probably orthorhombic ($a : b = 1 : 0.835$) with the three pinacoidal cleavages. The thinner fibres are very flexible, whilst the thicker ones are quite brittle. The sp. gr. is between 6-274 and 6-407. Analyses correspond with $5\text{PbS}\cdot 2\text{Sb}_2\text{S}_3$, as in some forms of boulangerite, and E. V. Shannon withdrew mullanite as a special name.

Several lead sulphoantimonites occur as minerals which are more basic than the ortho-salt. L. F. Navarro¹⁵ reported a lead-grey mineral from some Spanish lead mines which he called *quirogite*—after F. Quiroga. The analysis corresponds with $23\text{PbS}\cdot 3\text{Sb}_2\text{S}_3$, but, according to A. Schrauf, it may be only an impure galena. The tetragonal crystals have the axial ratio $a : c = 1 : 1.286$; the sp. gr. is 7.22; and the hardness 3.

L. F. Svanberg¹⁶ obtained from the silver mines at Sala, Sweden, a mineral which he named *geocronite*, or rather *geokronite*, from $\gamma\eta$, earth, and Κρόνος , Saturn—the

alchemists' name for lead. The mineral also contained some arsenic. C. Sauvage obtained from Meredo, Spain, a variety free from arsenic, and J. F. L. Hausmann called it *schulzite*—after W. Schulz. J. Apjohn obtained from Kilbricken, Ireland, a mineral which was called **kilbrickenite**. J. D. Dana suggested that this mineral is the same as geconrite, and this hypothesis was established by G. T. Prior, D. Forbes, F. A. Genth, C. H. T. Kerndt, and V. Goldschmidt. Analyses were reported by L. F. Svanberg, C. Guillemin, G. Nauckhoff, J. Apjohn, G. T. Prior, C. Sauvage, C. H. T. Kerndt, and G. d'Achiardi. The analysis by L. F. Svanberg corresponds with **lead octosulphodiantimonite**, $5\text{PbS}(\text{Sb,As})_2\text{S}_3$; J. Apjohn's analysis of kilbrickenite, with $6\text{PbS}(\text{Sb}_2\text{S}_3)$. C. F. Rammelsberg gave as the best representative value, $5\text{PbS}(\text{Sb}_2\text{S}_3)$, or $\text{Pb}_5(\text{Sb,As})_2\text{S}_8$. This is virtually in agreement with G. d'Achiardi's and C. Guillemin's results; and with G. T. Prior's observations on kilbrickenite and geconrite. H. Sommerlad obtained a grey, crystalline mass of the same composition by melting the constituent sulphides in an atm. of hydrogen sulphide. The light lead-grey mineral usually occurs massive, granular, or earthy; crystals are rare. C. H. T. Kerndt gave for the axial ratios of the rhombic crystals $a : b : c = 0.5805 : 1 : 0.5028$; and G. d'Achiardi, $0.6145 : 1 : 0.6797$. G. d'Achiardi considered the mineral to be isomorphous with stephanite. The crystals of geconrite were also examined by V. Goldschmidt, A. d'Achiardi, G. d'Achiardi, P. Groth, G. T. Prior, and R. H. Solly. The cleavage on the (110)-face is distinct; that on the (211)-face is not so clear. J. Apjohn gave 6.407 for the sp. gr.; C. Sauvage, 6.430; C. H. T. Kerndt, 6.470; L. F. Svanberg, 6.434; G. Nauckhoff, 6.260; and G. T. Prior, 6.450. For the artificial crystals H. Sommerlad gave 6.447–6.657. P. E. W. Oeberg found the sp. ht. to be 0.0659. J. Joly gave 430° – 440° for the sublimation temp.

Another related mineral from Bottino, Tuscany, was called, by E. Bechi,¹⁷ **meneghinite**—after G. Meneghini. Analyses were made by O. Sella, E. Bechi, G. vom Rath, A. Martini and A. Funaro, J. A. Krenner, A. Frenzel, B. J. Harrington, and G. Flink. C. F. Rammelsberg represented the results by the formula $4\text{PbS}(\text{Sb}_2\text{S}_3)$, **lead disulphopyrosulphoantimonite**, $(\text{Pb}(\text{S}(\text{Pb})_2\text{Sb}_2\text{S}_5))$ —*vide* jordanite. H. Sommerlad prepared the substance by melting a mixture of the constituent sulphides in an atm. of hydrogen sulphide. J. L. C. Schröder van der Kolk studied the colour of the mineral. The mineral occurs in dark lead-grey, fibrous, and compact masses, and in slender prismatic crystals which are vertically striated. H. A. Miers gave for the axial ratios of the rhombic crystals $a : b : c = 0.52891 : 1 : 0.36317$. The (100)-cleavage is perfect but interrupted, the (001)-cleavage is indistinct. Both H. A. Miers and C. Hintze emphasized the crystallographic relationship between jordanite, $\text{Pb}_4\text{As}_2\text{S}_7$, and meneghinite, $\text{Pb}_4\text{Sb}_2\text{S}_7$; the monoclinic prisms of the latter have the axial ratios $a : b : c = 0.4845 : 1 : 0.265$, and $\beta = 80^\circ 33'$; and the rhombic pyramids of the former $0.5289 : 1 : 0.3632$. E. Bechi gave for the sp. gr. 6.373; A. Frenzel, 6.360; J. A. Krenner, 6.4316; B. J. Harrington, 6.33; and G. Flink, 6.430. H. Sommerlad gave 6.296 for the artificial crystals. J. J. Saslawsky calculated the contraction in the formation of the mineral from its constituents. The hardness is 2–3. According to D. Iitsuka, **lead orthosulphotetantimonite**, $\text{Pb}_3\text{Sb}_4\text{S}_9$, appears on the f.p. curve of lead and antimonious sulphides, as being formed at 610° ; and there are two modifications with a transition temp. at 510° .

The *minerae antimoniæ plumosæ*, *plumose antimonial ores*, *les mines d'antimoine aux plumes*, or the *Federerze* of the old mineralogists—A. G. Werner,¹⁸ L. A. Emmerling, R. J. Haiiy, and J. G. Wallerius—were usually antimonial sulphides. H. Rose, V. R. von Zepharovich, and E. Kaiser showed that stibnite alone may occur in capillary (hair-like) crystals characteristic of the plumose minerals. According to L. J. Spencer, these minerals include varieties of stibnite, zinckenite, jamesonite, plumosite, boulangerite, and meneghinite. W. Haidinger called the feathery ore **plumosite**; E. F. Glocker, *plumite*; R. Jameson, *axotomous antimony glance*; and A. Breithaupt, *axotomous Chalybinglanz*, or *Stahlantimonglanz*. W. Haidinger

applied the term **jamesonite**—after R. Jameson—to a variety obtained by F. Mohs from Cornwall in 1820, and whose composition was represented by H. Rose by the formula $3\text{PbS} \cdot 2\text{Sb}_2\text{S}_3$, while the plumose ore from Wolfsberg, previously regarded as stibnite, had the composition $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$. D. Iitsuka obtained a substance of this composition which he regarded as artificial jamesonite—*vide infra*, plumosite. H. Rose's view was confirmed later by C. F. Rammelsberg, who observed that a compact mineral from the same locality had the same composition, and he called it **heteromorphite**—from *ἕτερος*, different; and *μορφή*, form. Jamesonite and heteromorphite were considered to be distinct mineral species until, in 1860, C. F. Rammelsberg united them as jamesonite, $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$; and H. Rose's formula $3\text{PbS} \cdot 2\text{Sb}_2\text{S}_3$ was supposed to have represented jamesonite contaminated with stibnite. F. Pisani obtained a feathery ore with a composition $7\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$, which he assumed to be crystalline heteromorphite. These crystals were regarded as pligionite by F. Sandberger, E. Kaiser, and L. J. Spencer, but L. J. Spencer later stated that F. Pisani was justified in applying the term heteromorphite to this mineral, and that C. F. Rammelsberg's heteromorphite was probably the same mineral.

Analyses of heteromorphite were reported by H. Rose, E. Bechi, M. Sénez, P. Berthier, C. Guillemain, and L. J. Spencer. The results calculated by C. F. Rammelsberg agree with $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$, and those by F. Zambonini approximate to this value, but, according to L. J. Spencer, they are better represented by the formula $11\text{PbS} \cdot 6\text{Sb}_2\text{S}_3$, the $9\text{PbS} \cdot 5\text{Sb}_2\text{S}_3$ given by C. F. Rammelsberg for a sample from Wolfsberg, or the $7\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$ given by F. Pisani, *i.e.* **lead enneadecasulphoctoantimonite**, $\text{Pb}_7\text{Sb}_8\text{S}_{19}$. According to L. J. Spencer, the monoclinic crystals have the axial ratios, and the angle β between those of pligionite and semseyite. For the relations between these two minerals, *vide infra*. The sp. gr. given by F. Pisani ranges from 5.60 to 5.73. The hardness is 2 to 3. T. W. Case found that jamesonite has a resistance greater than an ohm, and it becomes less in light.

J. C. L. Zincken reported a variety of Spiessglance from Wolfsberg which G. Rose named **pligionite**—from *πλάγιος*, oblique—in allusion to the unusual oblique crystallization. It has also been called *rosenite*. Analyses were reported by H. Rose, J. Kudernatsch, C. F. Rammelsberg, F. Zambonini, and L. J. Spencer. The formula derived from C. F. Rammelsberg's result is $5\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$; that from H. Rose's, $9\text{PbS} \cdot 7\text{Sb}_2\text{S}_3$; and that from J. Kudernatsch's, $4\text{PbS} \cdot 3\text{Sb}_2\text{S}_3$. L. J. Spencer adopts the formula $9\text{PbS} \cdot 7\text{Sb}_2\text{S}_3$ or $5\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$ —*i.e.* **lead heptadecasulphoctoantimonite**, $\text{Pb}_5\text{Sb}_8\text{S}_{17}$. L. J. Spencer, and F. Zambonini discussed the relations between pligionite, heteromorphite, and semseyite—*vide infra*. H. Sommerlad prepared $5\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$ by heating a mixture of lead chloride and antimony trisulphide; and by fusing together a mixture of the component sulphides. F. L. Ducatte, and J. Rondet doubt the chemical individuality of the former product; and F. M. Jäger and H. S. van Klooster obtained it from the constituent sulphides at about 570° —*vide Fig. 62*. There is a transformation temp. at 523° above which α -pligionite, and below which β -pligionite are formed. There is no marked evidence of the formation of sold soln. The mineral occurs in dark grey, granular, or compact masses, or in thick plates or short prisms in druses and geodes. O. Luedecke gave for the axial ratios of the monoclinic crystals, $a : b : c = 1.1331 : 1 : 0.4228$, and $\beta = 72^\circ 49' 5''$; L. J. Spencer, $1.1363 : 1 : 0.8410$, and $\beta = 72^\circ 28'$; G. Rose, $1.1363 : 1 : 0.4205$, and $\beta = 72^\circ 28'$; and F. Zambonini $1.1305 : 1 : 1.6844$, and $\beta = 72^\circ 45'$. The (111)-cleavage is nearly perfect. J. L. C. Schröder van der Kolk made observations on the colour. H. Rose gave 5.400 for the sp. gr.; L. J. Spencer, 5.500; and F. Zambonini, 5.600. H. Sommerlad gave 5.474–5.500 for the artificial crystals, and F. M. Jäger and H. S. van Klooster, 5.47 at $15^\circ/15^\circ$. J. J. Saslawsky calculated the contraction during the formation of the mineral from its constituents. The hardness is 2.5. T. W. Case observed that the mineral is non-conducting, and that light has no appreciable effect.

J. A. Krenner¹⁹ reported a grey, opaque mineral occurring at Felsöbanya,

Hungary, which he called **semseyite**—after A. von Semsey. The analysis reported by J. A. Krenner agrees with $21\text{PbS} \cdot 10\text{Sb}_2\text{S}_3$, or, according to L. Sipöcz, with $9\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$; J. Loczko gave $13\text{PbS} : 6\text{Sb}_2\text{S}_3$; and G. T. Prior and L. J. Spencer's analyses agreed with $21\text{PbS} \cdot 10\text{Sb}_2\text{S}_3$, or $9\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$, *i.e.* **lead hemicosisulphoctoantimonite**, $\text{Pb}_9\text{Sb}_8\text{S}_{21}$. F. Zambonini gave $5\text{PbS} \cdot 2\text{Sb}_2\text{S}_3$, in agreement with mullanite; but sp. gr. are different. The mineral occurs in small tabular, monoclinic tablets which, according to J. A. Krenner, have the axial ratios $a : b : c = 1.4424 : 1 : 1.0515$, and $\beta = 71^\circ 4'$. The (111)-cleavage is perfect. The sp. gr. is 5.952; G. T. Prior and L. J. Spencer gave 5.820–5.920. T. W. Case said that semseyite shows no change in its electrical resistance when exposed to light.

F. Zambonini supposes that solid soln. are formed with the end-numbers: pligionite, $5\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$, and semseyite, $5\text{PbS} \cdot 2\text{Sb}_2\text{S}_3$, but L. J. Spencer showed that this is improbable since the various analyses fall into these well-marked groups, and not into a continuous series between the two end-members. These three groups are represented by pligionite, heteromorphite, and semseyite. There is no evidence that the crystals enclose galena. The most probable hypothesis is that these three minerals form a morphotropic series analogous to that which occurs with the humite group of silicates, for in both these cases the crystals of members of each group are so similar in appearance that they cannot be distinguished by mere inspection, and the only essential difference between them is in the greater length of the vertical axis, which varies regularly with the chemical composition, while the parameters $a : b$ remain practically constant. Although the crystals of heteromorphite could not be accurately measured, it can be said that the three minerals, pligionite, heteromorphite, and semseyite, are very similar in appearance and physical characters, and the monoclinic crystals are the same in habit, striations, and the pyramidal cleavage (111); they differ in the specific gravity, percentage chemical composition, and in the length of the vertical crystallographic axis c .

	$a : b : c$	β	Formula.	Sp. gr.
Pligionite . . .	1.1361 : 1 : 0.8410	$72^\circ 28'$	$5\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$	5.5
Heteromorphite	$7\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$	5.7
Semseyite	1.1442 : 1 : 1.1051	$71^\circ 4'$	$9\text{PbS} \cdot 4\text{Sb}_2\text{S}_3$	5.9

V. C. Butureanu, and L. J. Spencer represent these minerals by the structural formation in which each bivalent Pb atom can be represented by a bivalent Pb.S-Pb-group :

The flexible feather ore called by W. Haidinger plumosite, mentioned above, is now considered to be best represented as **lead pyrosulphoantimonite**, $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$, or $\text{Pb}_2\text{Sb}_2\text{S}_5$. This is in agreement with analyses reported by C. F. Rammelsberg, B. S. Burton, O. Luedecke, and C. Guillemain. L. J. Spencer supposed that J. Loczka's analyses of plumosite were really made on specimens of jamesonite. H. Sommerlad prepared the compound by heating a mixture of the component sulphides at a high temp., and F. M. Jäger and H. S. van Klooster by fusing the component sulphides in a current of hydrogen sulphide. The conditions of equilibrium are shown in D. Iitsuka's diagram, Fig. 62. K. Wagemann made the pyrosulphoantimonite in a similar manner. The crystals are probably rhombic. C. F. Rammelsberg gave 5.697 for the sp. gr. of plumosite; B. S. Burton, 6.030;

and for the artificial crystals, H. Sommerlad gave 5-750-5-832; and F. M. Jäger and H. S. van Klooster, 5-62 at 15°/15°. D. Iitsuka gave 672° for the m.p.

J. C. L. Zincken²⁰ described a mineral which he obtained from Wolfsberg, Harz, and which was called by G. Rose, **zinckenite**. Analyses were reported by H. Rose, B. Kerl, C. Guillemin, H. A. Hilger, W. F. Hillebrand, P. Groth, F. Gonnard, F. Sandberger, A. Stelzner, and P. P. Pillipenko. According to C. F. Rammelsberg, and C. Guillemin, the results are best summarized by the formula $\text{PbS.Sb}_2\text{S}_3$, *i.e.* **lead metasulphoantimonite**, $\text{Pb}(\text{SbS}_2)_2$. F. Wöhler, and J. Fournet prepared it by fusing together the constituent sulphides; and H. Sommerlad, by melting lead chloride with antimony trisulphide: $3\text{PbCl}_2 + 4\text{Sb}_2\text{S}_3 = 3\text{Pb}(\text{SbS}_2)_2 + 2\text{SbCl}_3$; and by melting the component sulphides in an atm. of hydrogen sulphide. F. M. Jäger and H. S. van Klooster could not make it by this process, but D. Iitsuka observed that this compound is formed by the interaction of $3\text{PbS.2Sb}_2\text{S}_3$ with antimony trisulphide below 546°—Fig. 62. The mineral occurs in steel-grey, fibrous or columnar masses, and in crystals which are rarely distinct. The rhombic crystals were found by G. Rose to have the axial ratios $a : b : c = 0.5575 : 1 : 0.6353$. The crystals sometimes appear in hexagonal forms through twinning; the lateral faces may be longitudinally striated. L. J. Spencer described crystals free from twinning, and studied the isomorphism with wolfsbergite, etc. The cleavage is not distinct. The crystals were also described by G. A. Kenngott, O. Luedecke, E. S. von Fedoroff, E. Schulze, and V. Goldschmidt. L. J. Spencer showed that zinckenite, sartorite, emplectite, and chalcostibite, form a group of isomorphous minerals with the corresponding parameters:

	<i>a : b : c</i>
Zinckenite, $\text{Pb}(\text{SbS}_2)_2$	0.5575 : 1 : 0.6353
Sartorite, $\text{Pb}(\text{AsS}_2)_2$	0.5389 : 1 : 0.6188
Emplectite, CuBiS_2	0.5430 : 1 : 0.6256
Chalcostibite, CuSbS_2	0.5242 : 1 : 0.6376

The colour of zinckenite was discussed by J. L. C. Schröder van der Kolk. W. F. Hillebrand gave 5-21 for the sp. gr. of the mineral; W. F. Petterd, 5-16; and G. Rose, 5-303-5-310. H. Sommerlad gave 5-280-5-320 for the sp. gr. of the artificial crystals; and J. Fournet, and F. Wöhler, 5-30-5-35. J. J. Saslawsky calculated the contraction which occurs in the formation of zinckenite from its constituent sulphides. The hardness is 3.0-3.5. J. Joly found that when zinckenite is heated, sublimation occurs at about 460°. A. de Gramont examined the spark spectrum. T. W. Case observed that the resistance is less than a megohm, and insulation has no perceptible effect. J. Fournet said that when the compound is boiled with hydrochloric acid it is decomposed; and with nitric acid, or aqua regia, a white residue containing lead and antimony oxides is formed; while H. Sommerlad found that with a mixture of nitric and tartaric acids, lead sulphate is precipitated. The compound is also decomposed by soln. of alkali hydroxides or sulphides. When heated in hydrogen gas, F. Wöhler found that hydrogen sulphide is given off, and lead and antimony are formed.

S. G. Gordon²¹ described a mineral from Oruro, Bolivia, and he called it **keelelyite**—after F. J. Keeley. Its composition, allowing for impurities, approximates **lead hena-sulphohexantimonite**, $2\text{PbS.3Sb}_2\text{S}_3$, corresponding with *rezbanyite*. It is very like zinckenite. It occurs in dark grey radiating aggregates of acicular crystals—possibly rhombic. The sp. gr. is 5-21, and hardness 2. E. T. Wherry regarded keelelyite as a variety of zinckenite, but not so E. V. Shannon and M. N. Short.

I. Pouget²² prepared **potassium lead orthosulphoantimonite**, KPbSbS_3 , by adding a lead salt to a conc. soln. of potassium orthosulphoantimonite. The precipitate was rapidly washed by suction, pressed between bibulous paper, and dried in hydrogen. The chestnut-brown crystals are decomposed by water into soluble potassium and insoluble lead orthosulphoantimonites.

P. Rashleigh²³ described an ore of antimony from Endellion, Cornwall, which J. L. Bournon found to be a triple sulphuret of lead, antimony, and copper.

F. X. M. Zippe named it *endellione*, which was altered to *endellionite*; D. L. G. Karsten, *Spießglanzbleierz*; A. Breithaupt, *Tripelglanz*, or *Antimonkupferglanz*; F. Mohs, *prismatischer Spießglasglanz*, or *prismatoidischer Kupferglanz*; W. Haidinger, *wölkite*; F. Mohs and F. X. M. Zippe, *Dystomglanz*; J. F. L. Hausmann, *Bleifahlerz*; P. Groth, *Antimonbleikupferblende*; A. G. Werner, *Schwarzspießglanz*, and *Rädelerz—wheel ore*; and R. Jameson, **bournonite**—after J. L. Bournon. Analyses were reported by F. Babanek, C. Bromeis, I. Domeyko, P. A. Dufrenoy, F. Field, A. Frenzel, C. Guillemain, C. Hatchett, R. W. Helmhacker, C. Hidegh, P. Jannasch, B. Kerl, M. H. Klaproth, C. Kuhlemann, A. Lacroix, D. Lovisato, O. Luedecke, W. Meissner, A. W. F. Petterd, C. F. Rammelsberg, H. Rose, W. T. Schaller, A. von Schrötter, Z. Sipöcz, J. Smithson, P. Termier, H. Traube, G. Tschermak, F. G. Wait, and V. R. von Zepharovich. A variety with 5.47–28.64 per cent. of nickel and cobalt was described by C. F. Rammelsberg and J. C. L. Zincken as *Nickel-bournonite*; and as *bournonite-nickel glance*, by O. Luedecke. L. Sipöcz observed that part of the antimony in bournonite may be replaced by arsenic. C. F. Rammelsberg represented the composition of bournonite as **copper lead orthosulphoantimonite**, $2\text{PbS}\cdot\text{Cu}_2\text{S}\cdot\text{Sb}_2\text{S}_3$, or CuPbSbS_3 , and this is in agreement with the observations of C. Guillemain, and W. F. Foshag. C. Doelter heated a mixture of the chlorides or oxides of copper, lead, and antimony at a temp. below redness in a current of hydrogen sulphide and obtained a mass of homogeneous crystals of bournonite; he also obtained the crystals by heating the mixed chlorides with a soln. of sodium sulphide. B. von Cotta found crystals of a copper lead sulphoantimonite as a furnace product. A. Stelzner also found that crystals of jamesonite often contain copper.

Bournonite occurs in dark steel-grey, lead-grey, or iron-black compact or granular masses; and in plates or short prisms. The colour was studied by J. C. L. Schröder van der Kolk. The crystals are often aggregated in a parallel position. The prism faces may be vertically and the macrodomes horizontally striated. Twinning about the (110)-plane may be oft repeated so as to furnish cruciform or wheel-shaped crystals, or twin lamellæ. The cleavage on the (010)-face is imperfect; and less marked on the (010)- and (001)-faces. W. H. Miller gave for the axial ratios of the rhombic crystals $a : b : c = 0.93797 : 1 : 0.89686$. Observations on the crystals were made by H. A. Miers, G. Rose, F. Zirkel, V. Goldschmidt, O. Luedecke, F. B. Peck, N. von Kokscharoff, A. Schrauf, T. Haege, G. vom Rath, A. Frenzel, H. Traube, F. Babanek, G. Szellemy, V. R. von Zepharovich, F. Hensenberg, A. Schmidt, A. Lacroix, G. Benko, R. P. Greg and W. G. Lettsom, F. Gonnard, P. Groth, P. Termier, I. Domeyko, G. T. Prior and L. J. Spencer, A. d'Achiardi, and W. P. Jervis. The optical anisotropy of the crystals was examined by J. Königsberger. H. Schneiderhöhn examined polished surfaces of the crystals etched with nitric or hydrochloric acid, aqua regia, soln. of potassium hydroxide, permanganate, or cyanide, ferric chloride, or alkaline hydrogen dioxide. C. Guillemain gave 5.736–5.855 for the sp. gr.; C. Bromeis, 5.70–5.79; C. F. Rammelsberg, 5.82–5.86; V. R. von Zepharovich, 5.585–5.700; A. Breithaupt, 5.83; and P. Termier, 5.78. C. Doelter gave for the artificial crystals, 5.719. C. F. Rammelsberg and J. C. L. Zincken found 5.592 for the sp. gr. of nickel-bournonite, and O. Luedecke, 5.635–5.706. The hardness is 2–3. F. B. Peck measured the elliptical heat conductivity curve of the crystal. A. Sella gave 0.0730 for the sp. ht. A. de Gramont studied the spark spectrum, and found the mineral has a feeble electrical conductivity. P. H. Geiger studied the photoelectric effect; and W. W. Coblenz and J. F. Eckford, the photoelectric sensitivity. Bournonite has a high spectrophoto-electrical sensitivity from the extreme violet to 1μ in the ultra-red with two wide, ill-defined maxima in the region of 0.55μ and 0.95μ , its reaction being entirely different from that of the constituent sulphides. The intrinsic intensity is greatly increased with fall of temp., the maxima shifting towards the short wave-lengths. T. W. Case said that the mineral has a resistance greater than a megohm, and that light has a marked effect in reducing the resistance.

Bournonite is decomposed by nitric acid forming a blue soln., and a residue of sulphur, antimony oxide, and lead sulphate. C. A. Burghardt observed that when bournonite is heated with ammonium nitrate, it forms a greenish-yellow mass, which gives a blue soln. with water, and a residue of lead sulphate and antimony oxides. C. Doelter found that 100 parts of water dissolve 0.03 part of bournonite; and more is dissolved when the powdered mineral is heated with water in a sealed tube at 80°. C. Doelter also found that a soln. of sodium sulphide can dissolve about 0.1 per cent. of bournonite. The mineral is affected by water less than pyrite, zinc blende, or galena. The composition of soln. and residues were determined. The weathering of bournonite was studied by G. Tschermak, J. R. Blum, E. Döll, and G. Sillem.

H. Buttgenbach²⁴ described a fine-grained, lead-grey mineral from the Slatá mine, Tunis; the analyses corresponded with $9\text{Cu}_2\text{S}\cdot 5\text{PbS}\cdot 7\text{Sb}_2\text{S}_3$. It was called **berthonite**—after M. Berthon; and it is related to jamesonite. Its sp. gr. was 5.49, and its hardness 4-5.

J. A. Krenner²⁵ described a mineral from Felsőbánya, Hungary, which he called **andorite**—after Andor von Semsey—and which approximated in composition $\text{Pb}_2\text{Ag}_2\text{Sb}_6\text{S}_{12}$; soon afterwards, W. C. Brögger,²⁶ and R. Pöhlmann described a mineral from Oruro, Bolivia, which he called **sundtite**—after L. Sundt—and which approximated $(\text{Ag}_2, \text{Cu}_2, \text{Fe})\text{Sb}_2\text{S}_6$; and about the same time, A. Stelzner obtained from Oruro, Bolivia, a related mineral which he called **webnerite**—after A. Webner. According to G. T. Prior and L. J. Spencer, these three minerals are identical, and therefore the term andorite is retained for all. L. J. Spencer gave for the best representative formula $(\text{Pb}, \text{Ag}_2)\text{S}\cdot \text{Sb}_2\text{S}_3$, *i.e.* **lead silver metasulphoantimonite**, $(\text{Pb}, \text{Ag}_2)(\text{SbS}_2)_2$; W. F. Foshag, $\text{Ag}_2\text{S}\cdot 2\text{PbS}\cdot 3\text{Sb}_2\text{S}_3$; and E. V. Shannon, $\text{PbAgSb}_3\text{S}_6$. The mineral occurs in dark grey compact masses or crystal aggregates. The tabular or prismatic crystals belong to the rhombic system; W. C. Brögger gave for the axial ratios $a : b : c = 0.6771 : 1 : 0.6458$; with a different orientation, J. A. Krenner, $0.97756 : 1 : 0.86996$; and L. J. Spencer, $0.9846 : 1 : 0.6584$. J. A. Krenner found that the (010)-cleavage is good. L. J. Spencer said that although andorite is rhombic, it bears no crystallographic relationship with the rhombic zinckenite, $(\text{PbSb}_2\text{S}_4)$, and the few analyses all agree with the formula $\text{PbAgSb}_3\text{S}_6$. The mineral is therefore a double salt, and is not an isomorphous member of the zinckenite group as represented by the formula $(\text{Pb}, \text{Ag}_2)\text{Sb}_2\text{S}_4$. J. A. Krenner gave 5.341 for the sp. gr.; W. C. Brögger, 5.50; R. Pöhlmann, 5.377; and G. T. Prior and L. J. Spencer, 5.33-5.35. The hardness is 3. J. Joly gave 510° for the sublimation temp. H. E. McKinstry observed that the mineral is not changed by exposure to the light from an electric arc. J. A. Krenner and J. Loczka found an argentiferous lead ore at Kisbánya, Hungary, and they called it **fizelyite**. Its composition approximates **lead silver sulphoctoantimonite**, $5\text{PbS}\cdot \text{Ag}_2\text{S}\cdot 4\text{Sb}_2\text{S}_3$. It is dark grey, and brittle, with a hardness of 2. T. W. Case said that the mineral is a non-conductor, and that insolation has no appreciable effect.

The *argentum antimonio sulphurato mineralisatum* of A. Cronstedt, the *dunkles Weissgültigerz* of M. H. Klaproth, and the *mine d'antimoine grise tenant argent* of Himmelsfürst, Freiberg, were probably the *Schilfglaserz* described by J. C. Freiesleben, and named *Basitomglanz* by A. Breithaupt; *donacargryrite*—from *δόναξ*, a reed—by E. J. Chapman; and **freieslebenite**, by W. Haidinger. The crystals were represented as rhombic by W. Phillips, A. Breithaupt, and J. F. L. Hausmann; and monoclinic by W. H. Miller. V. R. von Zepharovich showed that there are both rhombic and monoclinic forms—the latter he called *freieslebenite*, and the former, **diaphorite**—from *διαφορά*, difference—in allusion to its resemblance to and difference from *freieslebenite*. A. Damour also described a mineral from Mexico which he called *brongniardite*—after A. Brongniardt. C. F. Rammelsberg regarded it as a variety of *Schilfglaserz*, and G. T. Prior and L. J. Spencer, as a variety of *diaphorite*.

Analyses of freieslebenite were reported by F. Wöhler, L. de la Escosura, N. y Garza, C. Vrba, L. G. Eakins, and I. Domeyko. The results are not easily represented by a single formula. C. F. Rammelsberg gave several formulæ, the latest was $R_2Sb_2S_5 \cdot R_3(SbS_3)_2$; $5RS \cdot 2Sb_2S_3$; W. S. von Waltershausen, and C. F. Naumann used $3PbS \cdot Sb_2S_3 \cdot 2AgS \cdot Sb_2S_3$; G. Tschermak, $Ag_3Pb_2Sb_3S_8$; G. Rose, $3(Pb, Ag)S \cdot Sb_2S_3$. J. D. Dana's latest formula was $5RS \cdot 2Sb_2S_3$; and this is considered by L. J. Spencer to be the best—**silver lead henasulpho-tetrantimonite**, $5(Pb, Ag_2)S \cdot 2Sb_2S_3$. W. F. Foshag gave $3Ag_2S \cdot 4PbS \cdot 3Sb_2S_3$ for diaphorite, and freieslebenite; and $Ag_2S \cdot PbS \cdot Sb_2S_3$ for brongniardtite. The mineral occurs in pale grey, inclining to silver-white, or dark grey, prismatic crystals with the prismatic planes vertically striated. W. H. Miller gave for the axial ratios of the monoclinic crystals $a : b : c = 0.58714 : 1 : 0.92768$, and $\beta = 87^\circ 46'$, and L. J. Spencer, $0.9786 : 1 : 0.9277$, and $\beta = 87^\circ 46'$. The crystals were also examined by A. Frenzel, A. Breithaupt, J. F. L. Hausmann, V. Goldschmidt, V. R. von Zepharovich, A. Lévy, C. Vrba, L. F. Navarro, and H. Bücking. J. C. Freiesleben gave 6.108–6.114 for the sp. gr.; F. Wöhler, 6.194; L. de la Escosura, 6.01–6.02; C. Vrba, 7.035–6.051, and L. J. Spencer gave 6.3 for the best representative value. The hardness is 2.0–2.5.

Analyses of diaphorite were reported by A. E. Reuss, R. W. Helmhacker, G. A. Kenngott, and C. Vrba. L. J. Spencer said that the best representative formula is near that of freieslebenite, and is probably intermediate between those of freieslebenite and andorite. Thus brongniardtite is represented by $2(Pb, Ag_2)S \cdot Sb_2S_3$. The steel-grey prismatic crystals may have faces vertically striated. The rhombic crystals were found by V. R. von Zepharovich to have the axial ratios $0.49194 : 1 : 0.73447$; and by L. J. Spencer, $0.9839 : 1 : 0.7345$. Twinning may occur about the (120)- and (122)-planes. A. E. Reuss gave 6.23 for the sp. gr.; R. W. Helmhacker, 5.731; V. R. von Zepharovich, 5.885–5.919; C. Vrba, 6.038–6.044; and L. J. Spencer, 6.9. The hardness is 2–3. A. de Gramont studied the spark spectrum. T. W. Case observed that freieslebenite has a resistance greater than a megohm, and that light has no perceptible influence. According to L. J. Spencer, the minerals andorite, diaphorite, and freieslebenite are strikingly similar in appearance, and between them there is the same kind of morphotropic relation as that existing between plagioclase, heteromorphite, and semseyite, since in diaphorite the vertical axis c and sp. gr. fall between those of andorite and freieslebenite, it is to be expected that they should also be intermediate in composition:

	$a : b : c$	Sp. gr.	
Andorite	0.9846 : 1 : 0.6584	5.35	$(Pb, Ag_2)S \cdot Sb_2S_3$
Diaphorite	0.9839 : 1 : 0.7345	5.9	—
Freieslebenite	0.9786 : 1 : 0.9277	6.3	$5(Pb, Ag_2)S \cdot 2Sb_2S_3$

I. Pouget²⁷ treated a conc. soln. of potassium orthosulphoantimonite with a lead salt, and on standing a short time, crystals of **potassium lead orthosulphoantimonite**, $KPbSb_3S_8$, were formed. The salt is decomposed by water into its component sulphides. V. Rosicky and J. Sterba-Boehn described a black mineral from Himmelsfürst, Freiberg, which they called **ultrabasite**—in allusion to the extremely basic composition. The analysis corresponds with $11Ag_2S \cdot 28PbS \cdot 3GeS_2 \cdot 2Sb_2S_3$. Assuming the silver sulphide and part of the lead sulphide are admixtures, the mineral can be regarded as **lead germanium sulphoantimonite**. P. Groth regarded it as being a compound of lead orthosulphogermanate, Pb_2GeS_4 , lead orthosulphoantimonite, and silver and lead sulphides. Morphologically but not chemically, it is related with teallite, for the rhombic crystals of teallite have the axial ratios $a : b : c = 0.93 : 1 : 1.31$; and those of ultrabasite, $0.988 : 1 : 0.462$. The sp. gr. is 6.026, and the hardness 5. A. Frenzel obtained from Poopo, Bolivia, a massive dark grey mineral which he called **cylindrite**—or rather *kylindrit*—in allusion to its occurrence in cylindrical forms which separate under press. into distinct shells or folia which like graphite are difficult to pulverize. A. Frenzel analyzed the

mineral and represented his results by the formula $6\text{PbS}\cdot\text{Sb}_2\text{S}_3\cdot 6\text{SnS}$, **lead sulpho-stannitantimonite**, or $3\text{PbS}\cdot\text{Sb}_2\text{S}_3 + 3(\text{PbS}\cdot 2\text{SnS}_2)$; G. T. Prior represented his analysis by $3\text{PbSnS}_2\cdot\text{SnFeSb}_2\text{S}_3$; and P. Groth regarded it as a salt of sulpho-stannous acid $\text{Hs}-\text{Sn}\equiv\text{S}_3\equiv\text{Sn}-5\text{H}$. C. Winkler found that it contained germanium. The sp. gr. is 5.42; and the hardness between 2 and 3. W. W. Coblenz and H. Kohler found that cylindrite is photoelectrically sensitive for spectral radiations of the highest intensity. The mineral is not attacked by cold acid; it is gradually dissolved by hot hydrochloric acid; and hot nitric acid decomposes it with the separation of sulphur, and oxides of tin and antimony. The mineral is related to plumbostannite; and to **franckeite**—named after C. and E. Francke—by A. Stelzner, who obtained it at Animas, Bolivia, where it is locally known as *Ulcetaria*. The mineral occurs massive with an imperfect radiated and foliated structure, and in part as reniform aggregates of a dark grey or black colour. Analyses reported by A. Stelzner corresponded with $5\text{PbS}\cdot 2\text{SnS}_2\cdot\text{Sb}_2\text{S}_3$, or $\text{Pb}_5\text{Sn}_2\text{Sb}_2\text{S}_{12}$; G. T. Prior gave formulæ ranging from 2.5 to $3\text{PbSnS}_2\cdot\text{Pb}_2\text{FeSb}_2\text{S}_3$. G. Lincio found 0.10 per cent. of germanium to be present. The hardness is between 2 and 3; and the sp. gr. 5.88–5.92. It behaves like cylindrite towards acids. Another related mineral **plumbostannite** was obtained by A. Raimondi from Mohs, Peru. C. Hintze assigned to it the formula $(\text{Fe},\text{Zn})_2\text{Pb}_2\text{Sn}_2\text{Sb}_2\text{S}_{11}$, and this formula is used by P. Groth. It is an amorphous, granular, grey mineral with a sp. gr. 4.5, and hardness 2. A. de Gramont examined the spark spectrum. The mineral was also found by C. Ochsensius along with franckeite; and A. Stelzner regards it as an admixture of franckeite and pyrite.

H. Pélabon²⁸ said that the f.p. curve of mixtures of bismuth monosulphide and antimony trisulphide has three straight lines inclined at angles which corresponds to *bismuth orthosulphoantimonite*, $3\text{BiS}\cdot\text{Sb}_2\text{S}_3$, or $\text{Bi}_3(\text{SbS}_3)_2$; and *bismuth metasulphoantimonite*, $\text{BiS}_4\text{Sb}_2\text{S}_3$, or $\text{BiSb}_4\text{S}_{13}$. This is probably all wrong because the trisulphides of these elements were found by Y. Takahashi to form a complete series of mixed crystals. At the m.p., bismuth trisulphide is dissociated to the extent of about 1.5 per cent.

I. Pouget²⁹ prepared **manganese orthosulphoantimonite**, $\text{Mn}_3(\text{SbS}_3)_2$, by adding a manganese salt soln. to a soln. of a mol of potassium orthosulphoantimonite in 10 litres of water; and also by treating the potassium manganese salt with water. The product is a dirty rose colour, and readily oxidized in air. If a conc. soln. of the potassium salt is used, the precipitate rapidly forms crystalline **potassium manganese orthosulphoantimonite**, KMnSbS_3 , which is decomposed by water as just indicated. I. Pouget also obtained **ferrous orthosulphoantimonite**, $\text{Fe}_3(\text{SbS}_3)_2$, by the action of a ferrous salt on a dil. soln. of potassium orthosulphoantimonite; with conc. soln., an impure *potassium ferrous orthosulphoantimonite*, KFeSbS_3 , is formed.

P. Berthier³⁰ observed a mineral occurring at Chazelle, Pay-de-Dôme, which corresponded with an impure ferrous metasulphoantimonite, and he named it *haidingerite*. This term, however, having been previously employed by E. Turner for a native arsenate, was replaced by W. Haidinger by **berthierite**. P. Groth called it *Eisenantimonglanz*. For the three varieties obtained by P. Berthier, N. G. Nordenskjöld introduced the names *anglarite*, $\text{FeS}\cdot\text{Sb}_2\text{S}_3$; *chazellite*, $3\text{FeS}\cdot 2\text{Sb}_2\text{S}_3$; and *martocirite*, $3\text{FeS}\cdot 4\text{Sb}_2\text{S}_3$. Analyses were reported by C. F. Rammelsberg, C. von Hauer, A. Hofmann, J. von Pettko, and P. Berthier: J. Loczka found that some varieties of berthierite are contaminated with stibnite. In agreement with the observations of J. D. Dana, F. L. Stillwell found that the best representative formula is $\text{Fe}(\text{SbS}_2)_2$, or **ferrous metasulphoantimonite**. P. Berthier obtained a product of the same composition by fusing together the correct proportions of the constituent sulphides; and he added that the two sulphides form

FIG. 63.—Freezing-point Curves of the System: Sb_2S_3 -BiS.

solid soln. in all proportions. The mineral occurs in dark grey or brown, plumose, fibrous, or granular masses, and in elongated, prismatic crystals with a rather indistinct longitudinal cleavage. J. L. C. Schröder van der Kolk made observations on the colour. J. von Pettko gave 4.043 for the sp. gr.; A. Breithaupt, 4.03–4.042; A. Hofmann, 3.89–3.91; and C. F. de Landero, 4.062. The hardness is 2–3. H. Fischer found some varieties fuse readily, others with difficulty. A. de Gramont examined the spark spectrum. Berthierite dissolves readily in hydrochloric acid, giving off hydrogen sulphide.

W. Skey described a mineral from Richmond Hill, New Zealand; and he accordingly called it **richmondite**. The black mineral may occur massive, and crystalline. It is represented as a **cuprous lead ferrous enneasulphodiantimonite**, $(\text{Pb}, \text{Cu}_2, \text{Ag}_2, \text{Zn}, \text{Fe})_6 \text{Sb}_2 \text{S}_9$. The sp. gr. is 4.317; and the hardness 4.5. The mineral comuccite from St. Georges, Sardinia, has the composition $18\text{PbS} \cdot 7\text{FeS} \cdot 15\text{Sb}_2 \text{S}_3$. It was described by P. Comucci. Its sp. gr. is 5.65; and it is probably a member of the pligionite group of solid soln. The history of the mineral *jamesonite* has been previously discussed. Analyses of jamesonite were reported by J. Antipoff, F. Boricky, F. P. Dunnington, F. A. Genth, C. Guillemain, W. Haidinger, J. Loczka, V. Novarese, A. Pichler, A. Raimondi, C. F. Rammelsberg, G. vom Rath, H. Rose, F. von Schaffgotsch, E. V. Shannon, L. J. Spencer, A. Stelzner, and C. E. Wait. For many years jamesonite was represented by the formula $2\text{PbS} \cdot \text{Sb}_2 \text{S}_3$, but, according to L. J. Spencer, it is best to reserve this formula for plumosite, and to represent the analyses made in material with characteristic and well-defined physical properties—*e.g.* basal cleavage—by the formula $7(\text{Pb}_{0.8}\text{Fe}_{0.2})\text{S} \cdot 4\text{Sb}_2 \text{S}_3$; while J. Loczka, and W. T. Schaller represented jamesonite by the formula $4\text{PbS} \cdot \text{FeS} \cdot 3\text{Sb}_2 \text{S}_3$ **lead ferrous tetradecasulphohexantimonite**, V. Novarese agreed that the iron of jamesonite is not to be regarded as an impurity, and added that the mineral may be regarded as a mixture of boulangerite and berthierite. There is no evidence in favour of this assumption. The mineral may occur in compact and fibrous masses coloured dark lead-grey, or steel-grey; usually, however, it occurs in acicular crystals, which, according to F. Slavik, are monoclinic, with axial ratios $a : b : c = 0.8316 : 1 : 0.4260$, and $\beta = 91^\circ 24' 5''$; and, according to S. Stevanovic, $0.9223 : 1 : 0.5218$. The crystals show basal cleavage. J. L. C. Schröder van der Kolk made some observations on the colour. H. Rose gave for the sp. gr. 5.560; F. von Schaffgotsch, 5.616; W. Haidinger, 5.601; C. F. Rammelsberg, 5.700; A. Stelzner, 5.540; F. A. Genth, 6.467; A. Pilcher, 5.20; and L. J. Spencer, 5.480. J. J. Saslawsky calculated the contraction occurring during the formation of the mineral from its components. The hardness is 2.5. W. W. Coblenz and H. Kohler found that jamesonite is photoelectrically sensitive for spectral radiation of the highest intensities. E. E. Fairbanks found the dielectric constant is less than 81. H. C. Bolton observed that the mineral is feebly attacked by a boiling soln. of citric acid. Jamesonite may be weathered to antimony ochre. W. Maucher, and J. R. Elum made some observations on the weathering of the mineral. E. V. Shannon³¹ described a kind of *silver-jamesonite* occurring in Owyhee County, U.S.A. It was called **owyheelite**; and the analysis corresponds with $(\text{Ag}, \text{Cu})_2 \text{S} \cdot 5(\text{Pb}, \text{Fe})\text{S} \cdot 3\text{Sb}_2 \text{S}_3$; or, according to E. T. Wherry and W. F. Foshag, $2\text{Ag}_2 \cdot \text{S} \cdot 8\text{PbS} \cdot 5\text{Sb}_2 \text{S}_3$; W. F. Foshag gave $\text{Ag}_2 \text{S} \cdot 5\text{PbS} \cdot 3\text{Sb}_2 \text{S}_3$.

L. G. Eakins³² described the occurrence at the Domingo mine, Colorado, of a mineral which he called *warrenite*—after E. R. Warren—and P. Groth *domingite*. It appears as an aggregate of acicular crystals, forming matted, wool-like masses, locally called mineral wool. Its composition approximates $3\text{PbS} \cdot 2\text{Sb}_2 \text{S}_3$. W. T. Schaller said that the crystals may be both brittle and flexible. H. Sommerlad obtained what he regarded as artificial warrenite, of sp. gr. 5.632, by melting a mixture of lead chloride and antimony trisulphide; and of sp. gr. 5.602, by melting together a mixture of lead and antimonious sulphides; and D. Iitsuka observed that **lead orthosulphotetrantimonite**, $\text{Pb}_2 \text{Sb}_4 \text{S}_9$, is formed below 610° , and that it has a transition point from the α - to the β -forms at 510° . He regards the α -form

as artificial warrenite. L. J. Spencer showed that warrenite is probably identical with jamesonite; and W. T. Schaller that it is probably a mixture of jamesonite and zinckenite in the proportions 2:3. G. Lehmann described what he called *Zundererz*, or *Bergzunderz-tinder ore*—occurring at Andreasburg and Clausthal, Harz. It is a soft, dirty-red mineral resembling tinder. It has been likened to kermesite, but, according to A. Bornträger, B. Rösing, and O. Luedecke, it is an impure jamesonite or feather ore. B. Rösing represented the tinder ore from Clausthal as *lead sulphodiantimonotetrantimonate*, $Pb_4Sb_6S_{17}$, or $4PbS \cdot Sb_2S_3 \cdot 2Sb_2S_5$. The *Bleischimmer* analyzed by C. H. Pfaff, and J. Antipoff, was called by J. J. N. Huot *pfaffite*. It is possibly a mixture of galena and antimony ochre.

W. Guertler and H. Schack³³ found that molybdenum dissolves in fused antimony trisulphide with the separation of an eq. amount of antimony, forming what appears to be **molybdenum sulphoantimonite**. W. Guertler studied the ternary system Mo-Sb-S, but obtained no *molybdenum sulphoantimonite*.

I. Pouget prepared **cobalt orthosulphoantimonite**, $Co_3(SbS_3)_2$, by the action of a cobalt salt on a dil. soln. of potassium orthosulphoantimonite; if conc. soln. be used, **potassium cobalt orthosulphoantimonite**, $KCoSbS_3$, is formed. Cobalt orthosulphoantimonite is very easily oxidized. By a similar process, I. Pouget prepared **nickel orthosulphoantimonite**, $Ni_3(SbS_3)_2$; and **potassium nickel orthosulphoantimonite**, $KNiSbS_3$.

W. Guertler and H. Schack³⁴ made a partial study of the ternary system Ni-Sb-S. J. C. Ullmann described a mineral occurring on the Jungfrau, at Gosensbach, Westphalia, and named it *Nickelspiessglaserz*; J. F. L. Hausmann called it *Nickelspiessglanzerz*. Many analogous terms were also employed by other writers, until J. Fröbel applied to it the term **ullmannite**—after J. C. Ullmann. Analyses were reported by J. C. Ullmann, M. H. Klaproth, J. F. John, J. F. L. Hausmann, H. Rose, H. Laspeyres, T. Haeger, C. F. Rammelsberg, V. R. von Zepharovich, P. Jannasch, F. Ullik, M. von Lill, and S. Traverso. The results fit the formula $NiSbS$ —**nickel sulphoantimonide**—fairly well. The antimony may be replaced in part by arsenic, and, in the extreme case may approximate to gersdorffite, $NiAsS$.

Thus, V. R. von Zepharovich's mineral *corynite*, $Ni(As,Sb)S$ —from *κορύνη*, a club—is a *nickel sulphoarsenoantimonide*, occurring in silver-white or steel-grey, cubic crystals at Olsa, Carinthia, has 13.45 per cent. of arsenic and 37.85 per cent. of antimony. W. Guertler made a partial study of the ternary system: Ni-Sb-S. There are four binary compounds, Ni_5Sb_2 , $NiSb$, Ni_3S_2 , and NiS , that melt unchanged, and one ternary compound, $NiSbS$, whose zone of stability is indicated in Fig. 64. There are indications of a ternary eutectic consisting of NiS and $NiSbS$. N. S. Kurnakoff and Y. Posternak melted a mixture of barium chloride with 10 per cent. of sodium chloride, in a graphite crucible; added nickel antimonide; raised the temp. to 200°, and added antimony trisulphide. On slowly cooling the mass, small cubes and dodecahedra were formed.

Ullmannite is steel-grey or silver-white; it occurs in masses with a granular structure or in cubic crystals which, according to C. Klein, may be pyritohedral; according to N. S. Kurnakoff and Y. Posternak, dodecahedral; or, according to V. R. von Zepharovich, tetrahedral. The cubic cleavage is perfect. The crystals were examined by A. Breithaupt, K. Mieleitner, G. Rose, E. F. Glocker, M. Hörnes, G. A. Kennigott, H. A. Miers, A. Russell, and J. Rumpf. M. L. Huggins studied the electronic and lattice structures. L. S. Ramsdell's X-radiograms corresponded with a structure like that of pyrite with the Sb-atoms occupying alternate positions with the S-atoms. The Sb-atoms occupy the same relative positions on the

FIG. 64.—The Ternary System: Ni-Sb S.

diagonals of the small cubes as do the S-atoms of pyrite, but with the Sb-atoms a little closer and the S-atoms a little farther from the vacant corners of the small cubes than do the S-atoms of pyrite. The length of the side of the unit cube is 5.91 Å. For the sp. gr. J. C. Ullmann gave 6.333–6.833; A. Breithaupt, 6.281–6.331; P. Jannasch, 6.625–6.883; V. R. von Zepharovich, 6.72; N. S. Kurnakoff and Y. Posternak, 6.62 at 20°; and M. von Lill, 6.63; the best representative value is 6.72. The hardness is about 5. H. Fizeau gave 0.041112 for the coeff. of linear expansion. J. Joly found sublimation occurs at 185°–285°. N. S. Kurnakoff and Y. Posternak said that it melts at 758° without decomposition. A. de Gramont examined the spark spectrum of ullmannite and corynite; and F. Beijerinck found the electrical conductivity is good—better than that of pyrite; T. W. Case said that the corynite is a poor conductor, but the resistance of ullmannite is less than a megohm; and that insulation has no measurable effect in either case. E. T. Wherry found the crystals of ullmannite to be poor radio-detectors. The mineral is soluble in warm nitric acid with the separation of sulphur and antimony oxide; it dissolves in aqua regia with the separation of sulphur; and is but little attacked by hydrochloric acid. E. F. Smith found that the mineral is attacked by sulphur monochloride, and that decomposition is complete at about 180°.

E. F. Pittman³⁵ described **cobalt nickel sulphoantimonide**, approximating CoNiSbS, which occurs at Willyama, New South Wales—hence the name **willyamite**. It occurs in tin-white or steel-grey masses or cubic crystals. The cubic cleavage is perfect. M. L. Huggins studied the electronic and lattice structures. The hardness is 5.5; and the sp. gr. 6.87. F. Sandberger described a mineral from Wolfach, Baden, and he called it **wolfachite**. Its composition approximates to **nickel bisulphoarsenoantimonide**, Ni(Sb,As,S)₂. It occurs in silver-white or tin-white columnar, or radiating aggregates of rhombic crystals. M. L. Huggins studied the electronic and lattice structures. F. Sandberger, and T. Petersen found the sp. gr. to be 6.372; and the hardness, 4–5.3. F. Beijerinck said that wolfachite is a good electrical conductor.

§ 25. The Higher Sulphides of Antimony

According to J. J. Berzelius,¹ and H. Rose, when hydrogen sulphide is passed through a soln. of antimony trioxide, or potassium antimonite in hydrochloric acid, **antimony tetrasulphide**, Sb_2S_4 , is formed; and M. Websky used a tartaric acid soln. of fused antimony trisulphide and potassium hydrosulphate. J. J. Berzelius obtained it by adding an acid to a soln. of antimony tetroxide in potassium hydrosulphide. J. J. Berzelius said that when the yellowish-red powder is heated, it loses sulphur, forming grey antimony trisulphide; and when treated with hydrochloric acid, it gives off hydrogen sulphide and forms antimony trichloride with the deposition of sulphur. H. Capitaine found that it produces a yellow soln. when treated with aq. ammonia.

O. Bosek reported that the tetrasulphide is formed as a red, crystalline powder when a soln. of potassium henachlorohypoantimonate is treated with hydrogen sulphide; and by the action of hydrogen sulphide on a hydrochloric acid soln. of antimony trioxide oxidized with potassium dichromate. T. Wilm reported it to be formed by treating antimony pentasulphide with carbon disulphide; and B. Brauner, by adding insufficient hydrogen sulphide for precipitating the antimony from a soln. of potassium metantimonate, adding ammonium chloride, and extracting the orange-red precipitate with carbon disulphide. There is nothing here proving that the alleged tetrasulphide is a chemical individual; it may be a mixture of the tri- and penta-sulphides. F. Kirchhof takes the contrary view and holds that while the tetrasulphide has a real existence, the pentasulphide *existiert überhaupt nicht*. According to F. Kirchhof, the latter possibility is disproved in the case of the tetrasulphide obtained by the action of dil. hydrochloric or sulphuric acid on the so-called zinc orthosulphoantimonate. $\text{Zn}_3(\text{SbS}_4)_2 : \text{Zn}_3\text{Sb}_2\text{S}_8 + 6\text{HCl} = \text{Sb}_2\text{S}_5 + 3\text{ZnCl}_2 + 3\text{H}_2\text{S}$, for the product, after drying at 100° , contains no free sulphur removable by extraction with carbon disulphide, and the analysis agrees with Sb_2S_4 . The tetrasulphide is also formed in the reaction $\text{Na}_3\text{SbS}_4 + \text{SbCl}_3 = \text{Sb}_2\text{S}_4 + 3\text{NaCl}$. The alleged orthosulphoantimonate is said to be a compound of trivalent, not quinquevalent antimony; either

He assumes that the tetrasulphide is constituted with ter- or quinque-valent antimony:

but added that it is *unwahrscheinlich* that quinquevalent antimony is present because of the formation of hydrogen disulphide from two mols. of sodium orthosulphoantimonate. The closed ring structure is supposed to account for the colour. This subject was discussed by L. M. Currie. For the action of heat, *vide infra*, the pentasulphide.

Basil Valentine² frequently speaks of a red antimony sulphide which, in some cases, may have been **antimony pentasulphide**, Sb_2S_5 , and, in other cases, the red trisulphide. In 1603, J. Quercetanus, and M. Ettmüller obtained a golden sulphide—*sulphur auratum*—by adding an acid to a soln. of antimony trisulphide and alkali sulphide. R. J. Glauber also obtained a similar product which he called *panacea antimonialis*, or *sulphur purgans universale* in allusion to its medicinal properties. This substance received many other names from the alchemists—e.g. *Saffran Spiessglanz*, *liver of spiesglance*, *golden antimony sulphide*, *sulphur antimonii auratum*, etc. The name *golden antimony sulphide* originally referred to a mixture of antimony sulphides, but it is now applied indiscriminately to the tri- or penta-sulphide or to a

mixture of both. Manufacturers of the golden sulphide for use in the rubber industry try to obtain as large a proportion of the pentasulphide as possible. The commercial golden sulphides vary in colour from a golden yellow to a deep orange, and in composition, from nearly pure trisulphide to one containing a relatively high proportion of the pentasulphide. The use of the golden sulphide is almost entirely confined to the rubber industry for producing the familiar orange-red colour. In the process of vulcanization, the colour is maintained in the presence of sulphur—except in the presence of certain impurities. Some *antimony vermilion*s, prepared by J. H. Long by the interaction of sodium thiosulphate and antimony trichloride, consist of the trisulphide either alone or mixed with some oxide.

J. J. Berzelius,³ and H. Rose prepared antimony pentasulphide by the action of hydrogen sulphide on hydrated antimony pentoxide suspended in water, or on a hydrochloric acid, or tartaric acid soln. of the pentoxide. Some trisulphide is usually formed at the same time. H. Rose, O. Bosek, B. Brauner, G. C. Wittstein, R. Bunsen, A. Classen and co-workers, T. Wilm, O. Klenker, J. Thiel, and F. Neher have made observations on this subject—*vide supra*, antimony trisulphide, and also the analytical reactions of antimony. According to O. Klenker, the precipitate obtained on passing a stream of hydrogen sulphide into a moderately conc. alkaline soln. of a quinquevalent compound of antimony consists of a mixture of antimony trisulphide and sulphur (pure antimony trisulphide remaining on extraction with carbon disulphide). Neutral or acid soln. give a precipitate composed of a mixture of the two sulphides and free sulphur, the largest proportion of pentasulphide being formed from a soln. containing 12 per cent. of free hydrochloric acid. As the quantity of free acid further increases, the proportion of pentasulphide formed decreases until from a soln. containing 27 per cent. of free hydrochloric acid, none is precipitated. The analyses of L. J. Thénard, P. L. Geiger, and L. A. Buchner showed that the dried precipitate obtained by the action of the gas on a soln. of the pentachloride, gives off water when heated. H. Rose said that the precipitate can be thoroughly dried at 100°, while G. C. Wittstein said that the precipitate dried at that temp. still retains less than one per cent. of water; R. Bunsen said that the drying is complete at 110°; and O. Bosek, at 105°–107°. The analyses of T. Wilm, G. C. Wittstein, R. Bunsen, O. Bosek, J. J. Berzelius, H. Rose, and L. M. Currie, correspond with the formula Sb_2S_5 . The golden sulphide may contain, as A. Short and F. H. Sharpe, and F. Kirchhof suggest, no sulphide higher than the tetrasulphide; or, as O. Klenker, and D. F. Twiss suggest, it may be a solid soln. or mixture of the tri- and penta-sulphides. L. Prunier said that the pentasulphide is formed by fusing antimony trisulphide with the necessary amount of sulphur—but this conclusion does not agree with the results indicated in Fig. 56.

When a soln. of alkali or alkaline earth sulphoantimonate is treated with a strong acid, the resulting precipitate has the composition of the pentasulphide. K. Schlippe, A. Sartorius, N. E. Wilson, F. Jahn, and W. Artus treated a sulphoantimonate with sulphuric acid, and M. Bertsch and M. Harmsen, with a soln. of antimony trichloride. L. M. Currie found that the product obtained by treating a sulphoantimonate with an acid is a mixture of sulphur, and a solid soln. of sulphur and antimony tetrasulphide. The upper limiting composition of this solid soln. corresponds with $Sb_2S_4.66$. Various old recipes for preparing the golden sulphide are mainly concerned with the preliminary formation of a soln. of the sulphoantimonate from antimony trisulphide. Thus, E. Mitscherlich, J. F. A. Göttling, and J. F. Westrumb boiled the trisulphide with a mixture of alkali-lye and sulphur; E. Mitscherlich, F. Musculus, and G. Abesser used alkali carbonate and lime-water; and A. Duflos obtained the sulphoantimonate by the action of a soln. of alkali polysulphide on powdered antimony. In another group of processes, the soln. of alkali sulphoantimonate is obtained by dissolving the crude alkali sulphoantimonate prepared in the dry way. Thus, C. F. Bucholz, P. L. Geiger, and J. B. Trommsdorff heated antimony trisulphide with a mixture of alkali sulphate and charcoal; W. A. Lampadius, and J. B. Trommsdorff used a mixture of the trisulphide with

barium sulphate and charcoal; E. Mitscherlich, J. J. Berzelius, G. W. Mullen, J. C. Wieglieb, J. F. Westrumb, A. L. Stark, and W. S. C. Hirsching, a mixture of alkali carbonate, etc., antimony trisulphide, and sulphur. According to T. Wilm, if the precipitate of the colloidal pentasulphide be washed, until the sodium sulphate is removed, it is deflocculated and passes through the filter-paper. A. Grein, therefore, recommended washing the precipitate with a mixture of alcohol and water (1 : 4) until the filtrate is no longer acid, and no longer contains sulphates or chlorides.

T. Wilm said that the precipitate may contain a little more sulphur than corresponds with the pentasulphide, owing to the decomposition of some hydrogen sulphide. O. Klenker found that the pentasulphide is readily converted into the black trisulphide at 150° in an air-bath, and at 230° oxidation occurs. Organic solvents boiling below 100° have no effect on antimony pentasulphide. Boiling alcohol, benzene, and chloroform extract as much sulphur from the pentasulphide as carbon disulphide does, but in the latter case less time is required for the extraction. Boiling oil of turpentine causes a partial decomposition of the pentasulphide. The precipitate formed on acidifying sodium sulphoantimonate consists of a mixture of sulphur, and antimony tri- and penta-sulphides. F. Kirchhof found that analyses of the purest golden antimony sulphide contain about 8 per cent. of free sulphur which can be extracted with acetone or carbon disulphide, and that the residue has the composition Sb_2S_4 . He therefore maintained that antimony pentasulphide does not exist; and that the alleged pentasulphide is really a mixture of the tetrasulphide (*q.v.*), and 8 per cent. of sulphur. The varieties of commercial *sulphur auratum* containing less than 8 per cent. of free sulphur extractable by solvents have probably been obtained by the reaction: $\text{Na}_3\text{SbS}_4 + \text{SbCl}_3 = 3\text{NaCl} + \text{Sb}_2\text{S}_4$.

F. V. von Hahn prepared fairly stable **colloidal solutions** of antimony pentasulphide by the hydrolysis of alkali antimony thiosulphate: $2\text{Na}_3\text{Sb}(\text{S}_2\text{O}_3)_3 = \text{Sb}_2\text{S}_5 + 3\text{Na}_2\text{SO}_4 + 3\text{SO}_2 + \text{S}$. A 0.5 per cent. soln. of sodium antimony thiosulphate is kept until it commences to turn yellow and to show a definite Tyndall cone; it is then placed in a dialyzer and washed with warm distilled water. After several hours' dialysis, the soln. has taken on a deep red colour. The main point to be observed in the preparation is the rapid removal of the alkali sulphate. In the presence of sodium chloride the sol cannot be prepared, nor can a sol having a greater molecular conc. than 0.4 be obtained. Sols of one-tenth this conc. are stable for a few hours only. The sols prepared from the sodium salt are more stable than those prepared from either lithium or potassium antimony thiosulphate. M. E. Wolvekamp obtained colloidal soln. with the pentasulphide associated with protein.

Antimony pentasulphide appears as a dark brown, yellowish-brown, or a fiery orange-red powder, with a feeble smell, and sweetish taste. T. Wilm said that when triturated the powder is electrified. H. Rose, L. Heffter, and T. Paul found that when the pentasulphide is heated to 120°, it loses one per cent. of sulphur; at 150°, about 2 per cent.; and at 170°, it gradually forms grey antimony trisulphide. This change occurs rapidly in a current of carbon dioxide at 200°–230°. O. Klenker noticed that there is an appreciable decomposition of the pentasulphide at 85°–90°, and the subject was discussed by F. de Bacho, V. Zani, and D. W. Luff and B. D. Porritt, while L. M. Currie showed that the main reaction which occurs when the pentasulphide is heated to about 110° is: $\text{Sb}_2\text{S}_5 = \text{Sb}_2\text{S}_4 + \text{S}$; and $\text{Sb}_2\text{S}_4 = \text{Sb}_2\text{S}_3 + \text{S}$ between 110° and 150°; while above 150°, the reaction in air is largely oxidation, and in the absence of air sublimation of sulphur, and a change in the physical properties of the trisulphide. O. Stelling studied the X-ray absorption spectrum with the K-series. R. Robl observed no fluorescence when the pentasulphide is exposed to ultraviolet light. L. Heffter observed that the pentasulphide is reduced when heated in **hydrogen**. T. Wilm found that when dried at 100°–110° for some hours exposed to **air**, it is partially oxidized and loses weight appreciably owing to

the volatilization of the oxide. O. Bosek said that it can be dried at 105°–107°, and R. Bunsen, at 110°, without decomposition. A. Classen observed a blackening of the pentasulphide at 110°, and this was attributed by B. Unger to the presence of a trace of oxide. E. Pollacci, F. J. Otto, and F. Jahn found that the moist pentasulphide rapidly oxidizes in air, but only slowly if the pentasulphide be dry. The resulting antimony trioxide can be extracted with tartaric acid. A. Vogel observed that when heated in air, it burns with a visible flame. An ammoniacal soln. of **hydrogen dioxide** was found by A. C. Classen and O. Bauer to oxidize the pentasulphide incompletely.

J. S. F. Pagenstecher showed that the pentasulphide is decolorized and decomposed by an aq. soln. of **chlorine**; and P. L. Geiger, that conc. **hydrochloric acid** at ordinary temp. colours the pentasulphide grey owing to the formation of the grey trisulphide, and the separation of sulphur. J. M. Scherer showed that hydrochloric acid of sp. gr. 1.12 dissolves the pentasulphide with the separation of sulphur; and A. Classen and O. Bauer's observations agreed with: $Sb_2S_5 + 6HCl = 2SbCl_3 + 3H_2S + 2S$, although G. O. Wittstein obtained less sulphur than corresponded with this equation. The conversion of the pentasulphide into trisulphide by exposure to light while suspended in dil. hydrochloric acid containing hydrogen sulphide was observed by B. Brauner, and a similar conversion by heating the pentasulphide in dil. hydrochloric acid alone or in the presence of chromic acid was observed by O. Bosek, and B. Brauner. O. Ruff found that **sulphuryl chloride** transforms the pentasulphide into pentachloride.

According to P. L. Geiger, 100 parts of cold, dil. aq. **ammonia** dissolve 2 parts of antimony pentasulphide leaving only a slight residue which dissolves as the liquid is warmed. If the proportion of sulphur is too small, kermes is left undissolved, and if too great, sulphur. Sometimes a little antimony trioxide remains undissolved. When the yellow ammoniacal soln. is treated with acids, the pentasulphide is again precipitated without the evolution of hydrogen sulphide. When the ammoniacal soln. is boiled, H. Capitaine observed that a mixture of sulphur and antimony trisulphide is precipitated, but precipitation does not occur with potassium hydrocarbonate. C. F. Rammelsberg said that the ammoniacal soln. contains ammonium sulphoantimonate. J. S. F. Pagenstecher, and T. Wilm observed that the pentasulphide is decomposed by **nitric acid**. E. Mitscherlich found that a boiling soln. of **carbon disulphide** extracts two gram-atoms of sulphur leaving behind a mol of antimony trisulphide. T. Wilm said that the amount of sulphur extracted from the pentasulphide depends on the mode of preparation, thus the pentasulphide obtained from sodium sulphoantimonate yielded 6–8 per cent. of sulphur, while that made from hydrogen sulphide and antimony pentachloride gave up about 14 per cent. of sulphur—the calculated amount for one gram-atom is 8 per cent., and for 2 gram-atoms, 16 per cent. F. Kirchhof's observations are indicated above. C. F. Rammelsberg extracted 2 per cent. of sulphur from the pentasulphide obtained from hydrogen sulphide and antimonic acid by boiling 15 minutes; A. Classen extracted 9.63 per cent. of sulphur from the pentasulphide obtained from sodium sulphoantimonate; and B. Unger, never more than 5.7 per cent. In these cases, the pentasulphide treated by the solvent may have originally contained free sulphur. C. O. Weber stated that boiling carbon disulphide decomposes the pentasulphide, but, added W. Esch and F. Balla, this occurs only when impure carbon disulphide is employed. R. Ditmar said that if the extraction with carbon disulphide is of long duration, some pentasulphide may be decomposed; A. van Rossem and P. Dekker attributed the partial decomposition of the pentasulphide to the action of this solvent. A. Hutin also said that the cold solvent has no action on the pentasulphide, but the boiling solvent decomposes the pentasulphide to tetrasulphide and sulphur. There is no suggestion that the boiling carbon disulphide acts chemically, and the decomposition is considered to be due to the thermal decomposition of the pentasulphide. If so, then solvents of sulphur with a higher b.p.—*e.g.* benzene, or acetone, as recommended by C. O. Weber, and

A. Hutin—should give a worse result than that attributed to carbon disulphide. A. Dubosc, indeed, stated that there is little likelihood of the pentasulphide decomposing at the b.p. of carbon disulphide, but at 130°–135°, the pentasulphide is reduced to the trisulphide. B. D. W. Luff and B. D. Porritt found that purified carbon disulphide does not decompose the pentasulphide at the boiling temp. This is in agreement with the observation of O. Klenker, who showed that the pentasulphide is not decomposed by boiling carbon disulphide; but there is a slow separation of sulphur at 85°–90°. Consequently, boiling water may cause the liberation of sulphur; but the pure pentasulphide is not appreciably affected by organic solvents boiling below 85°; and E. Mitscherlich found boiling turpentine extracts sulphur. L. M. Currie, for instance, found that cold carbon disulphide, chloroform, carbon tetrachloride, benzene and toluene have practically no effect on the pure pentasulphide; at their b.p., there is rather more action—particularly with carbon disulphide, for boiling acetone has less effect and yet its b.p. is higher. A. C. Vournasos observed that at 400° antimony trisulphide is reduced by **sodium formate** to antimony and hydrogen sulphide. H. Rose found that the pentasulphide is reduced by fused **potassium cyanide**, forming a little sulphoantimonite—*vide supra*, antimony trisulphide.

P. L. Geiger said that a cold aq. soln. of alkali hydroxide completely dissolves antimony pentasulphide; and F. Jahn added that the soln. in potash-lye is at first transparent, but furnishes a crystalline precipitate of potassium antimonate if allowed to stand overnight. E. Mitscherlich, C. F. Rammelsberg, and W. Feit and C. Kubierschky represented the reaction: $4\text{Sb}_2\text{S}_5 + 18\text{NaOH} = 5\text{Na}_3\text{SbS}_4 + 3\text{NaSbO}_3 + 9\text{H}_2\text{O}$, and the sodium metantimonate is precipitated. According to C. F. Rammelsberg, the filtrate from the soln. in potash-lye gives a brown precipitate of sulphoantimonate when treated with acids; and when treated with acids it gives off hydrogen sulphide and deposits antimony pentasulphide. A cold soln. of **potassium carbonate** does not sensibly affect antimony pentasulphide, but, on boiling, carbon dioxide is evolved and the liquor behaves like the soln. in potash-lye. A soln. of **barium or strontium hydroxide** behaves like potash-lye, but a greater proportion of antimonate is precipitated. When immersed in an aq. soln. of **silver nitrate**, the pentasulphide is coloured brown, and on boiling, it is blackened; a similar result is obtained with a soln. of **copper sulphate**. H. Schiff said that **stannous chloride** is without action; and with **mercurous chloride** the action resembles that with antimony trisulphide (*q.v.*).

§ 26. The Sulphoantimonates

Antimony pentasulphide reacts with metal sulphides, forming a series of **sulphoantimonates**, analogous to the sulpharsenates (*q.v.*). Many of these salts occur in nature. K. Schlippe,¹ E. Donath, F. Becker, H. Rose, and C. F. Rammelsberg obtained them by fusing together the component sulphides; C. F. Rammelsberg, and V. Stanek, by dissolving the pentasulphide, or a mixture of the trisulphide and sulphur in soln. of the alkali or alkaline earth sulphides or hydrosulphide—even at a boiling temp. no more is dissolved than corresponds with the formation of the orthosulphoantimonate; C. F. Rammelsberg, by the action of the pentasulphide on soln. of the hydroxides or carbonates; by the action of hydrogen sulphide on soln. of the antimonates; and by double decomposition between the alkali sulphoantimonates and salts of the heavy metals—in some cases the sulphoantimonate is decomposed by the acid formed during the reaction.

The sulphoantimonates of the alkalis and alkaline earths are colourless or yellow; and those of the heavy metals are yellow, orange, brown, or black. The sulphoantimonates of the alkalis can be heated in the absence of air without decomposition, but those of the heavy metals form sulphur and the trisulphide (*q.v.*). When the aq. soln. of the alkali and alkaline earth sulphoantimonates are allowed to stand in air, antimony trisulphide is precipitated, and carbonate and thiosulphate are formed; acids, even carbonic acid, decompose soln. of the sulphoantimonates, separating antimony pentasulphide; the soln. gave no precipitate with the alkali carbonates. A. Duflos found that the salts are decomposed by nitric acid, aqua regia, and potash-lye; they are insoluble in alcohol; and when boiled with powdered antimony they are reduced to sulphoantimonites. L. Storch found that cupric, cadmium, mercuric, and ferrous sulphides dissolve in soln. of the alkali sulphoantimonates. H. Rose said that fused potassium cyanide does not reduce the salts to antimony; and W. Feit and C. Kubierschky, that the aq. soln. is desulphurized by lead hydroxide, forming the antimonate.

V. Stanek² prepared **ammonium orthosulphoantimonate**, $(\text{NH}_4)_3\text{SbS}_4$, by dissolving powdered antimonite and flowers of sulphur in red ammonium sulphide and recrystallizing the product from colourless ammonium sulphide. The salt crystallizes in pale yellow prisms, which, after the removal of the mother-liquor, quickly decompose and become brown, and are easily soluble in water; it is decom-

posed by dil. acids, with the formation of antimony pentasulphide and hydrogen sulphide, and when heated in carbon dioxide yields ammonium sulphide, sulphur, and antimony trisulphide. When heated with antimony pentasulphide in a sealed tube at 150° , it is converted into **ammonium metasulphotetramtimate**, $(\text{NH}_4)_2\text{Sb}_4\text{S}_7$. It is obtained crystalline as the *tetrahydrate* $(\text{NH}_4)_3\text{SbS}_4 \cdot 4\text{H}_2\text{O}$, in aggregates of colourless needles by saturating colourless ammonium sulphide with antimony pentasulphide, adding an equal quantity of ammonium sulphide and then alcohol until a precipitate commences to form; the filtered soln. is then covered with a layer of alcohol and allowed to stand. A. D. Donk also obtained the tetrahydrate from aq. soln., in ethyl alcohol and water, and in aq. ammonia. The solubility is shown in Fig. 65. A. D. Donk also examined the ternary system: $(\text{NH}_4)_3\text{SbS}_4\text{--NH}_4\text{OH--H}_2\text{O}$.

FIG. 65.—The Solubility of Ammonium Orthosulphoantimonate.

A. Brinkmann boiled sulphur with a soln. of lithium orthosulphoantimonite—obtained from a soln. of antimony trisulphide and lithium hydrosulphide—and obtained yellow prisms of *enneahydrated* lithium orthosulphoantimonate, $\text{Li}_3\text{SbS}_4 \cdot 9\text{H}_2\text{O}$, which, when heated, lose water and fuse, forming a brown mass which is soluble in water. The salt becomes covered with a reddish film on exposure to moist air. A. D. Donk's solubility curve is shown in Fig. 66. A. D. Donk obtained crystals of the *decahydrate*, $\text{Li}_3\text{SbS}_4 \cdot 10\text{H}_2\text{O}$, from aqueous-alcoholic soln. ;

FIG. 66.—Solubility Curve of Lithium Orthosulphoantimonate.

FIG. 67.—The Ternary System: $\text{Li}_3\text{SbS}_4\text{--LiOH--H}_2\text{O}$ at 30° .

and from mixtures of lithium sulphoantimonate and hydroxide at 30° . The equilibrium conditions in the presence of lithium hydroxide at 30° are illustrated by the diagram, Fig. 67, for the ternary system: $\text{Li}_3\text{SbS}_4\text{--LiOH--H}_2\text{O}$. At A, Fig. 67, there are two solid phases, $\text{LiOH} \cdot \text{H}_2\text{O}$ and $\text{Li}_3\text{SbS}_4 \cdot 10\text{H}_2\text{O}$.

In 1821, K. Schlippe³ prepared *enneahydrated sodium orthosulphoantimonate*, $\text{Na}_3\text{SbS}_4 \cdot 9\text{H}_2\text{O}$ —which came to be called *Schlippe's salt*—by fusing a mixture of antimony trisulphide, dry sodium sulphate, and charcoal in the proportions 4 : 8 : 2. The cold mass was boiled with water and one part of sulphur. When the filtrate is allowed to stand, it deposits crystals of the salt, and the mother-liquor is thus almost freed from antimony. A. Duflos added that some antimony may be produced during the transformation of the sulphoantimonite into sulphoantimonate. Modifications of the process were described by G. Kohl, J. S. F. Pagenstecher, P. L. Geiger, B. Unger, E. van den Corput, C. Jansen, and J. Kirchner. A. Duflos made the sulphoantimonate by fusing a mixture of sodium sulphate with about six times its weight of carbon, and digesting the boiling cold mass with sodium sulphide for half an hour with six parts of water, 18 of antimony trisulphide, and 3 of sulphide. The filtered soln. deposits about 36 parts of sodium orthosulphoantimonate. Modifications of the process were made by F. C. Buchholz, and F. Jahn. E. Mitscherlich, J. von Liebig, and C. Frederking boiled a mixture of antimony

trisulphide, sulphur, sodium carbonate and lime-water for a couple of hours, filtered, and crystallized. According to A. Sartorius, in the usual method of preparing sodium orthosulphoantimonate, by boiling antimony trisulphide and sulphur with soda-lye for 1½ to 2 hrs., theoretically sodium sulphoantimonate and sodium metantimonate should be formed. If, however, the process is stopped after one-quarter of an hour's boiling, it is found that scarcely any of the antimony trisulphide has been acted on, the reaction that takes place being expressed by $6\text{NaOH} + 4\text{S} = 2\text{Na}_2\text{S} + \text{Na}_2\text{S}_2\text{O}_3 + 3\text{H}_2\text{O}$. To avoid this formation of thiosulphate, the mixture of antimony trisulphide and sulphur is added to the boiling sodium hydroxide soln., in small portions at a time. Under these conditions, the reaction proceeds according to the following equation: $4(\text{Sb}_2\text{S}_3 + 2\text{S}) + 18\text{NaOH} = 5\text{Na}_3\text{SbS}_4 + 3\text{NaSbO}_3 + 9\text{H}_2\text{O}$, and in a shorter time a larger yield of sodium orthosulphoantimonate of a better quality is obtained. In another process, J. von Liebig saturated a soln. of sodium sulphoantimonite with antimony trisulphide and sulphur. L. Prunier melted a mixture of antimony trisulphide and sulphur, and digested the cold mass with a soln. of sodium sulphide. I. Pouget found that a soln. of the sulphoantimonite forms the sulphoantimonate when it is oxidized by exposure to air. B. Unger also prepared the sulphoantimonate by warming at 60°–80° a conc. soln. of sodium sulphide with finely divided antimony, while exposed to air. F. Kirchof melted a mixture of antimony pentasulphide and twice its weight of sodium sulphide with about one

FIG. 68.—Solubility of Sodium Orthosulphoantimonate.

FIG. 69.—The Ternary System: $\text{Na}_3\text{SbS}_4\text{--NaOH--H}_2\text{O}$ at 30°.

per cent. of sulphur. The cold mass was dissolved in hot water, filtered, and cooled for crystallization. A. D. Donk's solubility curve is shown in Fig. 68. A. D. Donk also obtained the enneahydrate from aq. soln. at 0° and 30°, as well as from soln. in alcohol and water, and from soln. in dil. soda-lye at 30°. The equilibrium diagram for the system $\text{Na}_3\text{SbS}_4\text{--NaOH--H}_2\text{O}$ at 30° is shown in Fig. 69. At A, there are two solid phases, $\text{NaOH}\cdot\text{H}_2\text{O}$ and $\text{Na}_3\text{SbS}_4\cdot 9\text{H}_2\text{O}$.

Analyses of the salt made by A. Duflos agreed with $\text{Na}_4\text{Sb}_2\text{O}_7\cdot 8\text{H}_2\text{O}$; and that made by J. von Liebig with $\text{NaSbS}_3\cdot 6\text{H}_2\text{O}$; but the analyses by C. F. Rammelsberg, A. D. Donk, B. Unger, and I. Pouget, correspond with $\text{Na}_3\text{SbS}_4\cdot 9\text{H}_2\text{O}$, or, in the case of K. Schlippe, with $\text{Na}_3\text{SbS}_4\cdot 10\text{H}_2\text{O}$. F. Kirchof regards the so-called sulphoantimonates as salts, not of quinquevalent antimony $\text{S}=\text{Sb}\equiv(\text{SNa})_3$, but as derivatives of compounds of the type $M_m(\text{SbS}_4)_n$, in which, when $m=n$, and M represents Sb, the tetrasulphide is formed. The sodium salt

then becomes $\text{NaS--S--Sb}=(\text{SNa})_2$, and the zinc salt :

Zinc orthosulphoantimonate, $\text{Zn}_2(\text{SbS}_4)_2$.

The colour of the antimony tetrasulphide, and of the sulphoantimonates of the heavy metals, is attributed to the presence of closed ring systems, in the structure of these compounds; the sodium salt, $\text{NaS.Sb}:(18\text{Na})_2$, having no closed ring, is colourless. F. Kirchhof also represents the formation of the sodium salt from sulphur, antimony trisulphide, and sodium sulphide by the equations: (i) $2\text{Na}_2\text{S}+\text{S}_2=2\text{Na}_2\text{S}_2$; (ii) $\text{Sb}_2\text{S}_3+2\text{Na}_2\text{S}_2=\text{Na}_4\text{Sb}_2\text{S}_7$; and (iii) $\text{Na}_4\text{Sb}_2\text{S}_7+\text{Na}_2\text{S}=2\text{Na}_3\text{SbS}_4$. The sodium orthosulphoantimonate, and sodium pyrosulphoantimonate, $\text{Na}_4\text{Sb}_2\text{S}_7$, then have the respective graphic formulæ:

R. Robl observed no fluorescence occurs when the dehydrated salt, Na_3SbS_4 , is exposed to ultra-violet light. M. von Laue studied piezoelectric properties of the crystals of enneahydrated sodium orthosulphoantimonate. The methods of C. F. Rammelsberg, J. von Liebig, P. L. Geiger, and I. Pouget, indicated in connection with sodium orthosulphoantimonate, were also employed for the potassium salt, but the soln. required more concentration by evaporation for crystallization. The analyses of C. F. Rammelsberg, and I. Pouget correspond with the formula for *hemienneahydrated* **potassium orthosulphoantimonate**, $\text{K}_3\text{SbS}_4 \cdot 4\frac{1}{2}\text{H}_2\text{O}$. A. D. Donk obtained the *trihydrate*, $\text{K}_3\text{SbS}_4 \cdot 3\text{H}_2\text{O}$; and the *pentahydrate*, $\text{K}_3\text{SbS}_4 \cdot 5\text{H}_2\text{O}$, from

FIG. 70.—The Solubility Curves of Potassium Orthosulphoantimonate.

FIG. 71.—The Ternary System: K_3SbS_4 - KOH - H_2O at 30° .

a soln. in water, in a mixture of ethyl, alcohol, and water, and in dil. potash-lye; the *hexahydrate*, $\text{K}_3\text{SbS}_4 \cdot 6\text{H}_2\text{O}$, from aq. soln. at 30° ; the *enneahydrate*, $\text{K}_3\text{SbS}_4 \cdot 9\text{H}_2\text{O}$, from a soln. in methyl alcohol and water at 15° ; and the solubility curve is shown in Fig. 70. There is no sign of the hemienneahydrate. The equilibrium diagram with the ternary system, K_3SbS_4 - KOH - H_2O , at 30° is shown in Fig. 71, where the solid phases are the anhydrous salt, the tri- and penta-hydrates, and $\text{KOH} \cdot \text{H}_2\text{O}$. These are the two hydrates as solid phases in equilibrium at the transition point *A*; the trihydrate and the anhydrous salt at *B*; and the anhydrous salt and $\text{KOH} \cdot \text{H}_2\text{O}$ at *C*.

C. F. Rammelsberg, and H. Marbach described enneahydrated sodium orthosulphoantimonate as a pale yellow, almost colourless solid, having cubic, hemihedral crystals, which show circular polarization when solid, but when melted in their water of crystallization or dissolved in water, they do not polarize light. P. L. Geiger, and C. F. Rammelsberg said that the crystals of hemienneahydrated potassium orthosulphoantimonate are colourless or pale yellow, hygroscopic crystals, or radiating masses of crystals. H. G. F. Schröder gave 1.806 for the sp. gr. of the enneahydrated sodium salt, and C. Soret, 1-839. C. F. Rammelsberg found that

the crystals of the hemienneahydrated potassium salt melt in their water of crystallization, give off water, and form a brown mass; the ennea-hydrated sodium salt behaves similarly, forming a greyish-white mass which, in air, forms a voluminous white powder; when the salt is heated in the absence of air, it melts without decomposition to a liver-brown mass, which dissolves in water except for a little antimony trisulphide. When heated in vacuo, I. Pouget found very little sulphur is given off at the softening temp. of hard glass. A. Classen, and G. Vortmann studied the electrolysis of aq. soln. of the salt.

H. Rose observed that water but not sulphur is given off when the salt is heated in **hydrogen**. K. Schlippe found that when heated in **air** the salt quickly reddens after the water has passed off; it then blackens, and the liberated sulphur catches fire. C. F. Rammelsberg said that when the salt is exposed to air, it attracts carbon dioxide, and slowly acquires a brown film of antimony trisulphide, while sodium carbonate and thiosulphate are formed. 100 parts of water dissolve 34.5 parts of the salt; A. Duflos said that 100 parts of cold water dissolve 25 parts of salt, and hot water dissolves an equal weight of salt. J. von Liebig said that when a conc. soln. is exposed to air, it deposits antimony pentasulphide, and forms a soln. of sodium carbonate and thiosulphate. The decomposition is effected by the **carbon dioxide**, for when the air is freed from that gas, and is passed through a conc. soln., no change can be observed; while H. Rose observed that if carbon dioxide be passed through the soln., antimony pentasulphide, etc., are formed. Ammoniacal **hydrogen dioxide** was found by F. Raschig to convert the salt into sodium metantimonate. The aq. soln. is decomposed by **acids**—even by those so feeble as carbonic acid—antimony pentasulphide is precipitated, and hydrogen sulphide is formed. Boiling hydrochloric acid dissolves the salt with the separation of sulphur. A soln. of the salt is decomposed when it is boiled for a few hours with **sulphur**. According to B. Unger, if a soln. of sodium orthosulphoantimonate be mixed with much **sodium thiosulphate**, it furnishes yellowish-green, pyramidal crystals, probably belonging to the rhombic system; their composition corresponds with **sodium thiosulphatosulphoantimonate**, $\text{Na}_2\text{S}_2\text{O}_3 \cdot \text{Na}_3\text{SbS}_4 \cdot 20\text{H}_2\text{O}$; they melt when heated and lose their water; some is lost over sulphuric acid; they are soluble in water, but decompose into their constituents on concentrating the soln. A. Duflos found that the boiling aq. soln. is converted by powdered **antimony** into the sulphoantimonite, and on cooling deposits some antimony trisulphide; the boiling aq. soln. also dissolves hydrated **antimony pentoxide**, and on cooling, it deposits a mixture of antimony pentoxide and trisulphide; with an excess of the hydrated antimony pentoxide, some sodium antimonate as well as antimony pentoxide and trisulphide are precipitated. A boiling soln. of the salt also dissolves **antimony trisulphide** and gives it up again on cooling; C. F. Rammelsberg said that **antimony pentasulphide** is not dissolved by the boiling soln.; and that the salt is not dissolved by **alcohol**, even when largely diluted with water. R. Palm found that aq. soln. of the salt give coloured precipitates with many salts of the **alkaloids**. C. F. Rammelsberg found that a soln. of potassium antimonyl tartrate gives an orange precipitate, $2\text{Sb}_2\text{O}_3 \cdot \text{Sb}_2\text{S}_3 \cdot \text{Sb}_2\text{S}_5$, with sodium orthosulphoantimonate. H. Rose found that an **alkali carbonate** does not give a brownish-red precipitate with a soln. of sodium orthosulphoantimonate as it does with sodium orthosulphoantimonite. C. F. Rammelsberg studied the action of this salt on **metal salt** soln.

A. Stelzner⁴ described a mineral from the Sierra de Famatina, Argentina, and he called it **famatinite**. It also occurs in the Cerro de Pasco, Peru. It may occur massive and reniform, and it is grey more or less tinged copper-red in colour. Analyses were made by M. W. Siewert, A. Frenzel, S. Stevanovic, and F. L. Ransomé. A. Stelzner represented it by the formula $4(3\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3)(3\text{Cu}_2\text{S} \cdot \text{As}_2\text{S}_3)$, that is, $\text{Cu}_3(\text{Sb}, \text{As})\text{S}_3$; C. F. Rammelsberg, $4\text{CuS} \cdot \text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$; A. Frenzel, $3\text{Cu}_2\text{S} \cdot \text{Sb}_2\text{S}_3$; S. Stevanovic, $\text{Cu}_3(\text{As}, \text{Sb})\text{S}_4$; and P. Groth and K. Mieleitner, **cuprous sulphoantimonate**, Cu_3SbS_4 . F. Klockmann investigated the famatinite of the Sierra de Famatina, and also the mineral luzonite, Cu_3AsS_4 , from the same locality; he

suggested that both minerals are isomorphous, and unlike enargite, Cu_3AsS_4 , in form, although famatinite and enargite are considered by G. vom Rath to be isomorphous. If famatinite is isomorphous with luzonite, H. W. Witt said that it is monoclinic, and if isomorphous with enargite, rhombic. The sp. gr. is 4.5–4.6, or, according to J. J. Saslawsky, 4.57, and the contraction constant in its formation from its elements is 0.93. A. de Gramont studied the spark spectrum; and E. T. Wherry said that it is a fair radio-detector.

C. F. Rammelsberg⁵ prepared **cupric orthosulphoantimonate**, $\text{Cu}_3(\text{SbS}_4)_2$, by adding cupric sulphate to an excess of a soln. of the sodium salt. When heated in a retort, a fused residue of cuprous sulphoantimonite is formed. If an excess of the copper salt is used in the precipitate, and the liquids are mixed cold, a precipitate with a variable composition is formed, but on boiling the mixture, the precipitate is converted into $8\text{CuS}\cdot\text{Sb}_2\text{O}_5$, which when treated with potash-lye leaves a residue of copper sulphide. When the oxysulphide is heated to redness in a retort, it furnishes a basic cuprous sulphoantimonite: $3\text{Cu}_8\text{Sb}_2\text{S}_8\text{O}_5 = 2\text{Cu}_{12}\text{Sb}_2\text{S}_9 + \text{Sb}_2\text{O}_3 + 6\text{SO}_2$. C. F. Rammelsberg prepared **silver orthosulphoantimonate**, Ag_3SbS_4 , by boiling antimony pentasulphide with an excess of a soln. of silver nitrate whereby the product is first brown and then black: $8\text{Sb}_2\text{S}_5 + 15\text{Ag}_2\text{O} = 10\text{Ag}_3\text{SbS}_4 + 3\text{Sb}_2\text{O}_5$; it is also made by adding silver nitrate soln. to an excess of a soln. of sodium orthosulphoantimonate. The precipitate dried at 130° , when heated in a retort gives off sulphur, and forms artificial red silver ore. Potash-lye converts it into silver sulphide. If in its preparation the sodium orthosulphoantimonate be dropped into an excess of silver nitrate soln. and boiled, the black precipitate may be a mixture or an oxysulphide, $\text{Ag}_{16}\text{Sb}_2\text{S}_8\text{O}_5$, which when boiled with potash-lye yields silver sulphide. It is decomposed when heated.

The so-called *calx antimonii cum sulphure Hofmannii*, or the *calcaria sulphurato-sibiata*, of the alchemists is produced by igniting a mixture of antimony trisulphide, sulphur, and calcium oxide or carbonate (oyster shells) out of contact with air as recommended by J. G. Bremser, and C. F. Bucholz. The product is probably a mixture of **calcium orthosulphoantimonate**, and sulphate; or of calcium sulphoantimonate and antimonate. When boiled with a large proportion of water it partly dissolves, forming an impure soln. of calcium sulphoantimonate, which was called, once upon a time, *solutio calcia antimonii cum sulphure*. J. S. F. Pagenstecher also obtained an impure soln. of calcium orthosulphoantimonate by boiling a mixture of antimony trisulphide and lime-water; and C. F. Rammelsberg, by boiling antimony pentasulphide and calcium sulphide with water. The yellow soln. does not deposit any crystals, and deposits an oily liquid when treated with alcohol. C. F. Rammelsberg obtained a similar result in the attempt to prepare **strontium orthosulphoantimonate**, but I. Pouget obtained **strontium pyrosulphoantimonate**, $\text{Sr}_2\text{Sb}_2\text{S}_7\cdot 11\text{H}_2\text{O}$, in white, needle-like crystals by oxidizing a soln. of the pyrosulphoantimonite in air. C. F. Rammelsberg obtained **barium orthosulphoantimonate**, $\text{Ba}_3(\text{SbS}_4)_2\cdot 6\text{H}_2\text{O}$, by dissolving antimony pentasulphide in a soln. of barium sulphide, evaporating the filtrate to a small volume, and adding alcohol. In the absence of alcohol, the crystallization proceeds with difficulty. The same compound is formed along with barium antimonate when antimony pentasulphide is dissolved in baryta-water. It is also formed by igniting a mixture of barium sulphate, charcoal, antimony trisulphide and sulphur, and extracting the mass with water. J. S. F. Pagenstecher seems to have obtained the salt by boiling antimony trisulphide with a soln. of barium sulphide. According to C. F. Rammelsberg, the salt appears in stellate masses of white needles which when heated leave a brown mass without fusing. When exposed to air, the salt becomes brown from the separation of antimony pentasulphide.

C. F. Rammelsberg prepared **magnesium orthosulphoantimonate**, $\text{Mg}_3(\text{SbS}_4)_2$, as an orange-red substance, which could not be crystallized, by treating antimony pentasulphide with a soln. of magnesium hydrosulphide, and adding alcohol to the yellow liquid. He also dropped a soln. of zinc sulphate into an excess of a soln.

of sodium sulphoantimonate, and obtained a deep orange-yellow precipitate of **zinc oxysulphoantimonate**, $Zn_3(SbS_4)_2 \cdot ZnO$, which dissolves in the boiling liquid, and passes through the filter-paper in a colloidal form on washing. If the zinc sulphate soln. be in excess, and the liquid be boiled for a short time, a deep orange-yellow precipitate is formed, which, when washed and dried, forms a brownish-red mass with a shining fracture. It is decomposed when ignited in a retort; it dissolves in boiling hydrochloric acid; it dissolves in potash-lye with the separation of zinc sulphide, and the formation of a yellow soln. from which acids precipitate antimony pentasulphide with a slight evolution of hydrogen sulphide. F. Kirchhof mixed 25 grms. of sodium orthosulphoantimonate with 10.5 grms. of zinc chloride, and water. The chrome-yellow precipitate was allowed to stand for some time when it became crystalline. It was thoroughly washed in boiling water, dried at 80° ; ground to powder, and then dried at 100° . It changes colour when heated to 160° , and decomposes at 200° . It yields about 6 per cent. of sulphur when extracted about 4 hrs. with carbon disulphide, or 10 hrs. with acetone. The analyses then correspond with **zinc orthosulphoantimonate**, $Zn_3(SbS_4)_2$. For F. Kirchhof's observations on the constitution of this salt, *vide supra*. By working as in the case of the zinc salt, C. F. Rammelsberg obtained **cadmium sulphoantimonate** as a light orange-yellow precipitate when the sodium sulphoantimonate is in excess, and a darker coloured precipitate if the cadmium sulphate be in excess. It becomes reddish-brown if allowed to stand in its mother-liquor for some time. C. F. Rammelsberg obtained **mercurous orthosulphoantimonate**, Hg_3SbS_4 , as a black precipitate by adding a mercurous salt, in any proportion, to a soln. of sodium orthosulphoantimonate, and **mercuric orthosulphoantimonate**, $Hg_3(SbS_4)_2$, as a dark yellow precipitate, by adding mercuric chloride to an excess of the sodium salt.

Some observations on **thallium sulphoantimonate** have been made in connection with the sulphoantimonites. L. F. Hawley⁶ could obtain only solid soln. of the component sulphides. B. Jezek found a mineral associated with the realgar and orpiment at Allechar, Macedonia; and he called it **vrbaite**—after C. Vrba. The analyses by F. Krehlik correspond with **thallium pentasulphodiarsenoantimonate**, $Tl_2S \cdot 2As_2S_3 \cdot Sb_2S_3$, $TlAs_2SbS_5$, or $Tl \cdot S \cdot Sb(S-As=S)_2$. E. T. Wherry and W. F. Foshag represent it as a member of the group $Tl_2S \cdot 3(As, Sb)_2S_3$. The dark red to greyish-black crystals are tabular or pyramidal in habit; they occur in groups; and belong to the rhombic system, having the axial ratios $a : b : c = 0.5659 : 1 : 0.4836$. The (010)-cleavage is good. The sp. gr. ranges from 5.271 to 5.333; and the hardness is 3.5. The mineral is soluble in aqua regia, and nitric acid; and if warmed sulphur separates from the soln. It is soluble in conc. sulphuric acid; but not in hydrochloric acid. It is partly decomposed by alkali-lye.

According to C. F. Rammelsberg,⁷ stannous chloride gives a dark brown precipitate of **stannous sulphoantimonate** with a soln. of sodium orthosulphoantimonate. When a soln. of lead acetate is gradually added, with constant agitation, to an excess of a soln. of sodium orthosulphoantimonate, C. F. Rammelsberg, and F. Kirchhof observed that a dark brown precipitate of **lead orthosulphoantimonate**, $Pb_3(SbS_4)_2$, is formed which when heated out of contact with air forms orthosulphoantimonite. Boiling potash-lye decomposes it leaving a residue of lead sulphide. If the lead acetate soln. be in excess, and the mixture boiled for some time, the precipitate is probably a mixture of lead sulphide and antimony pentoxide, $8PbS + Sb_2O_5$. C. F. Rammelsberg found that a soln. of ammonium uranyl chloride gives a yellowish-brown precipitate of **uranyl sulphoantimonate** with a soln. of sodium orthosulphoantimonate. He also obtained a reddish-brown precipitate of **manganese sulphoantimonate** by adding a soln. of manganese sulphate to one of sodium orthosulphoantimonate. It readily oxidizes during the washing and drying. Similarly with ferrous sulphate, a black precipitate of **ferrous sulphoantimonate** was formed which turns rusty-yellow on exposure to air; ferric salts likewise yield **ferric sulphoantimonate** as a black precipitate,

but if the ferric salt is in excess, a yellowish-brown precipitate containing sulphur and antimony pentasulphide is formed. When an excess of a cobalt salt is added to a soln. of sodium orthosulphoantimonate, a black precipitate of **cobalt sulphoantimonate** is formed which gradually oxidizes in air, and is decomposed by hot hydrochloric acid. Nickel salts under similar conditions furnish **nickel sulphoantimonate**, which resembles the cobalt salt in its general properties.

§ 27. Antimony Oxysulphides

H. Rose¹ found that fused antimony trioxide and trisulphide mix together in all proportions, forming oxysulphides which are to be regarded as mixtures of isomorphous crystals; but E. Quercigh observed that although the fused compounds are miscible in all proportions, the formation of solid soln. in the binary system, $\text{Sb}_2\text{S}_3\text{-Sb}_2\text{O}_3$, is really very limited, Fig. 72. There is an antimony oxypentasulphide, Sb_4OS_5 , or $5\text{Sb}_2\text{S}_3\text{.Sb}_2\text{O}_3$, formed which does not melt unchanged, but

decomposes at 520° into crystals of antimony trisulphide and a liquid phase. Solid soln. of antimony trioxide, and oxypentasulphide exist between the conc. 0–18 per cent. Sb_2S_3 and 16.66–23 per cent. Sb_2O_3 . The eutectic at 489° , and 33.33 per cent. Sb_2O_3 has the composition of the mineral kermesite, which cannot therefore be obtained from fused mixtures of its components.

The product obtained by fusing mixtures of antimony trioxide and trisulphide is the *Spiessglanzglas*, *antimony glass*, or *vitrum antimonii* of the alchemists. According to H. Rose, if the molten mixture is rapidly cooled, a glassy mass is produced. The product is redder, the larger the proportion of the trioxide; and darker, the more trisulphide present. If the molten mixture is cooled slowly, it forms a black, crystalline mass; and when the molten mixture is dropped into cold water, the portion near the surface may be glassy and red, while the core is black and crystalline. The glassy product is a non-conductor of electricity; the crystalline is a poorer conductor than the crystalline trisulphide.

A. Werner made *antimony glass* by rapidly fusing in a fireclay crucible a mixture of *antimony-ash*—i.e. the trisulphide roasted without fusion in a reverberatory furnace—with about one-twentieth of its weight of antimony trisulphide until its molten surface becomes bright like a mirror. It is then poured on to a marble slab or polished copper plate. With antimony-ash and antimony trisulphide in the proportions 100 : 3.35, the product is a reddish-yellow, transparent glass; 100 : 5.28, yellowish-red; and 100 : 6.69, hyacinth-red. J. L. Proust, and E. Soubeiran obtained analogous products. The so-called *Spiessglanz-safran*, or *antimonial saffron*, *crocus antimonii*, or *crocus metallorum*, was described by M. Ettmüller. It was prepared by J. L. Proust by melting a mixture of antimony pentoxide and 25 per cent. of the trisulphide, or a mixture of antimony tri- or penta-oxide with the proper proportion of sulphur. J. J. Berzelius recommended mixing freshly precipitated trisulphide with antimony pentachloride in acid soln., and adding water until the hydrated pentoxide begins to separate. The *regulus antimonii medicinalis*, or *rubinus antimonii*, of the alchemists is an antimony trisulphide containing very little trioxide. It is black when *en masse*, and dark red when powdered. It was made by fusing a mixture of potassium carbonate with five times its weight of antimony trisulphide, and rejecting the upper stratum of potassium sulphoantimonite from the cold mass. The *Miniere e fonderie d'antimonio* prepared a chocolate-brown oxysulphide by roasting antimony sulphide ores.

O. Schumann² obtained **antimony oxypentasulphide**, Sb_4OS_5 , or $5Sb_2S_3 \cdot Sb_2O_3$, by passing a current of dry hydrogen sulphide over antimony pentoxide. At ordinary temp., the oxide is coloured yellow, but at a higher temp., sulphur and water are evolved and the black oxypentasulphide appears. E. Quercigh showed the limits of stability of this compound when prepared from mixtures of the trioxide and trisulphide, as well as the solid soln. which it forms when an excess of either component is present. It decomposes at 522° into trisulphide and a liquid—*vide* Fig. 72.

In 1747, J. G. Wallerius described a native antimonial earth whose red colour was attributed to the presence of arsenic. The mineral was also mentioned by A. Cronstedt, and I. S. R. I. Eques a Born, and J. B. L. Romé de l'Isle called it *antimonium plumosum*; B. G. Sage, *mine d'antimoine en plumes*; A. G. Werner, L. A. Emmerling, M. H. Klaproth, *Rothspiessglaserz* or *Rothspiessglanzzerz*; and R. J. Haüy, *antimoine oxydé sulphuré*. J. F. L. Hausmann united tinder ore and this red antimonial earth under the name *Spiessglanzblende*; and C. C. von Leonhard, *Antimonblende*, or *antimony blende*. F. S. Beudant called it *kermès*; E. J. Chapman, **kermesite**—possibly from a Persian word, *qurmizq*, crimson—E. F. Glocker, *pyrantimonite*, and also *pyrostibite*. Analyses of the mineral were reported by M. H. Klaproth, H. Rose, and H. Baubigny. The results agree with the empirical formula, $2Sb_2S_3 \cdot Sb_2O_3$, or Sb_2OS_2 , or $Sb_4O_2S_4$, **antimony dioxytetra-sulphide**. H. V. Regnault obtained this compound, as an orange-red mass, by heating antimony trisulphide in a current of steam; O. Schumann, as a black

FIG. 72.—Freezing-point Curve of Antimony Trisulphide and Trioxide.

powder, by the action of dry hydrogen sulphide on antimony trioxide; R. Schneider, as a reddish-brown powder, by boiling antimony sulphoiodide with zinc oxide and water; and H. Rose, by fusing together a mixture of the components—antimony trioxide and trisulphide. There is no evidence of the formation of this compound on the f.p. curve of the components—Fig. 72. According to H. Baubigny, and N. Teclu, the oxysulphide reported by R. Wagner, A. Carnot, and A. Strohl, to be formed by the action of sodium thiosulphate on antimonious salt soln.—*e.g.* antimony trichloride—is only impure antimony trisulphide.

Kermesite usually occurs in tufts of capillary crystals of a cherry-red colour, belonging to the rhombic or monoclinic system. F. Mohs called the mineral prismatic *Purpurblende*, and considered the crystals to be monoclinic; G. A. Kennigott came to the same conclusion. P. Pjatzitzky found the axial ratios of the crystals to be $a : b : c = 3.9650 : 1 : 0.8535$, and $\beta = 90^\circ$. The (100)-cleavage is perfect; and the (101)-cleavage imperfect. The crystals were also examined by V. Goldschmidt; and the colour by J. L. C. Schröder van der Kolk. Pseudomorphs after the antimony sulphide ores, particularly stibnite, have been observed by J. R. Blum, V. R. von Zepharovich, etc. P. Pjatzitzky said that the indices of refraction are large; and the birefringence small. The pleochroism is feeble. The sp. gr. of the mineral given by P. Pjatzitzky is 4.5–4.6; A. Breithaupt gave 4.493. The hardness is between 1 and 2. L. H. Borgström gave 517° for the m.p.; and J. Joly said that a sublimate appears at 430° . F. Beijerinck found the mineral to be a non-conductor of electricity; T. W. Case also said that kermesite is a non-conductor, and that its resistance is not appreciably affected by light. H. Rose said that this compound melts easily—*vide* Fig. 72—that it forms a black glass when heated in a current of carbon dioxide; and that it is reduced when heated in a current of hydrogen. The compound was found by H. Baubigny to be attacked by hot hydrochloric acid, and by potash-lye. It is not dissolved by a 7 per cent. soln. of tartaric acid.

According to C. F. Rammelsberg, when a soln. of potassium antimonyl tartrate is treated with sodium orthosulphoantimonate, an orange-red precipitate of *antimonyl sulphoantimonate*, $(\text{SbO})_3\text{SbS}_4$, or **antimony trioxytetrasulphide**, $\text{Sb}_4\text{O}_3\text{S}_4$, is formed. This compound melts when heated, forming a very dark red mass; the red powder dissolves in hot hydrochloric acid; and it is reduced to metal when heated in hydrogen. With potash-lye, a yellow residue is formed. F. J. Faktor boiled aq. soln. of potassium antimonyl tartrate and sodium thiosulphate, prepared in the cold, and obtained a fiery-red precipitate, which, when washed with water, alcohol, and carbon disulphide, and dried at 100° , has the composition, **antimony dioxy-sulphide**, SbO_2S . When this product is suspended in water, at ordinary temp. or at 80° , and treated with hydrogen sulphide, no change in colour or composition was observed. It is, however, darkened by exposure to sunlight. If a soln. of potassium antimonyl tartrate and sodium thiosulphate is prepared with boiling water, and boiled, F. J. Faktor said that the dark brown precipitate is **antimony tetroxysulphide**, $\text{Sb}_2\text{O}_4\text{S}$, or **antimony pentoxysulphide**, $\text{Sb}_2\text{O}_5\text{S}$.

J. J. Berzelius³ obtained an antimony oxysulphide, by igniting a mixture of antimony trisulphide with about one part of potassium carbonate or nitrate, and extracting the product with hot water. It was formerly regarded as an *antimonial crocus* or *saffron with potash*. It was also made by boiling the grey trisulphide with potash-lye, or by digesting the red trisulphide in the cold lye. The product fuses to a yellowish glass. When the crocus is digested with dil. hydrochloric acid, potassium antimonite passes into soln. The crocus was also prepared by J. von Liebig, and B. Unger. According to C. F. Rammelsberg, if antimony pentasulphide be treated with a conc. soln. of potash-lye, potassium trihydrotriantimonate separates out (*q.v.*), and when the clear liquid is evaporated, **potassium hydrodioxydisulphoantimonite**, $\text{K}_2\text{HSbO}_2\text{S}_2 \cdot 2\text{H}_2\text{O}$, is formed. L. W. McCay made it by allowing a cold soln. of potassium hydroxide to act on antimony pentasulphide for 24 hrs. H. Schiff employed an analogous process. If sodium thiosulphate be

heated with a conc. soln. of sodium antimonite, sodium pyroantimonate, sulphantimonate, and sulphite are formed; potassium salts under similar conditions yield potassium antimonate and sulphoantimonate. If action with the potassium salts takes place in the cold, antimony trisulphide is precipitated, and the mother-liquor, on evaporation, gives crystals of what is probably the hydrodioxidisulphoantimonate. The same salt was produced by the action of potassium hydroxide and sulphur on antimony trioxide: $\text{Sb}_2\text{O}_3 + 5\text{KOH} + 2\text{S} = \text{K}_2\text{HSbO}_2\text{S}_2 + \text{KH}_2\text{SbO}_4 + 2\text{KOH}$; and also by the action of potassium hydroxide and polysulphide on antimony trioxide: $3\text{Sb}_2\text{O}_3 + 18\text{KOH} + 2\text{K}_2\text{S}_4 = 3\text{K}_2\text{HSbO}_2\text{S}_2 + 3\text{KH}_2\text{SbO}_4 + 2\text{K}_2\text{S} + 9\text{KOH}$. C. F. Rammelsberg also made it by boiling antimony trisulphide with a soln. of potassium carbonate and calcium oxide. The salt furnishes pale yellow clusters of radiating needles; which, when dried over sulphuric acid out of contact with air, were found by H. Schiff to become dark yellow; and in moist air L. W. McCay observed that the salt becomes red or crimson without deliquescing. C. F. Rammelsberg said that the salt deliquesces in air, and acquires a brown film; and that it does not lose its water below 100° . L. W. McCay observed that the salt loses its water of crystallization at 150° , but a temp. of 250° is necessary for the expulsion of the combined water. C. F. Rammelsberg found that the salt melts to a reddish-brown liquid, which, on cooling, forms a yellow solid. Cold water dissolves the salt with the partial separation of potassium antimonate; hot water dissolves it completely. The salt is decomposed by acids, forming potassium trihydrotriantimonate, antimonie acid, antimony pentasulphide, and some hydrogen sulphide; but L. W. McCay represented the reaction: $8\text{H}_3\text{SbO}_2\text{S}_2 = \text{Sb}_2\text{S}_5 + 2\text{Sb}_2\text{S}_3 + 5\text{S} + \text{H}_3\text{SbO}_4 + \text{H}_3\text{SbO}_3 + 9\text{H}_2\text{O}$. He said that aq. soln. of the salt react with alkaline earth salts, forming white precipitates which become crystalline; with silver salts, a black precipitate; with copper and lead salts, red precipitates which gradually turn black. C. F. Rammelsberg said that with barium chloride, the hot aq. soln. gives barium antimonate; and the filtrate yields antimony pentasulphide when treated with acids.

C. F. Rammelsberg could not prepare analogous sodium, calcium, or barium salts. H. Schiff's, and W. Feit and C. Kubierschky's attempts were also nugatory. When antimony pentasulphide is treated with soda-lye, the orthosulphoantimonate and metantimonate are produced; and similar products are obtained when antimony chloride is treated with sodium sulphide; or sulphoantimony chloride with soda-lye. Lead hydroxide desulphurizes sodium orthosulphoantimonate; and a boiling soln. of sodium sulphide and metantimonate gives the orthosulphoantimonate. For a possible *copper pentaoxyoctosulphodiantimonate*, $8\text{CuS.Sb}_2\text{O}_5$, but more probably a mixture *vide* copper sulphoantimonate; similarly with *silver pentaoxyoctosulphodiantimonate*, $8\text{Ag}_2\text{S.Sb}_2\text{O}_5$.

§ 28. Antimony Sulphates

Like arsenic trioxide, antimony trioxide behaves as a base towards the stronger acids. According to J. J. Berzelius,¹ antimony trioxide is sparingly soluble in sulphuric acid. R. Brandes, and W. P. Dexter obtained crystals of normal **antimony sulphate**, $\text{Sb}_2(\text{SO}_4)_3$, by cooling a hot soln. of antimony trioxide in hot sulphuric acid. A similar product was obtained by C. Schultz-Sellack, and C. Hensgen. S. Metzl washed the crystals with xylene to remove the sulphuric acid. According to R. H. Adie, if the acid employed has the composition $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, normal antimony sulphate is formed, but if a more dil. acid is used, basic salts are formed. W. P. Dexter also heated antimony trioxide or antimonyl chloride with sulphuric acid, and distilled off the excess acid. C. Hensgen found that if antimony trisulphide be heated with conc. sulphuric acid until sulphuric acid fumes are no longer evolved, the normal sulphate is produced. S. Metzl added that sulphuric acid transforms antimony trisulphide into sulphate at 300° , and the product is contaminated with acid and a basic salt. If alkali or magnesium sulphate be present, the reaction is facilitated so that even with a dil. acid at 130° , the reaction may be represented: $\text{Sb}_2\text{S}_3 + 12\text{H}_2\text{SO}_4 = \text{Sb}_2(\text{SO}_4)_3 + 12\text{SO}_2 + 12\text{H}_2\text{O}$. Antimonial sulphide ores can be used as the source of the antimony. The analyses of R. Brandes, W. P. Dexter, C. Schultz-Sellack, C. Hensgen, R. H. Adie, and S. Metzl are in agreement with the empirical formula $\text{Sb}_2(\text{SO}_4)_3$.

W. P. Dexter described the crystals as four-sided prisms, the other workers as acicular crystals, or as a crystalline powder. S. Metzl gave 3.6216 for the sp. gr. at 4° . C. Hensgen, and C. Schultz-Sellack found that the crystals are stable in dry air, but in moist air, they deliquesce rapidly taking up, according to C. Hensgen, 3 mols of water, or, according to S. Metzl, 2.5 mols. C. Hensgen said that only part of the absorbed water is removed by drying the product over sulphuric acid, but crystals separate from the liquor after some time. When the normal sulphate is treated with a small proportion of water, heat is developed and a solid mass is produced; with more water, the mass dissolves, and the soln. forms a crystalline mass when evaporated in vacuo over sulphuric acid. W. Ipatieff and co-workers observed that antimony sulphate is reduced by hydrogen under press. to form antimony sulphide. The normal sulphate is partly hydrolyzed by water furnishing various basic sulphates (*q.v.*), and, according to R. Brandes, and C. Hensgen, the hydrolysis may be completed with hot water. R. H. Adie found that absolute alcohol also converts it into a basic salt. According to J. I. Gay Lussac, C. Schultz-Sellack, and A. Bussy, when the sulphate is heated, it gives off sulphur trioxide

and dioxide and oxygen; C. F. Bucholz observed that some antimony trioxide sublimes; and S. Metzl found that if heated slowly, sulphur trioxide is given off, and the residue contains both trioxide and tetroxide. R. Robl observed no fluorescence when the sulphate is exposed to ultra-violet light. J. A. Arfvedson found that when heated in hydrogen, antimony, and antimony trioxide and trisulphide are formed. C. Hensgen found that up to 5.2 mols of hydrogen chloride are absorbed with some avidity, and the fused mass solidifies on cooling, forming, possibly, chlorosulphates. F. Ephraim obtained a complex of antimony sulphate and hydrogen chloride. A. B. Prescott observed no change when a gram of the sulphate is evaporated on a water-bath to dryness with 3.5 c.c. of hydrochloric acid of sp. gr. 1.153.

C. Schultz-Sellack found that a soln. of antimony trioxide in fuming sulphuric acid furnishes **antimony tetrasulphate**, or **antimony tetrasulphatotrioxide**, $\text{Sb}_2\text{O}_3 \cdot 4\text{SO}_3$, or $\text{Sb}_2(\text{SO}_3)(\text{SO}_4)_3$, in small crystals; and E. Péligot obtained the same salt from a soln. of antimonyl chloride in conc. sulphuric acid. According to R. H. Adie, when the trioxide is treated with fuming sulphuric acid, $2\text{H}_2\text{SO}_4 \cdot \text{SO}_3$, it forms a hard cake which dissolves when heated, and on cooling furnishes fine needles which rapidly deliquesce in moist air. They are decomposed by water. R. H. Adie found that when a mixture of antimony and sulphur trioxides is heated in a sealed tube, the composition of the product depends on the proportion of sulphur trioxide present, and on the temp. At 120° , the product had 55.87–61.55 per cent. SO_3 ; at 160° , 73.55 per cent.; and at 180° , 74.56 per cent. The value calculated for $\text{Sb}_2\text{O}_3 \cdot 8\text{SO}_3$ is 68.98 per cent., and for $\text{Sb}_2\text{O}_3 \cdot 10\text{SO}_3$, 73.52 per cent. The formation of the compound with the highest proportion of sulphur trioxide requires a temp. of 160° ; and would appear to be $\text{Sb}_2\text{O}_3 \cdot 9\text{SO}_3$, but, since the corresponding arsenic compound can be completely freed from the excess of sulphur trioxide, and is probably $\text{As}_2\text{O}_3 \cdot 8\text{SO}_3$, it is best to assume that the compound formed is **antimony octosulphatotrioxide**, or **antimony octosulphate**, $\text{Sb}_2\text{O}_3 \cdot 8\text{SO}_3$.

A number of basic sulphates can be obtained by the hydrolysis of antimony sulphates. R. H. Adie said that alcohol furnishes $\text{Sb}_2\text{O}_3 \cdot 2\text{SO}_3$; cold water, $2\text{Sb}_2\text{O}_3 \cdot \text{SO}_3$; and hot water, $7\text{Sb}_2\text{O}_3 \cdot 2\text{SO}_3$. There are many doubts which, if any, of the reported basic sulphates are chemical individuals. Arsenic sulphate is hydrolyzed by cold water to form arsenic trioxide. The basic antimony sulphates are also produced by the action of acid more dilute than $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ on antimony trioxide. Thus, while H_2SO_4 forms with arsenic trioxide $\text{As}_2\text{O}_3 \cdot 2\text{SO}_3$, this acid as well as $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, with antimony trioxide, furnishes normal antimony sulphate; $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$ yields $\text{Sb}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot \text{H}_2\text{O}$; and $\text{H}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$ gives $\text{Sb}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$. After comparing the arsenic and antimony sulphates, R. H. Adie added that antimony trioxide with sulphuric and weaker acids forms a different order of sulphates from As_2O_3 , while it resembles it in forming acidic sulphates when subjected to the action of stronger acids. The characteristic group salt $\text{Sb}_2(\text{SO}_4)_3$, which is produced by the former, is replaced by the basic $\text{As}_2\text{O}(\text{SO}_4)_2$ in the latter case. The limits of existence both as regards dilution and temp., are much narrower for the arsenic than for the antimony salt. The practically complete formation of $\text{Sb}_2(\text{SO}_4)_3$ in one crystallization also contrasts with the formation of $\text{As}_2\text{O}(\text{SO}_4)_2$ only by repeated crystallization. Arsenic trioxide does not form any basic sulphates containing water, whilst the oxide of the more metallic antimony does form hydrated sulphates in acids weaker than $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$. This acid is the limit of existence of $\text{Sb}_2(\text{SO}_4)_3$ in soln. and of any arsenic sulphates whatever. In contrast to the case of the arsenic compounds, one cannot remove all the SO_3 from the antimony sulphates by water. The stability of the latter in dil. acids far exceeds that of the former. M. Websky made a basic sulphate by the action of antimony or its trisulphide on molten potassium hydrosulphate. W. P. Dexter said that all the sulphates are soluble in hydrochloric acid, and if tartaric acid be present, the soln. can be diluted with water. The soln. are decomposed by alkali hydroxides or carbonates yielding antimony trioxide.

S. Metzl said that *antimony heptasulphatotrioxide*, $7\text{Sb}_2\text{O}_3 \cdot \text{SO}_3$, is produced by boiling the normal sulphate with 14 times its weight of water, and allowing the mixture to stand at rest for 24 hrs. According to R. H. Adie, if normal antimony sulphate be treated with boiling water until the washings are free from sulphuric acid, *antimony diheptasulphatotrioxide*, $7\text{Sb}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 3\text{H}_2\text{O}$, is formed as a white powder. Both R. Brandes, and C. Hensgen said that by repeatedly treating the normal sulphate with hot water, antimony trioxide and sulphuric acid are formed. Hence the two products just indicated are probably mixtures of antimony trioxide with one of the other basic sulphates.

According to R. Brandes, R. H. Adie, and W. P. Dexter, when the normal sulphate, or, according to E. Péligot, when the tetrasulphate is decomposed by cold water, **antimony hemisulphatotrioxide**, $2\text{Sb}_2\text{O}_3 \cdot \text{SO}_3 \cdot 7\text{H}_2\text{O}$, is produced. C. Hensgen gave $5\text{Sb}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 7\text{H}_2\text{O}$ for the composition of the product obtained in this way. R. H. Adie supposes that this compound is a sulphate of meta-tetrantimonic acid, $\text{H}_2\text{Sb}_4\text{O}_7$. R. Brandes obtained the same compound by treating the normal sulphate with twice its weight of water, and so much sulphuric acid as is necessary for dissolution; and then adding water to precipitate the white powder. The product contains a variable proportion of water dependent on the mode of drying; and the temp. of the water employed for the hydrolysis. That prepared by water at 18° and dried in air had 4 mols. of water; that prepared by water at 6° , and air-dried, 2-3 mols.; that prepared by water at 6° and dried by press. between porous tiles, 16 mols. of water. W. P. Dexter said that the powder becomes crystalline if allowed to stand in contact with the mother-liquor, and it then contains one mol. of water. R. H. Adie said that all the water is expelled at 100° ; and W. P. Dexter, at 240° . R. Brandes found that the salt is completely hydrolyzed by boiling water.

S. Metzl found that if the normal sulphate be decomposed by ten times its weight of cold water, **antimony sulphate**, $(\text{SbO})_2\text{SO}_4$, is produced; R. Brandes obtained it as a white powder by the action of alcohol on antimony disulphatotrioxide; and W. P. Dexter, by the action of boiling sulphuric acid of sp. gr. 1.554, or $\text{H}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$, on antimony trioxide—the second crop of crystals contains $(\text{SbO})_2\text{SO}_4 \cdot \text{H}_2\text{O}$; the first crop contains four-sided prisms with the composition $3\text{Sb}_2\text{O}_3 \cdot 5\text{SO}_3 \cdot 2\text{H}_2\text{O}$, or $(\text{SbO})_2\text{SO}_4 \cdot 4(\text{SbOH})\text{SO}_4$.

According to R. H. Adie, **antimony disulphatotrioxide**, $\text{Sb}_2\text{O}_3 \cdot 2\text{SO}_3$, or $\text{SO}_4 : \text{Sb} \cdot \text{O} \cdot \text{Sb} : \text{SO}_4$, is formed from a soln. of antimony trioxide in boiling sulphuric acid of the composition $\text{H}_2\text{SO}_4 \cdot 2$ to $4\text{H}_2\text{O}$; on cooling the *monohydrate* separates, as a white powder, which, if left in contact with its mother-liquor, crystallizes as the *trihydrate*. W. P. Dexter made the compound by the prolonged boiling of antimony trioxide with sulphuric acid dil. with its own vol. of water; by S. Metzl, and R. H. Adie, by the action of absolute alcohol at 18° on the normal sulphate; and by E. Péligot, by the action of fuming sulphuric acid on antimony chloride. The product loses all its water at 100° , and decomposes at about 250° . It is scarcely affected by cold water, but is hydrolyzed by hot water, it is slowly dissolved by hot dil. sulphuric acid. G. Karl considered that the *les anhydrides mixtes*—*cf.* arsenic—are represented by:

A. Gutmann obtained crystal plates of **ammonium antimony sulphate**, $(\text{NH}_4)_2\text{SO}_4 \cdot \text{Sb}_2(\text{SO}_4)_3$, by cooling a boiling soln. of 5-6 grms. of ammonium sulphate in 15 grms. of sulphuric acid, and about as much antimony trioxide as the soln. will dissolve, about half a gram. The salt is dried by press. between warm porous tiles. S. Metzl said that the exact proportioning of the components is not necessary. The sp. gr. of the crystals is 3.0948 at 4° . The salt is slowly dissolved by water, and the aq. or alcoholic soln. behaves like a mixture of the components. A. Gutmann prepared **sodium antimony sulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{Sb}_2(\text{SO}_4)_3$, in an analogous way, using 5 grms. of sodium sulphate, 20 of conc. sulphuric acid, and 10 of antimony trioxide. S. Metzl gave 3.2298 for the sp. gr. at 4° . The salt

resembles that of ammonium. A. Gutmann prepared the analogous **potassium antimony sulphate**, $K_2SO_4 \cdot Sb_2(SO_4)_3$, using one part of potassium sulphate, 3 parts of sulphuric acid, and about half a part of antimony trioxide. S. Metzl showed that these proportions need not be strictly observed, and he gave 3-3396 for the sp. gr. at 4°. A. Gutmann said that it forms with water a basic sulphate. E. Péligot obtained another complex sulphate which N. Svensson formulates $\{6K_2SO_4 \cdot Sb_2(SO_4)_3\} 2KHSO_4 \cdot 2H_2O$, or **potassium antimony henasulphate**, $7K_2O \cdot Sb_2O_3 \cdot 11SO_3 \cdot 3H_2O$. E. Péligot obtained it from a boiling soln. of antimony tetrasulphate and potassium sulphate; and N. Svensson, by boiling with a soln. of potassium hydrosulphate the cold cake obtained by melting a mixture of potassium hydrosulphate and antimony oxychloride or trioxide. The salt is decomposed by water. H. Kühn prepared **silver antimony sulphate**, $Ag_2SO_4 \cdot Sb_2(SO_4)_3$, in colourless, cubic, doubly refracting crystals, by concentrating a soln. of antimony sulphate and an excess of silver sulphate in conc. sulphuric acid. Slender needles of **calcium antimony sulphate**, $CaSO_4 \cdot Sb_2(SO_4)_3 \cdot 6H_2O$, were obtained by mixing a soln. of 3 grms. of antimony trioxide in 150 c.c. of conc. sulphuric acid, and 4 grms. of dihydrated calcium sulphate in about 80 c.c. of sulphuric acid. The soln. is conc. until crystals begin to form, and then cooled. The corresponding **strontium antimony sulphate**, $SrSO_4 \cdot Sb_2(SO_4)_3 \cdot 6H_2O$; and **barium antimony sulphate**, $BaSO_4 \cdot Sb_2(SO_4)_3 \cdot 6H_2O$, were obtained in a similar way.

§ 29. Antimony Sulphohalides or Halogenosulphides

Complex salts with ammonium sulphate and antimony trifluoride have been mentioned in connection with the latter salts, and $SbCl_5 \cdot SCl_4$ is mentioned in connection with antimony pentachloride. According to J. F. W. Johnston,¹ the trisulphide precipitated when hydrogen sulphide is passed into a soln. of antimony trichloride, contains some chloride which cannot be removed by washing; and when the precipitate is heated, some antimony trichloride volatilizes. E. G. Beckett assumed that in precipitating antimony sulphide from hydrochloric acid soln. of the trichloride by hydrogen sulphide in the ordinary course of analysis, a series of **antimony chlorosulphides**, as well as the normal hydrosulphide, may be formed:

Antimony
trihydrosulphide.

Antimony
monochloro-
dihydrosulphide.

Antimony
dichloro-
hydrosulphide.

Antimony
trichloride

M. Berthelot studied the heat of formation of the sulphochlorides. L. Ouvrard treated antimony trichloride, not quite at its m.p., with dry hydrogen sulphide, and obtained small crystals of **antimony pentasulphodichloride**, $Sb_4S_5Cl_2$, as soon

as the evolution of hydrogen chloride had ceased; but, by stopping the operation before that stage is reached, **antimony sulphochloride**, SbSCl , or $\text{Sb}_4\text{S}_4\text{Cl}_4$, was obtained in reddish-brown crystals, insoluble in carbon disulphide, but decomposed by acids. If the temp. of the reaction be increased, antimony trisulphide is the end-product. H. J. Taverne obtained the pentasulphodichloride by passing dry hydrogen sulphide into a soln. of antimony trichloride in dry carbon disulphide or tetrachloride, or in a mixture of these solvents, when there is formed a white precipitate, which is converted by a little water into antimony trisulphide. On continued passage of hydrogen sulphide, the colour of the white compound changes to yellow, yellowish-red, orange, and finally dark red. The end product is crystalline, and has the formula $\text{Sb}_4\text{S}_5\text{Cl}_2$. It probably results from replacement of one S-atom in two mols of antimony trisulphide by two Cl-atoms. The light orange, crystalline, intermediate product, **antimony hexasulphotrichloride**, $\text{Sb}_5\text{S}_6\text{Cl}_3$, has also been isolated. According to R. Schneider, 100 parts of boiling antimony trichloride dissolve 6.67 parts of antimony trisulphide, and on cooling a mass of yellow, rhombic crystals of **antimony sulphodocosichloride**, Sb_8S_{22} , or SbSCl.SbCl_3 , is produced. This compound decomposes when heated, giving off antimony trichloride and forming the trisulphide. It deliquesces in air, producing a clear liquid, which later becomes turbid. The salt is hydrolyzed by water, and with absolute alcohol passes into a yellow amorphous powder, **antimony henasulphodichloride**, $\text{Sb}_9\text{S}_{11}\text{Cl}_2$. It is decomposed, when heated, with the evolution of antimony trichloride; it is decomposed at ordinary temp. by dil. hydrochloric acid, forming antimony trisulphide; the conc. acid produces hydrogen sulphide. By treating antimony pentachloride with dry hydrogen sulphide, S. Cloez obtained a crystalline mass of **antimony sulphotrichloride**, SbSCl_3 ; A. Bertrand and E. Finot obtained it by the action of carbon disulphide on cold antimony pentachloride. The white crystalline mass is fusible, and is decomposed by heat into sulphur and antimony trichloride. It is stable in dry air, but deliquesces in moist air. It is decomposed by water into oxychloride, SbOCl , and sulphur, and by tartaric acid with the separation of antimony trisulphide, and trioxide.

L. Ouvrard prepared **antimony sulphobromide**, SbSBr , by the action of dry hydrogen sulphide on molten antimony tribromide. It forms small crystals insoluble in carbon disulphide.

J. F. W. Johnston obtained no satisfactory evidence of the formation of a sulphide by the action of a hydrogen sulphide on a dil. soln. of antimony triiodide in hydrochloric acid. O. Henry and M. Carot heated a mixture of equal parts of iodine and antimony trisulphide, and obtained what was regarded as **antimony trisulphohexaiodide**, $\text{Sb}_2\text{S}_3\text{I}_6$, in blood-red needles or plates, which melt at a lower temp. than the triiodide, and sublime without decomposition. The compound decomposes when heated in air; when treated with water; conc. acids; or alkali-lye. R. Schneider found that antimony trisulphide dissolved a molten triiodide, and when the cold product is treated with hydrochloric acid, **antimony sulphoidide**, SbSI , or $\text{Sb}_4\text{S}_4\text{I}_4$, remains. L. Ouvrard obtained it from a molten mixture of equal parts of antimony trisulphide and iodine—R. Schneider obtained a very small yield by this process. L. Ouvrard obtained the sulphide by passing hydrogen sulphide over antimony triiodide at 150° . R. Schneider said that the dark brown, acicular crystals resemble those of kermesite; they are not decomposed by hot or cold water; nor by dil. acids. Conc. hydrochloric acid decomposes the compound with the evolution of hydrogen sulphide; and nitric acid, with the separation of sulphur and iodine; a soln. of alkali hydroxide or carbonate furnishes iodine and sulphoantimonite; and with zinc oxide and water, antimony oxydisulphide, Sb_2OS_2 , is formed. L. Ouvrard heated a mixture of 5 gram-atoms of iodine with a mol of antimony trisulphide in an evacuated tube, and obtained a sublimate of antimony triiodide, crystals of **antimony sulphotriiodide**, SbSI_3 , and unchanged trisulphide. The compound is soluble in carbon disulphide, and when protected from air can be recrystallized unchanged. It is decomposed by moist air into antimony triiodide

and sulphur. V. Auger prepared **antimony tetracosisulphoiodide**, $\text{SbI}_3 \cdot 3\text{S}_8$, in long, bright yellow prisms of m.p. 117° , by mixing carbon disulphide soln. of the two constituents.

P. Gruhl found that it is not possible to prepare halogenized antimonites analogous to the halogenized arsenites because of the low solubility of antimony trioxide in soln. of the alkali iodides. By melting a mixture of potassium iodide and antimony trioxide, he obtained **potassium oxyiodoantimonite**, $\text{K}_4\text{Sb}_{16}\text{O}_{25}\text{I}_2$, or $8\text{Sb}_2\text{O}_3 \cdot \text{K}_2\text{O} \cdot 2\text{KI}$, as an amber-yellow crystalline mass. It is insoluble in cold or hot water; acids and alkali-lye do not act on it; aqua regia decomposes it slowly; and tartaric acid dissolves it gradually.

§ 30. Antimony Nitrates and Phosphates

No *antimony carbonate* has been prepared. A. Naumann¹ reported that **antimony nitrate**, $\text{Sb}(\text{NO}_3)_3$, is obtained along with silver chloride, by adding silver nitrate to a soln. of antimony trichloride in acetone. In aq. soln. the nitrate is hydrolyzed. As shown by J. J. Berzelius, and H. Rose, neither antimony trioxide nor the pentoxide is soluble in nitric acid. C. F. Bucholz, and J. J. Berzelius treated antimony or an antimony oxide with nitric acid, and obtained a basic nitrate as a white powder. E. Péligot dissolved antimony oxide in cold fuming nitric acid, and on adding water obtained crystals of **antimonyl nitrate**, $2\text{Sb}_2\text{O}_3 \cdot \text{N}_2\text{O}_5$, or $(\text{SbO})_4\text{N}_2\text{O}_7$, with a nacreous lustre. J. B. Senderens also obtained it as a grey powder on reducing 0.5*N*- AgNO_3 with antimony. The grey powder burns like tinder. J. J. Berzelius said that water decomposes the salt, forming nitric acid. By passing nitrogen peroxide into a soln. of antimony tribromide in chloroform, or of antimony triiodide in ether. V. Thomas obtained a white, crystalline precipitate of **antimony nitrate bispentoxide**, $2\text{Sb}_2\text{O}_5 \cdot \text{N}_2\text{O}_5$. It is not decomposed by water; but when heated it gives antimony pentoxide or tetroxide.

According to C. F. Wenzel,² aq. phosphoric acid dissolves a little antimony trioxide, and on evaporation a dark green mass is obtained which fuses to a glass when heated. R. Brandes obtained small crystals of **antimony phosphate**, $2\text{Sb}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5$, $4\text{SbPO}_4 \cdot \text{P}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, which, with cold water, form antimonyl pyrophosphate, $2\text{Sb}_2\text{O}_3 \cdot \text{P}_2\text{O}_5$, or $(\text{SbO})_4\text{P}_2\text{O}_7$; and with hot water, a more basic salt $(\text{SbO})_8\text{P}_2\text{O}_9$. These statements all want revision. H. Rose found that sodium hydrophosphate gives a white incomplete precipitation with antimony salts, and A. Brand that sodium or ammonium pyrophosphate also gives a white precipitate soluble in excess. According to A. Schwarzenberg, when antimony trioxide is boiled with a soln. of sodium pyrophosphate, and the soln. evaporated over sulphuric acid, a cauliflower-like mass is obtained, which, when treated with water, leaves the greater part of the antimony trioxide undissolved.

E. Glatzel's work on *antimony orthosu'phosphosphate*, SbPS_4 , is discussed in connection with the thiophosphates—**8**. 50, 39. Complex salts with antimony pentachloride and phosphorus pentachloride, and phosphoryl chloride have been mentioned in connection with phosphorus pentachloride.

CHAPTER LIII

BISMUTH

§ 1. The History of Bismuth

It is sometimes stated that bismuth was probably known to the ancients, but was confused with lead and tin. Even as late as the seventeenth century, Basil Valentine¹ could write in his *Letztes Testamentum* (Hambourg, 1777) :

Antimony is the bastard of lead, and bismuth is marcasite, the bastard of tin. . . . Antimony comes between tin and lead, while bismuth or magnesia comes between tin and iron.

The term *marcasite* was used by Albertus Magnus, in his thirteenth-century *De rebus metallicis et mineralibus* (Rouen 1476), and by A. Libavius in his fourteenth-century *Alchymia* (Francofurti, 1595), for a variety of different minerals. It is therefore unlikely, as G. Hoffmann has shown, that bismuth was known to the Orientals under the name *markaschite*, or *marcasite*. Towards the end of the sixteenth century, G. Agricola referred to *bisemutum* or *plumbum cinereum* as a specific metal different from lead and from tin ; A. Libavius said that the regulus of bismuth does not differ from that of antimony ; and it was sometimes called *antimonium femininum* or *female antimony*. M. Ettmüller, about the end of the seventeenth century, regarded bismuth as a kind of lead, for he said : Three kinds of lead are known : (i) ordinary lead, (ii) tin, and (iii) bismuth ; and added that the third approaches more nearly to silver. This seems to have been an untested hypothesis because for at least a century longer bismuth was confused with other metals. Thus, G. Agricola said that bismuth was also called *testum argenti*, since it was supposed to be silver which nature had not perfected. N. Lemery did not consider bismuth to be a specific metal. He said :

Bismuth is a sulphureous marcasite found in tin mines. Many believe that bismuth is an imperfect tin which partakes of a good store of arsenic. . . . It is more probably a regulus of tin prepared artificially in England in imitation of a rare natural bismuth. . . . The pores of bismuth are disposed in another manner than those of tin because the menstruum which dissolves tin cannot entirely dissolve bismuth.

Similar views were held by M. Po'i, C. F. du Fay, and J. H. G. von Justi. J. Hellot did not accept N. Lemery's opinion that bismuth can be made by melting arsenic and tin with potassium tartrate and nitrate ; and he prepared a button of *véritable bismuth* from a cobaltiferous bismuth ore. In 1739, J. H. Pott observed the action of many reagents on bismuth ; and in 1753, C. J. Geoffroy showed that bismuth is a specific metal which has many analogies with lead. The reactions of bismuth were studied by J. d'Arcet, B. G. Sage, B. Pelletier, T. Bergman, L. B. G. de Morveau, L. E. Pouchet, R. J. Haüy, L. Clouet, C. Hatchett, W. Lewis, W. A. Lampadius, C. L. Cadet de Gassicourt, J. Davy, P. Lagerhjelm, L. J. Chaudet, G. S. Sérullas, etc.

The origin of the word *bismuth* has not been clearly established. F. von Kobell² accepted the opinion that the word comes from the Arabian *wiss majah*t—in allusion to its melting as easily as storax, but S. Fraenkel could not accept this. According

to C. Hintze, M. de Lazard connects it with the Persian word *sipedak* or *isfidaz*, meaning white; and G. Hoffmann, and M. Ruland connect the word with *Bleuweiss*—white-lead. J. Matthesius, and E. O. von Lippmann consider that the word is of German origin, for *wismat* is a German miner's term, *wis mat* meaning *weisse masse*, i.e. a white mass or a white metal. The *w* passes into *b* when latinized.

§ 2. The Occurrence of Bismuth

Bismuth is a common element, but it is neither abundantly nor widely diffused in nature. F. W. Clarke and H. S. Washington¹ estimated that the igneous rocks of the earth's crust contained $n \times 10^{-7}$ per cent. of bismuth, and J. H. L. Vogt, $n \times 10^{-8}$ per cent. According to H. Rowland,² and M. N. Saha, the spectral lines of bismuth have not been detected in sunlight; although J. N. Lockyer, and C. C. Hutchins and E. S. Holden attributed to bismuth some of the lines in the solar spectrum. The bismuth lines in the spectra of meteorites were examined by J. N. Lockyer.

Elemental bismuth occurs in veins in gneiss and other crystalline rocks, and in clay slate. It usually accompanies various ores of silver, cobalt, lead, zinc, and tin. It may also be associated with gold and silver. G. Agricola³ referred to the deposits of bismuth in Saxony and Bohemia; and J. Hellot, to those in Cornwall. Native bismuth probably results from the reduction of other ores of the metal, although the Bolivian deposit may be primary. The bismuth is intergrown with cassiterite, and wolframite may also be present. The following analyses of native bismuth were reported respectively by H. Sjögren, D. Forbes, F. A. Genth, P. T. Cleve and C. H. J. von Feilitzen, and V. I. Vernadsky and A. E. Fersman:

	Bi	Te	As	Pb	Sb	Fe	S	SO ₂
Nordmark	63	—	—	28-65	—	2-46	5-18	—
Illampu, Bolivia	94-46	5-09	0-38	—	—	—	0-07	—
Pic, Bolivia	99-91	0-04	—	—	—	trace	—	—
Fahlun	91-95	—	—	—	—	—	—	—
Transbalkans	79-45	—	—	—	0-35	—	18-61	0-19

The occurrence of native bismuth in Cornwall was described by R. Höernes, J. H. Collins, and R. P. Greg and W. G. Lettsom; in Devonshire, by G. A. Kennigott; and in Cumberland, and Stirlingshire by R. P. Greg and W. G. Lettsom. The German and Czechoslovakian deposits—Schneeberg, Annaberg, Johangeorgenstadt, Altenburg, Reuss,

Württemberg, Wittichen, Bieber, Hartz, Silesia, Bohemia—were described by A. Frenzel, P. Groth, F. Sandberger, L. Fletcher, G. Leonhard, W. von Gümbel, M. Websky, V. R. von Zepharovich, and C. Zimmermann; those in Hungary, by V. R. von Zepharovich; in Steiermark, by V. R. von Zepharovich, and E. Hatle; in Carinthia, by V. R. von Zepharovich, and A. Brunlechner; in Salzburg, by V. R. von Zepharovich, and E. Fugger; in Switzerland, by C. Heusler, and M. Ossent; in France, by G. Leonhard, and A. Carnot; in Norway, by G. Leonhard; in Sweden, by A. Erdmann, H. Sjögren, L. J. Igelström, G. Leonhard, and P. T. Cleve and C. H. J. von Feilitzen; in Russia, by M. von Tscheffkin, and N. von Kokscharoff; in Canada, by G. C. Hoffmann; in Connecticut, South Carolina, and Colorado, by J. D. Dana, G. F. Kunz, and H. J. Burkart; in Mexico, by H. J. Burkart, and C. F. de Landeroy; in Bolivia and Chili, by I. Domeyko, G. Rose, D. Forbes, F. A. Genth, and A. Arzruni; in Tasmania, by G. vom Rath, and H. von Foullon; in Victoria, by C. H. F. Ulrich; in New South Wales, and Queensland, by A. Liversidge; in South Australia, by A. L. Sack; and in South-West Africa, by G. Gürich.

Native bismuth is perhaps the most important ore mineral. The bismuth minerals rarely occur alone, and are nearly always associated with other ores. The bismuth deposits are grouped in these classes: (i) The *bismuth-tin deposits* in which the bismuth is associated with tin and copper, with tungsten and molybdenum as accessories—e.g. the Bolivian deposits, and those at Chili, Peru, Argentina, Queensland, New South Wales, Tasmania, France, and Cornwall. (ii) The *bismuth-cobalt deposits* have the bismuth associated with cobalt and uranium—e.g., the deposits in Saxony. (iii) The *bismuth-gold deposits*—e.g., Queensland, New South Wales, Norway, and United States.

The bismuth minerals include: **Bismuthides**.—*Chilenite*, or bismuth-silver, Ag_5Bi or Ag_6Bi ; *matildite*—a bismuth-silver alloy; *maldonite*, bismuth-gold, Au_2Bi . **Sulphides, selenides, or tellurides**.—*Bismuthinite* (sometimes *bismuthite*) Bi_2S_3 ; *guanajuatite*, or *frenzelite*, $Bi_2(Se,S)_3$; *alaskite*, a galeno-bismuthinite; *silaonite*—a mixture of guanajuatite, bismuthinite, and bismuth; *tapalpite*, a silver bismuth sulphotelluride; *tellurobismuth*, Bi_2Te_3 ; *tetradymite*, Bi_2Te_2S ; *joselite*, $Bi_2Te(S,Se)$; *grünlingite*, Bi_4S_3Te ; and *wehrlite*, Bi_2Te_2 , or $AgBi_2Te_2$. **Sulpharsenide, and sulphantimonides**.—*Callitite*, $(Ni,Co,Fe)(Sb,Ad,Bi)S$; *bismutosmaltite*, $Co(As,Bi)_3$; *alloclase*, $Co(As,Bi)_2$; *hauecornite*, $(Ni,Co,Fe)(S,Bi,Sb,As)_3$; and *saynite*, a mixture of polydymite, Ni_4S_8 , and bismuthinite. **Sulphobismuthites**.—*Chiviatite*, $Pb_2Bi_8S_{11}$; *cuprobismutite*, $Cu_6Bi_8S_{15}$; *rezbanyite*, and *dognacskaite*, $Pb_4Bi_{10}S_{19}$; *plenargyrite*, and *matildite*, $AgBiS_2$; *empletite*, $Cu_2Bi_2S_4$; *galenobismutite*, $PbBi_2S_4$; *bismutoplagionite*, $Pb_5Bi_3S_{17}$; *alaskite*, $(Pb,Ag,Cu)_2Bi_2S_4$; *selenobismutite*, $PbBi_2(S,Se)_4$; *klaprothite*, $Cu_6Bi_8S_9$; *schirmerite*, $(Ag,Pb)_3Bi_4S_9$; *kobellite*, $Pb_2(Bi,Sb)_2S_5$; *cosalite* or *bjelkite*, $Pb_3Bi_2S_5$; *schapbachite*, $(Pb,Ag)_2Bi_2S_6$; *wittichenite*, Cu_3BiS_3 ; *tapalpite*, $Ag_3Bi(S,Te)_3$; *aikainite*, or *needle-ore*, or *parvite*, $Cu_2Pb_2Bi_2S_8$; *lillianite*, $Pb_3Bi_2S_6$; *zeegerite*, $Pb_6Bi_2S_9$; and *fahlerz*, in which some of the antimony is replaced by bismuth. **Oxides, and oxidized ores**.—*Bismite* or *bismuth ochre* is a yellow earth approximating in some cases to Bi_2O_3 ; *tanzite* is a mixture of bismuth ochre with other substances; and *bolivite*, a mixture of bismuth ochre and bismuthinite. Amongst other oxidized ores are *carelinite*, Bi_4O_9S ; *atelesite*, $(BiO)_2Bi(OH)_2(AsO_4)$; *montanite*, $\{Bi(OH)_2\}_2TeO_4$; *arsenobismite*, $2Br_2O_3 \cdot As_2O_5 \cdot 2H_2O$; *rhagite*, $Bi(BiO)_3(AsO_4) \cdot 4H_2O$; *pucherite*, $BiVO_4$; *mixite*, $BiCu_{10}(AsO_4)_5(OH)_3 \cdot 7H_2O$; *walpurkite*, $Bi_{10}(VO_3)_3As_4O_{28}$; *uranosphärite*, $(BiO)_2U_2O_7 \cdot 3H_2O$; *eulytite* and *agricolite*, $Bi_4(SiO_4)_3$; *bismutoferrite*, $Bi_2Fe_4Si_4O_{27}$ (probably a mixture); *bismuthspar*, *bismuthite*, or *bismutosphaerite*, $(BiO)_2CO_3$; and *daubréeite*, $BiOCl$.

It will be observed that of the three related amphoteric elements, arsenic, antimony, and bismuth, the acidic property is dominant in arsenic; and the basic property is dominant in bismuth; while in antimony, the acidic property is rather more pronounced than the basic quality. Most of the minerals just enumerated are not of common occurrence. Bismuth and its sulphide, bismuthinite, are the principal ores; and bismuth ochre or bismite is the commonest oxidation product. The geographical distribution of the bismuth ores is illustrated by the map, Fig. 1.

Europe.—In *Britain*,⁴ small, unimportant deposits occur in Cornwall, and Cumberland; and also at Alva, Stirlingshire. Formerly a small amount of bismuth was produced in England. In *Germany*,⁵ Saxony for a long time had the world monopoly in the production of bismuth, but the output in recent years has been small. The ores are found mainly at Schneeberg, Johangeorgenstadt, Schwarzenberg, Altenberg, Annaberg, and Zinnwald in Saxony. Ores also occur near Nassau, at Wittschen, and at Schutzbach. There is a small deposit in *France* at Meymac, Corrèze; Pay-les-Vignes; and at Framont, Vosges. In *Spain*,⁶ a small amount of bismuth ore is also produced in the Conquista district of Cordoba.

Some veins of bismuth occur in the Val d'Anniviers, Switzerland. In *Austria*, fahlbands occur at Schladming, Styria, where they are known as *Brandes* on account of the brown, weathered zone they form at the surface. Native bismuth also occurs in the Lolling-Hüttenberg district of Carinthia. In *Czechoslovakia*, bismuth ores occur at Joachimstal, Bohemia. In *Yugo-Slavia*,⁷ there are bismuth deposits at Gradiste, Aldinats, Algin Dol. and Jasikova. In *Rumania*, bismuth ore is found at Cziklova, and at Rezbanya. In *Russia*, bismuth-gold occurs at Schil-Isset, Urals. Small amounts occur in the cobalt ores of Scandinavia. In *Norway*, bismuth is associated with gold ores at Svartdal; and with copper near Drammen. The bismuth mines are at Kjennar. In *Sweden*, bismuth is found at Fahren, and in some of the deposits of the cobalt fahlbands.

Asia.—Bismuth ores occur in Lower *Burma*.⁸ Small quantities have been found in the *Dutch East Indies*⁹—near Lake Toba; Banca; Western Borneo; and Western Celebes. In *China*,¹⁰ some bismuth ochre has been produced in the Kiangsi Province; but the districts of Wong Yuen, Yuigte, Pao Au, Shiang Shau, and Chin Chow have deposits of bismutite and bismuth ochre, which are worked from the surface, and furnish over 5 per cent. of the world's production. In *Japan*,¹¹ there are scattered occurrences of bismuth ore which may be associated with ores of tungsten and molybdenum, and with gold, silver, or copper. The chief occurrences are at Nisizawa in Shimotsuke; Nakanosawa in Yechigo; Ikuno in Tajima; Imooka, and Hade in Mimasaka; Tomikuni in Tamba; and Kamioka in Hida. In *Korea*,¹² there are deposits in the Hwang Hai Province. In *Siberia*,¹³ bismuth ore occurs between Olovyana and Berezoff, and also in the Zabaykalye region.

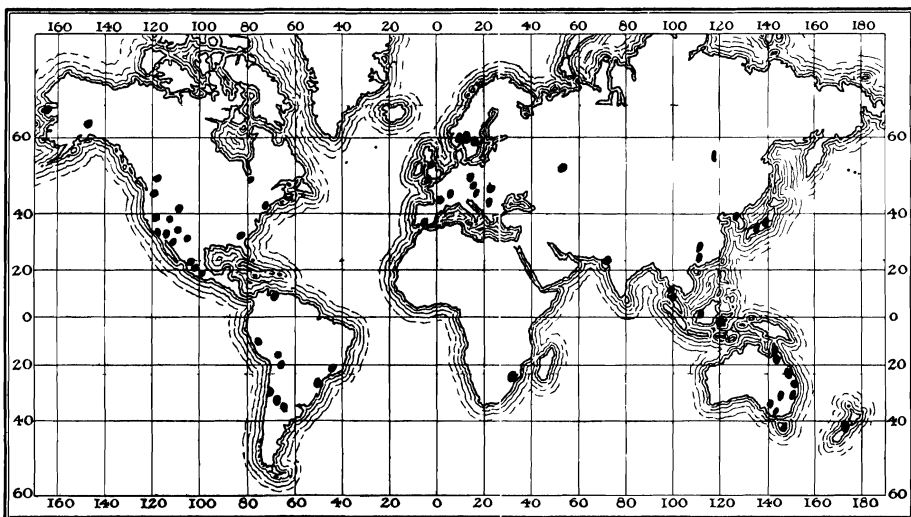

FIG. 1.—Geographical Distribution of Bismuth-bearing Districts.

Africa.—Bismuth ore is distributed in Northern *Rhodesia*,¹⁴ particularly in the Kaomba field of the Luana Valley. Ores have also been found in the Lomagundi, Umtali, and Victoria districts of Southern Rhodesia. In the *Transvaal*, bismuth is associated with the gold ores of the Sabi and Lydenberg districts.

North America.—In *Canada*,¹⁵ bismuthinite is associated with the gold-silver-copper ores of Rossland, British Columbia; and native bismuth is associated with the ores of the Cobalt District, South Lorrain, Otter Township, Shining Tree, and Port Arthur, Lake Superior. Bismuth ores are found in many parts of the *United States*; ¹⁶ but the metal is produced only as a by-product in the smelting of lead, copper, gold, and silver ores. Thus some is recovered from the flue-dust of the copper smelters; and some from the slimes in the electrolytic refining of lead. Bismuth minerals occur in Alaska—Eva Creek, Cherley Creek, and Fairbanks; in Yuma Co., Arizona; in Rincon, and Nevada City, California; in Leadville, Colorado; Trumbull, Connecticut; at Dahlonga, and Ashbury, Georgia; at Cooper, Maine; at Elkhorn, Montana; in the goldfield district, Nevada; at Eagle, New Mexico; in the Chesterfield district, South Carolina; Garfield, Utah; near Loon Lake, Washington; and in the Jelm mountains of Wyoming. Bismuth minerals occur in several parts of *Mexico*¹⁷—in the States of Guanajuato, Jalisco, Queretaro, Sinaloa, Sonora, and Zacatecas.

South America.—A small amount of bismuth ore is produced in *Argentina*,¹⁸ from the provinces of La Rioja, and Sierra de San Luis. *Bolivia*¹⁹ is the principal producer of bismuth ores in the world, and it could easily supply all the world's demands. The ores

are always associated with tin; they occur in the departments of Potosi, and La Paz on the Cordillera Real, or the eastern branch of the Andes. In *Brazil*,²⁰ native bismuth and bismuth ochre occur in the gold mines of Minas Geraes; in the State of Rio Grande do Sul; and at Brijões and St. Antonio du Jesus in Bahia. In *Chili*, native bismuth and bismuth ores occur near Juan Godoy and San Antonio, Atacania. In *Peru*,²¹ there is an important mine in the Department of Junin. Deposits of bismuth minerals occur near Tocuyo, Venezuela.

Australasia.—Native bismuth occurs in the Owen gold-field, *New Zealand*.²² In *Australia*,²³ native bismuth and bismuth minerals occur with those of tin, tungsten, and molybdenum. In *New South Wales*, bismuth deposits occur in the districts of New England, Cobar, and Whipstick; in Queensland in the Eastern districts, particularly Cook, and Burnett—and comprising the districts of Kennedy, and Port Curtis, Moreton, Burke, Darling Downs, Leichardt, and Wide Bay; in *Victoria*, bismuth and bismuth ores occur at Linton, and Maldon; in *Tasmania*, in the Middlesex district, and at Dundas, South Heemiskirk, Mount Ramsay, Mount Lyell, and King Island; in *South Australia*, there is an important deposit in the Onkaparinga Hundred; and in *Western Australia*, at Melville.

In 1909, Australia produced 19.2 metric tons of bismuth; Spain, 76.5; and Peru, 30.3. In 1911, Australia produced 18 metric tons; Bolivia, 550; Spain, 51; and Peru, 24.4. Incomplete returns are indicated in Table I. The average price in

TABLE I.—THE WORLD'S PRODUCTION OF BISMUTH OR BISMUTH ORE.

London was 7s. 6d. per lb. in 1892; 3s. in 1895; 5s. in 1897; 7s. 6d. in 1900; 10s. in 1904 and in 1914; 11s. in 1917; 12s. 6d. in 1919; 9s. in 1922; and 8s. 6d. in 1924. According to R. Allen,²⁴ refined bismuth is usually put on the market in 25-lb. bars, which are packed in wooden boxes, holding 150 lb., with wooden wedges between the bars, the minimum wholesale lot being 500 lb. There are no standard specifications, but the refined metal must be 99.9 per cent. pure. When used for making medicines the metal must be absolutely free from arsenic; for alloy-making the freedom from arsenic is not so important.

Bismuth occurs as an accessory constituent in many minerals. Antimony and bismuth are not so commonly associated as is the case with arsenic and bismuth. K. A. Hofmann²⁵ found bismuth in *bröggerite*; and W. F. Hillebrand, in *uraninite*; but F. Soddy observed none in Singalese *thorite*. C. M. Kersten, A. Frenzel, and A. Carnot found bismuth associated with arsenic or arsenical *pyrites*; T. Petersen, with *arsenical nickel*; H. Laspeyres, and C. F. Rammelsberg, with *smaltite*; C. Winkler, with *trögerite*; H. Laspeyres, with *corneycite*; A. Piutti and E. Stoppani, with *pyrites*; H. Ramage, with the flue-dust from South Yorkshire *coals*; G. T. Lindroth, with *scheelite*; F. Field and F. A. Abel, with *copper ores*; and H. N. Warren, and W. N. Hartley and H. Ramage, with *iron ores*. In consequence of the association of bismuth with many of metal ores, bismuth is sometimes found

associated with metals—e.g. copper, iron, tin, and lead. F. Field said that bismuth is contained in all copper coinage—from the Bactrian coins, 181 B.C., to our own—in all cupreous ores except the carbonates, and in nearly all specimens of commercial copper.

Traces of bismuth have been reported in some spring waters, or in the ochreous deposits from the same. Thus, A. and G. de Negri²⁶ found traces in the water of Casteggio, Cremona; and T. Poleck, in the water of Flinsberg, Silesia. H. A. L. Wiggers found a trace of bismuth in the ochreous deposit from the spring-water of Driburg, but R. Fresenius did not confirm this. T. Poleck found 0.003 per cent. Bi_2O_3 in the ochreous deposit of the spring-water of Flinsberg, Silesia, and E. Reichardt, the same amount of bismuth trioxide in the deposit from the spring-water at Liebenstein, Thuringia.

§ 3. The Extraction of Bismuth

Bismuth ores are usually associated with other minerals; and the ore requires concentrating before the bismuth is extracted. The ore is first milled in a stamp-battery, and then undergoes a system of water concentration. In the case of an ore containing, say, quartz gangue, native bismuth, bismuthinite, bismite, molybdenite, and wolframite, the water classification furnishes concentrates which are dried, and screened to three products. The over-size is re-ground. The three products are passed through magnetic concentrators, and the resulting products are a bismuth concentrate, a tungsten concentrate, and a tungsten-iron concentrate. The magnetic concentration of the bismuth ores in Tasmania was described by W. E. Hitchcock and J. R. Pound.¹ The tailings from the slime tables are passed on to the flotation plant. They contain the bulk of the molybdenite which is classified by differential treatment with kerosene liquor as described by W. H. Bowater.

Bismuth can be extracted from its ores by dry or wet processes. These operations have been discussed by C. F. Plattner,² C. Winkler, and C. Schnabel. When the ores contain bismuth in the form of metal, it can be separated by a *process of liquation*. The bismuth melts at a relatively low temp., 270°. When the ore is heated to the m.p. of bismuth in inclined, cylindrical, cast-iron retorts, the molten bismuth separates from the gangue, trickles down the retort, and is tapped at the lower end. The process was formerly used at Saxony. The objection to the process is that it is very wasteful, since from 5 to 33 per cent. bismuth may escape extraction and remain in the residues. In the *fusion or smelting process*, the whole of the ore is melted with a suitable flux. The gangue separates as a slag, and floats on the surface of the metal. On account of the volatility of the bismuth and its oxide, the smelting has to be conducted at a relatively low temp. The fluxes employed are soda-ash with 10–30 per cent. of lime, and hæmatite. In some cases pyrolusite replaces the hæmatite so as to give a slag with a smaller sp. gr. Fluorspar can also be employed to make the slag fluid. All depends on the nature of the gangue to be slagged. Shaft furnaces are not used for the work because of the severe corrosive action of bismuth on the lining of the furnace. On a small scale, the smelting is effected in crucibles made of fireclay or of fireclay fortified with 10–20 per cent. plumbago. The crucibles are heated in the ordinary wind furnace. On a large scale, the smelting is effected in a reverberating furnace built on an iron pan because of the rapid penetration of the brickwork by the bismuth.

The fusion process allows the addition of desulphurizing or of reducing agents to ores so as simultaneously to extract the bismuth from the bismuth sulphides or oxides which may be associated with metallic bismuth. Ores containing a high proportion of sulphide are often roasted; and coal, or iron, or both, may be used as the reducing agent. Sulphide ores can be directly reduced by fusion with iron; or the roasted ore is reduced with carbon. The direct reduction process resembles the extraction of lead by the precipitation process. During the roasting, the chemical processes resemble those which occur during the extraction of lead from galena by roasting and reduction. A certain quantity of sulphate is formed during the roasting of bismuth sulphide, and the sulphate is only incompletely decomposed by raising the temp. of the charge, but it is reduced in the fusion. The arsenic and antimony are converted into trioxides during the roasting, and are partly volatilized and partly converted into arsenates and antimonates. The latter are decomposed by coal, coke, or charcoal added towards the end of the roasting, and much of the arsenic and antimony volatilized. Any bismuth oxide volatilized is caught in condensers attached to the flues. A. Valenciennes³ described the treatment of some Bolivian ores containing 22.80–30.05 per cent. Bi; 10.20–16.90 per cent. Fe; 9.50–12.15 per cent. Cu; and 16.90–19.50 per cent. S. He said:

The powdered mineral was roasted for 24 hrs. in a reverberatory furnace. The oxidized mass was then mixed with 3 per cent. of carbon, and a flux of lime, carbonate of soda, and fluorspar, and placed in another reverberatory furnace having a basin-shaped bed. For two hrs. a reducing flame was made to play over the mass, which was frequently stirred; the heat was then urged to whiteness, and in two hrs., the whole being quite fused, the furnace was tapped at the side, and the fused mass collected in a cast-iron receiver lined with clay, in which it was allowed to become quite cold. Three layers were found in the receiver, the lowest being metallic bismuth, the next a matle of sulphides of bismuth and copper, and the uppermost a slag containing all the iron. The bismuth contained 2 per cent. of antimony and lead, and 2 per cent. of copper, with traces of silver. The antimony was removed by fusion with nitre, the other metals being separated by the wet process. The matle contained 5 per cent. to 8 per cent. of bismuth, and was treated exactly as above, whereby all but 1 per cent. of bismuth was removed, which was recovered by the wet process.

Oxidized ores are rarely available for smelting. They can be reduced by carbon in crucibles or reverberatory furnaces. The oxycarbonate ore at Meymac was formerly treated by a wet process described by A. Carnot. A. Valenciennes thus described the process for an oxidized ore containing tungsten:

The bismuth was extracted by treating the powdered mineral with hydrochloric acid; the acid decanted and partially neutralized with sodium carbonate, was then turned into a large quantity of water; and the precipitated bismuth oxychloride collected and washed, was placed in contact with metallic iron. The bismuth so reduced was dried and fused with an alkaline flux. It still retained traces of lead and silver. The residues, insoluble in hydrochloric acid, were dried and calcined with sodium nitrate. This on extraction with boiling water gave sodium tungstate.

The oxide is dissolved by hydrochloric acid more cheaply than by nitric acid. W. Mrazek proposed sulphuric acid as a solvent for bismuth in argentiferous lead; V. de Luynes, nitric acid for lead-bismuth alloys; C. Rössler, sulphuric acid. Aqua regia or hot conc. sulphuric acid may be necessary to dissolve the metal or alloy. F. F. G. Eulert proposed a salt soln. and nitric and sulphuric acid as solvent, and ferric chloride has also been proposed. Once in soln., the bismuth can be precipitated as metal by iron—the metals lead, zinc, tin, cadmium, copper, or manganese also precipitate the bismuth. The bismuth can also be precipitated as a basic salt by diluting the chloride with water. The precipitated oxychloride is reduced by fusion with lime and charcoal; or by treating the moist oxychloride with iron or zinc along with some slaked or caustic lime to remove the acid. Precipitated bismuth is fused in graphite or iron crucibles with an alkaline flux if necessary. J. W. Kynaston recovered bismuth from cupriferous flue-dust by treatment with hydrochloric acid, precipitation with calcium carbonate; and reduction with carbon under molten sodium chloride. Guggenheim Bros. obtained bismuth from ores, etc., by volatilization as sulphide when heated in the vapour of sulphur, hydrogen sulphide, or carbon disulphide at 800°–900°. W. Buddëus reduced the ore with silicon or silicides.

Bismuth is generally obtained from metallurgical products—mattes and alloys—by wet processes. In special cases, mattes can be treated for bismuth by roasting followed by smelting with carbon. When a lead-bismuth alloy is submitted to an oxidizing fusion, the lead is first oxidized, and the bismuth commences to oxidize only when the greater proportion of lead has been removed. If the alloy be cupelled the cupel first removes the litharge, then litharge containing bismuth oxide, and last, if the oxidation be stopped at the right moment, bismuth is produced. The bismuth is ground fine, and digested with hydrochloric acid, when the bismuth and a little lead are dissolved as chlorides. The soln. is neutralized with sodium carbonate, and the bismuth precipitated as oxychloride by water. The washed oxychloride is reduced to bismuth as previously indicated. W. Borchers proposed to extract bismuth from lead by an electrolytic process. The alloy is fused with molten alkali chlorides through which is passed an electric current. The lead is dissolved as chloride, and deposited as metal at the cathode or at the bottom of the cathode compartment, while, with a suitable current density, the bismuth and silver remain undissolved, and collect at the bottom of the anode compartment. The results are less satisfactory than smelting processes. The electrodeposition of bismuth was discussed by A. Engelenburg, and J. Lukas and A. Jilek.

The crude bismuth obtained by these processes may contain lead, copper, arsenic, antimony, sulphur, tellurium, iron, cobalt, nickel, thallium, etc. Johnson, Matthey, and Co.⁴ gave the following as typical analyses of South America crude bismuth metal:

Bi	Pb	Sn	Sb and As	Cu	Ag	Au
96·0	3·5	0·2	0·2	0·1	—	—
84·800	4·925	0·725	5·525	3·450	0·3005	0·0045

The former had 34 ozs. of silver per ton, and the latter had traces of iron and sulphur, and 0·270 per cent. of oxygen and loss. This composition of bismuth was discussed by R. Schneider, V. Sill, H. Thürach, C. Ekin, N. G. O. Coad, F. A. Genth, D. Forbes, A. Classen, E. Matthey, and G. Brownen. E. A. Smith found from 0·0003 to 0·0110 per cent. of gold, and 0·0705 to 0·3319 per cent. of silver in various samples of bismuth. Impure bismuth is not suited for many of the purposes for

which bismuth is employed. Bismuth intended for the pharmaceutical preparations must be freed from arsenic and tellurium. The so-called pure commercial bismuth on the market should be freed from copper, tellurium, antimony, lead, and contain not more than 2 parts per million of arsenic. The silver content varies from 3 to 10 ozs. per ton.

The purification of bismuth by the dry methods is less effective, but cheaper, than by wet processes. In the cases when a number of foreign elements are present, the dry method cannot be completed in one operation. The dry process of refining bismuth may involve a liquation of the nickel, or remelting the metal with fluxes of various kinds. C. Méhu removed arsenic by heating the bismuth above its m.p. so as to expose a large surface to air; sulphur is also removed as sulphur dioxide. The residue is remelted with soda and charcoal and tartar or dry soap, and again heated in air. E. Matthey said that all the arsenic can be eliminated from the well-stirred alloy heated above its m.p.—say, to 395° – 513° —in air—no loss of bismuth was observed; and antimony can likewise be removed by prolonged fusion and constant stirring. The arsenic volatilizes as oxide, the arsenic oxide separates as an oily film. H. Thürach removed arsenic and iron by fusing the bismuth with potassium chlorate mixed with 2–5 per cent. of sodium hydroxide. G. A. Quesneville removed the arsenic by melting the bismuth with nitre and common salt—some iron and lead are removed at the same time. W. Borchers also removed arsenic and antimony by melting the metal with nitre and sodium hydroxide taking care to avoid overheating; he used a mixture of sodium hydroxide and sulphur when a considerable proportion of antimony is present. H. Tamm removed arsenic by fusing the metal with iron in the presence of a flux, say borax, and removing the compound of iron and arsenic as a scum. Much bismuth is lost by volatilization. G. Werther removed arsenic by fusing the bismuth with one-eighth of its weight of sodium hydroxide, and one-sixty-fourth of its weight of sulphur. E. Matthey said that antimony can be completely removed by melting in clay crucibles the bismuth with bismuth oxide in an amount equal to 2.5–3 times the weight of the antimony to be removed. The reaction is $2\text{Sb} + \text{Bi}_2\text{O}_3 = \text{Sb}_2\text{O}_3 + 2\text{Bi}$. The antimony oxide mixed with some bismuth oxide rises to the surface as a scum. E. Matthey removed copper by fusing the bismuth with small proportions of sodium sulphide, and skimming off the scoria, which contains all the copper. The temp. is low and there is very little loss of bismuth by volatilization. According to H. Tamm, copper can be removed by projecting a mixture of potassium cyanide and sulphur (8 : 3) on to molten bismuth. The potassium thiocyanate which is formed with the evolution of heat causes the copper to form sulphide which separates as a scum; any bismuth sulphide formed is reduced to metal. Lead, antimony, and arsenic are removed at the same time. E. Matthey said that copper is removed as sulphide by melting the bismuth with bismuth sulphide, which is in turn reduced to bismuth. To remove lead, W. Borchers recommended fusing the metal in cast-iron pots for 3 hrs. with a mixture of bismuth oxychloride sodium and potassium chlorides, and sodium hydroxide. Gold and silver can be removed by the aid of zinc, and the zinc is removed by oxidation in air as recommended by W. Mrazek.

The wet processes usually furnish bismuth of a higher degree of purity than the dry processes; and are employed only when the salts are required for medicinal purposes, or for use in the laboratory. According to H. Thürach, silver is not all precipitated from a soln. of bismuth nitrate by adding hydrochloric acid; and R. Schneider said that traces of silver follow the precipitate of the basic nitrate. According to H. Rose, H. Thürach, and A. Classen, the lead cannot be all removed by repeatedly precipitating the bismuth as basic nitrate; nor by repeatedly precipitating the bismuth as oxychloride. W. B. Herapath dissolved the metal in nitric acid; precipitated the basic nitrate with water; boiled the residue with alkali-lye to remove arsenic or lead; redissolved the washed oxide in nitric acid; and again precipitated the basic nitrate with water. E. C. Deschamps dissolved bismuth in nitric acid, so that tin or tin oxide remained in the residue. When the

soln. is treated with ammonia, bismuth hydroxide is precipitated leaving copper and silver in soln. The precipitate was boiled with potash-lye to dissolve lead and arsenic. The precipitate was then dissolved in nitric acid, and the basic nitrate precipitated by water. R. Schneider dissolved the bismuth in nitric acid at 75°–90° when the arsenic separates out as bismuth arsenate accompanied by some basic nitrate. If cold acid is used, sparingly soluble bismuth arsenite is formed. The filtered soln. is evaporated for crystals of bismuth nitrate which are quite free from arsenic. J. Löwe treated an acid soln. of the metal with ammonia, and washed the precipitate with ammonia-water. The residue was dissolved in a mixture of 8 per cent. soda-lye mixed with one-twelfth its vol. of glycerol. The filtrate from the insoluble iron and nickel hydroxides was boiled with glucose to precipitate the bismuth. The washed precipitate, often fused with carbon in a covered crucible, contained no arsenic. W. Hampe melted the bismuth with a mixture of sodium carbonate and sulphur; dissolved the well-washed sulphide in nitric acid; precipitated the basic nitrate by water; again dissolved in nitric acid, and precipitated the oxide by ammonia. The dried oxide was reduced to metal by heating it in a current of hydrogen. G. W. Kahlbaum and co-workers, and F. Krafft and co-workers, purified the metal by distillation in vacuo. Other observations on the wet process of extraction, or the purification of bismuth, were made by J. J. Berzelius and P. Lagerhjelm, R. Böttger, H. M. Forstner, J. L. Smith, C. Winkler, P. L. Haskisson, E. Rupp, E. R. Darling, and W. Spring. A. Yamada and co-workers dissolved the crushed ore in 5–20 per cent. sulphuric or hydrochloric acid—preferably the former; precipitated the bismuth by adding iron; and washed the precipitate with acid, and water, and dried in inert or reducing gases or in vacuo. The product was put in paraffin and heated to 300°–500° to expel impurities—arsenic or molybdenum—and the molten bismuth poured into a mould.

According to A. Classen, the bismuth obtained by repeated precipitation as oxychloride still contains lead; but it is possible to obtain the metal spectroscopically pure by electrolysis. The purified salt can be deposited from a nitric acid soln. so that lead and bismuth peroxides are deposited on the anode, and crystalline bismuth on the cathode. The bismuth is washed with alcohol, melted under 98 per cent. potassium cyanide, cast in a mould, and when cold, washed with water and polished. B. Zakorsky and co-workers proposed to refine bismuth commercially by using the impure metal, cast into plates, as anode, and a carbon, purified bismuth, or platinum cathode in the electrolysis of dil. nitric acid with a current density of 3 amps. per sq. dm. The purified bismuth which collects on the cathode is washed with dil. nitric acid, dried, melted, and cast into ingots. If the electrolyte becomes too rich in lead, the bismuth in soln. can be precipitated by lead; and the lead nitrate recovered from the liquor. In refining lead electrolytically, the anode mud contains bismuth, lead, and silver. F. Förster and E. Scwabe said that the mixture can be separated electrolytically by using a soln. of bismuth fluosilicated as electrolyte. The lead passes into soln., the silver remains undissolved. The potentials of lead and silver in soln. of their fluosilicates containing an eq. per litre are +0.144 and –0.295 volt respectively. Soln. containing as little as 26 grms. of bismuth per litre give perfect deposits with 0.004 amp. per sq. cm. More conc. soln., and higher temp. allow higher current densities to be used.

According to F. Mylius and P. Groschuff, in the further purification of commercially "pure" bismuth, by precipitation as oxide and sulphide the amorphous precipitates retain other metals tenaciously. The electrolytic method of separation also fails. The basic salts form amorphous precipitates, and the best method of separation is found to be the crystallization of the normal nitrate from conc. nitric acid. This is also suitable for the purification of bismuth. The nitrate, if already of fair purity, is dissolved in half its weight of 8 per cent. nitric acid, and mixed with an equal weight of the conc. acid. The crystals, which separate on cooling to 0° or –10°, are washed with a little ice-cold nitric acid. All impurities are thus conc. in the mother-liquor. The nitrate is converted into oxide by heat, and

the oxide is then reduced by fusion with potassium cyanide. A further purification, if necessary, is effected by melting the metal under paraffin and removing the first (purest) crystals by means of a glass spoon.

According to P. Thibault,⁵ when bismuth mellitate, $\text{Bi}_2\text{C}_{12}\text{O}_{12}$, is heated under reduced press. in closed tubes, decomposition begins at about 350° , carbon dioxide is evolved, and *pyrophoric bismuth*—a mixture of carbonaceous matter with finely divided bismuth—is formed. It inflames spontaneously when thrown into air, forming bismuth trioxide. L. Vanino and A. Menzel obtained pyrophoric bismuth by reducing a mixed precipitate of aluminium and bismuth hydroxide by heating to 170° – 210° in hydrogen. F. Hérard reported *amorphous bismuth* to be formed by heating ordinary bismuth to bright redness in a current of nitrogen—hydrogen and carbon dioxide do not give the same result. The product contains 99.6 per cent. of bismuth and 0.4 per cent. of oxygen. The presence of oxide explains the high m.p., 410° , but not the low sp. gr. 9.483. The amorphous bismuth is more readily attacked by reagents than the ordinary form—*e.g.* it dissolves almost instantly in nitric acid. E. Cohen and J. Olie said that this form of bismuth can be obtained only by the use of imperfectly purified nitrogen, and that it really consists of the ordinary metal, in a finely divided state, mixed with more or less bismuth trioxide.

G. F. Taylor⁶ described the manufacture of thin filaments of bismuth; and J. A. Becker and L. F. Curtiss, F. K. Richtmyer and L. F. Curtiss, and B. Pogany examined the properties of these films of bismuth; and H. Kahler, the structure. V. Kohlschütter and J. L. Tüscher obtained highly dispersed bismuth trioxide by volatilization in the electric arc. T. Goldschmidt and V. Kohlschütter condensed the vapour either by a drop in temp., or oxidation in a blast; and L. Gurwitsch obtained highly dispersed bismuth by shaking bismuth shot in a liquid. C. Paal and L. di Pol found sodium protalbinat to be an effective protective agent; and they obtained a hydrosol by the addition of bismuth nitrate dissolved in aq. glycerol to an aq. soln. of sodium protalbinat or lysalbinat containing sodium hydroxide; after being centrifuged, the soln. are dialyzed against water and subsequently evaporated in vacuo at 50° , and finally over conc. sulphuric acid. They also obtained colloidal bismuth by reducing commercial *bismon*—*i.e.* colloidal bismuth hydroxide—by formaldehyde. The reduction of a dil. aq. soln. of a bismuth salt with an organic substance furnishes a **colloidal solution of bismuth**. For example, L. Vanino dissolved 2 grms. of bismuth tartrate in a soln. of tartaric acid and potassium hydroxide, and made it up to about 600 c.c., and obtained a clear brown liquid when the soln. was treated with 1.5 grms. of stannous chloride dissolved in dil. alkali-lye. Nearly all the bismuth remains in suspension as a **hydrosol**. The sol behaves like the hydrosol of gold towards the electric current and is deposited on the anode. If the bismuth be salted out, only part of it again forms a hydrosol. R. Schneider assumed that the suspensoid is bismuth suboxide, but L. Vanino and F. Treubert hold that it is elemental bismuth. According to A. Lottermoser, when bismuth nitrate (2 mols) is dissolved in water containing a little nitric acid, and a soln. of ammonium citrate is added until the resulting precipitate dissolves, the soln. made alkaline with ammonia, added to a soln. of stannous chloride (3 mols) prepared in a similar manner, and the mixture quickly heated, colloidal bismuth is deposited in the form of a very fine, black precipitate of the **hydrogel**. This will dissolve in water, but is reprecipitated on addition of a soln. of any salt, or of an acid. It is transformed into the insoluble form of the metal by continued boiling of its soln., or by a large excess of stannous salts. L. Kalle and Co. mixed a dialyzed soln. of egg-albumen in soda-lye, with a glycerol soln. of bismuth nitrate, and after dialysis, evaporated the soln. to dryness in vacuo below 60° . The product is *bismuth colloidal*. A. Gutbier and G. Hofmeier obtained an unstable colloidal form of bismuth by the action of hypophosphorous acid on bismuth oxychloride. When a dil. soln. of hydrazine hydrate is added to a hot soln. of ammoniacal copper sulphate, a copper hydrosol is obtained from which copper gradually separates. In the presence of

gum arabic, this hydrosol is more stable. A. Gutbier and co-workers also used titanous chloride as reducing agent, and they studied the action of the protective colloids—agar-agar, tubera salep, and gum arabic. They obtained colloidal soln. by the action of sodium thiosulphate on bismuth nitrate in the presence of the protective colloid. According to A. Kuhn and H. Pirsch, bismuth sols containing 3.5 mgrms. per c.c. may be prepared by the reduction of bismuth tartrate soln. with sodium hyposulphite in weakly alkaline soln. This shows an improvement on the methods which with stannic acid as a protective colloid give sols containing 1.5 mgrms. per c.c. A. Gutbier used hæmoglobin as protective colloid in preparing the colloid by reducing soln. of bismuth salts with sodium hyposulphate, or with formaldehyde. E. Fouard prepared colloidal bismuth by electrolyzing a soln. of a salt of the metal containing a pure organic colloid (albumin, starch, or gelatin) with a current of a few milliampères. At the cathode, the metal ions are neutralized by the repelled negatively-charged colloid micelles. A colloidal organo-metallic complex is thus formed. The anode is separated by immersion in a collodion cell rendered semi-permeable by precipitated copper ferrocyanide. The cathode should be a bad conductor so as to reduce the frequency with which formation of the complex occurs on the cathode. T. Svedberg prepared **organosols** by the electrical spluttering of bismuth electrodes dipping in say ethyl ether, or isobutyl alcohol—**3, 23, 10**. According to E. F. Burton, some of the particles of the electrically prepared bismuth sol are positively charged, presumably in consequence of the formation of hydroxide.

§ 4. The Physical Properties of Bismuth

Bismuth metal is tin-white with a reddish tinge and a high lustre. F. Hérard¹ said that the vapour in a current of nitrogen is green; and W. L. Dudley, greenish-blue. A. W. Wright found that these films are also greyish-blue. J. C. Poggendorff also obtained films coloured yellow, red, violet, blue, and green. G. A. Quesneville obtained it as a mass of **crystals** by melting the commercial metal in a crucible, adding nitre from time to time, and stirring, until a portion of the fused metal taken out and exposed to the air no longer assumes an indigo-blue and afterwards a violet or rose colour which disappears on cooling, but rather assumes a green or golden-yellow tint which is retained on cooling. The fused metal is then poured into a heated pot which is covered so as to prevent the surface from solidifying before the other part. If the metal be cooled too slowly, it forms layers, and not fine crystals. As soon as the mass is half solidified, the crust formed on the surface is pierced with a hot coal, and the still liquid portion poured out. A. Nies obtained crystals by suspending pieces of iron in a bath of molten metal and allowing it to cool. It is difficult to obtain crystals in the wet way. N. W. Fischer, J. Löwe, C. W. C. Fuchs, and J. Barlot obtained a black crystalline powder by the action of zinc or iron on a soln. of bismuth nitrate. N. A. Puschin obtained crystals from the soln. in mercury. P. P. Heberdey observed acicular crystals of bismuth in the slag from a smelting furnace at Przibran, Bohemia.

The early observers reported that bismuth crystallizes in cubes and octahedra, but G. Rose showed that the crystals are trigonal, and have the axial ratio $a : c = 1 : 1.3036$. Observations were also made by W. Haidinger, C. W. Zenger, F. Stolba, J. Barlot, H. C. H. Carpenter, and F. Wöhler. The **cleavage** on the (0091)-face is perfect; while that on the (02 $\bar{2}$ 1)-face is not so good. M. L. Huggins studied the relation between the cleavage and the electronic structure. O. Mügge studied the **percussion figures**; and A. Johnsen, the **gliding planes**. The **X-radio-grams** were found by A. Johnsen to agree with the assumption that the molecule is diatomic, with atomic centres 3×10^{-8} cm. apart. This is in agreement with the fact, observed by H. Biltz and V. Meyer, that bismuth dissolved in a large proportion of lead is diatomic, and that the vap. density of bismuth between 1600° and 1700° lies between 10.125 and 11.983 when the value calculated for Bi is 7.2, and for Bi₂, 14.4. R. W. James found that the edge of unit rhomb of bismuth is 3.28×10^{-8} cm., and the closest approach between two atomic centres is 3.11×10^{-8} . A. Ogg calculated 6.52×10^{-8} for the length of the bismuth

rhombs. W. P. Davey gave $a=4.539$ A., and $c/a=2.606$ A. O. Hassel and H. Mark represented the atoms arranged on two interpenetrating face-centred rhombohedra; and L. W. McKeehan represented the lattice as a simple rhombohedron with a set of rhombohedral axes mutually inclined at $57^\circ 16'$. The atoms are not uniformly placed along the trigonal axis. The data were collected by P. P. Ewald and C. Hermann. The results with arsenic, antimony, and bismuth are:

	As	Sb	Bi
Edge a of the face-centred rhomb	5.60 A.	6.20 A.	6.56 A.
Angle α	$84^\circ 36'$	$86^\circ 58'$	$87^\circ 34'$
Short atomic distances	2.51 A.	2.87 A.	3.11 A.
Long atomic distances	3.15 A.	3.37 A.	3.47 A.

H. Kahler examined the structure of thin films. M. L. Huggins, and J. Barlot studied the lattice and electronic structure. H. Kahler found that thin films obtained by spluttering have a crystalline structure. Polished surfaces of the metal were examined by W. Campbell, and W. Herold. F. Stöber, J. A. M. van Liempot, and I. V. Obreimoff and L. V. Shubnikoff described the preparation of large crystals, and E. von Gomperz, the properties of single crystals drawn into wires; while G. Tammann and H. Bredemeier observed the vol. of the channels opening out on the surface of the metal. E. Bekier measured the velocity of crystallization. The analogies between the phosphorus-bismuth family of elements were discussed by P. Möller, G. Linck and H. Jung, etc.—*vide* arsenic.

Among the early records of the **specific gravity** of bismuth, P. von Muschenbroek² gave 9.67; T. Bergman, 9.861; J. Dalton, 9.8; M. J. Brisson, 9.822; G. Leonhard, 9.800; L. J. Thénard, and J. J. Berzelius, 9.8827; W. Herapath, 9.831; C. J. B. Karsten, 9.6542; H. G. F. Schröder, 9.713; A. Matthiessen and M. Holzmann, 9.823 at 12° ; G. Quincke, 9.819 at 0° ; E. Grüneisen, 9.78; and F. L. Perrot, 9.848–9.887. R. F. Marchand and T. Scheerer gave 9.799 for the sp. gr. of the purified metal, at 19° ; 9.783 for the commercial metal; and 9.556 for the compressed metal; C. J. St. C. Deville, 9.935 for the crystals; and 9.677 for the metal which had been rapidly cooled from the fused state. For native bismuth, D. Forbes gave 9.77–9.98; and P. T. Cleve and C. H. J. Feilitzen, 9.1. A. Classen gave 9.7474 for the sp. gr. of the highly purified metal; J. F. Spencer and M. E. John, 9.23 at 20° ; H. G. Dorsey, 9.84 at 20° for cast bismuth; R. von Dallwitz-Wegner, 9.80; and G. W. Kahlbaum, 9.78143 at $20^\circ/4'$ for the metal distilled in vacuo. I. I. Saslawsky gave 9.806 for the sp. gr. at room temp., and 21.3 for the at. vol. C. del Fresno studied this subject. T. M. Lowry and R. G. Parker gave 9.8093 for the sp. gr. of bismuth *en masse*, and 9.7798 when in the form of filings. G. Quincke gave 9.819 for the sp. gr. at 0° , and 9.709 for the sp. gr. of the molten metal; L. Playfair and J. P. Joule gave 9.798 for the molten metal; and H. Siedentopf, 10.004. W. C. Roberts-Austen and T. Wrightson gave 9.82 for the sp. gr. at ordinary temp., and 10.039 for that of the molten metal; while G. Vicentini and D. Omodei gave 9.787 for the sp. gr. at 0° , 9.673 for the sp. gr. of the solid at 270.9° , and 10.004 for the liquid at 270.9° . L. L. Bircumshaw gave 10.03 at 300° ; 9.91 at 400° ; 9.66 at 600° ; 9.40 at 802° ; and 9.20 at 962° . K. Bornemann and P. Siebe measured the sp. vol. at different temp. F. Nies and A. Winkelmann gave 1.0310–1.0497 for the ratio of the sp. gr. of bismuth in the liquid and solid states. R. Böttger observed that a glass tube can be broken by the expansion of the contained bismuth during solidification. J. Johnston and L. H. Adams gave 0.00342 c.c. per gram for the expansion which occurs on melting; K. Bornemann and P. Siebe found a 3 per cent. contraction and A. Hess a 3.5 per cent. expansion, and H. Endo, 3.32 per cent. K. Töpler found the expansion to be 3.27 per cent. Observations were also made by W. C. Roberts-Austen and T. Wrightson. C. Lüdeking showed that the maximum density is attained some degrees above the m.p.—between 268° and 270° —for in rising to that temp. from the m.p., there is a 3 per cent. contraction. C. J. St.

C. Deville gave 9.935 for the sp. gr. of bismuth before fusion, and 9.677 after fusion; but T. Murray was unable to detect the slightest expansion at or after the moment of solidification. The metal attains a maximum density just above its f.p., and it decreases in density until its f.p. is attained, after which it contracts uniformly. T. R. Hogness gave 10.00 for the sp. gr. of the liquid at 320°; 9.95 at 365°; 9.88 at 426°; and 9.82 at 472°; or, the sp. gr., D , at θ° is $D=10.07-0.00125(\theta-269)$. M. Plüss gave 9.999 for the sp. gr. of the liquid at 283°; 9.981 at 330°; 9.973 at 350°; 9.968 at 361°; and 9.967 at 365°; R. Arpi, 9.75 at 528°; 9.82 at 452°; 9.89 at 390°; 9.91 at 366°; 9.94 at 335°; and 9.99 at 280°; but F. Sauerwald and K. Töppler, 9.430 at 600°; 9.810 at 451°; and 9.984 at 304°. According to W. Spring, the sp. gr. is increased by compression until the pores are closed, and thereafter, compression makes very little difference. Thus, the sp. gr. of a sample at 13.5° before compression was 9.804; after 3 weeks' compression at 20,000 atm., the sp. gr. at 15°, rose to 9.856; and after a second compression, the sp. gr. at 15° was 9.863. He also found that the sp. gr. fell from 9.783 to 9.779 by compression at 50,000 kgrms. per sq. cm.; to 9.655 by compression at 75,000 kgrms.; and to 9.556 by compression at 100,000 kgrms. per sq. cm. The sp. gr. was also reduced a little by torsion. J. Johnston and L. H. Adams found that the sp. gr. of these cylinders after compression at 15,000 atm. were 9.8012, 9.7886, and 9.8001, and after annealing for 2 hrs. at 340°, respectively 9.8028, 9.7898, and 9.7971. A wire which had been considerably deformed had a sp. gr. 9.7692–9.7693, and 9.7767–9.7768 after annealing for 2 hrs. at 230°. T. M. Lowry and R. G. Parker noticed an expansion on annealing. These data do not agree with the assumption of W. Spring, and G. T. Beilby that by deformation a part of the metal passes into the amorphous state, although it fits in with the assumption that there are enantiotropic forms of bismuth. O. Faust and G. Tammann hold that the hardening during the deformation is not due to the formation of a harder crystalline form, or to a change to the amorphous condition, but rather to a diminution in the size of the crystallites of which the metal is composed, owing to the formation of systems of sliding surfaces. M. Polanyi studied the changes in structure produced in bismuth by cold-work. A. Ludwig found that when molten bismuth is subjected to a press. of 8000–17,000 atm. during cooling, the sp. gr. of the solid did not differ from that of ordinary bismuth; the crystalline structure was different, for the texture was very finely crystalline, resembling that of fine-grained iron. When the press. was 3000 atm. the piston sprang back with an audible shock corresponding with the expansion on solidification. W. L. Bragg calculated 1.48 Å. for the **atomic radius**; M. L. Huggins, 2.6 Å.; V. M. Goldschmidt, 1.82 Å.; and E. N. Gapon, 1.88 Å. H. G. Grimm made observations on the ionic radius. H. H. Potter found no difference between the **gravitational accelerations** of bismuth and brass; H. A. Wilson examined the relation between the mass and weight of bismuth; and G. F. Brush found that bismuth falls slightly faster than zinc under conditions where the time of descent would be the same if equal masses represented equal weights.

H. Biltz and V. Meyer found the **vapour density** of bismuth to be 10.125–11.983 between 1600° and 1700°. The value calculated for the molecule Bi is 7.2, and for Bi₂, 14.4. A. Johnsen said that the mol. wt. of the vapour between 1600° and 1700° corresponds with Bi and Bi₂. According to H. von Wartenberg, the **molecular weight** of bismuth corresponds with monatomic molecules at 2070°. C. T. Heycock and F. H. Neville found that the lowering of the f.p. of bismuth dissolved in cadmium or tin agrees with a monatomic mol; and with lead as solvent, with a diatomic mol; and G. McP. Smith, with mercury as solvent, found the results agree with a monatomic mol; and I. Traube found that the properties of bismuth are in general agreement with a monatomic mol. A. Jouniaux obtained the average mol. wt. 245 over the range from the m.p. to the b.p. A. Johnsen said that the molecule in the rhombohedral crystals is diatomic; dissolved in lead, diatomic; and dissolved in mercury or cadmium, monatomic. W. R. Fielding discussed the polymerization of bismuth.

According to G. Linck, **allotropic forms** of bismuth analogous to the three forms of antimony and arsenic have not been discussed, although he assumed that anisotropic and isotropic forms remain to be discovered. F. L. Perrot noticed that the thermoelectric force of cast bismuth changes spontaneously with time. According to E. Cohen, and A. L. T. Moesveld, bismuth exists in two allotropic forms with a transition temp. at 75° and 760 mm.; and the transition of the α -bismuth, stable below this temp., into the β -bismuth stable above this temp., is accompanied by an increase in vol. The β -variety can exist in a metastable state below the transition temp. E. Cohen showed that the transition temp. varies with the previous history of the metal. Finely-divided bismuth which has been in contact with a 10 per cent. soln. of potassium chloride for 12 hrs. diminishes in vol. at 70°, although the same sample of metal, before treatment with the salt soln., showed no change in vol. at this temp. J. Würschmidt observed anomalies in the changes in volume with bismuth amalgams near 75°; and he said that the sp. gr. of bismuth *en masse* is 9.80, and in powder, 9.70. This is taken to mean that during the comminution, the material passes from one allotropic form to another. J. Johnston and L. H. Adams said that the sp. gr. of most substances is variable owing to the lack of homogeneity, and that, in consequence, slight changes of sp. gr., whether produced by compression or other means, cannot be regarded as satisfactory evidence of a transformation or chemical reaction. E. Jänecke³ observed a break at 112° in the press.-temp. curve of bismuth. This is assumed to correspond with an allotropic transformation.

The **hardness** of native bismuth on Mohs' scale is 2.0–2.5; R. J. Rydberg gave 2.5. C. A. Edwards and A. M. Herbert gave 14.0 for Brinell's hardness. P. Ludwig gave for hardness by the press. of a sphere for 300 seconds at 17°, 8.90; at 55°, 6.85; at 108°, 4.55; at 160°, 2.96; at 227°, 1.69; and at 263°, 1.16; and when the load is exerted for 15 seconds, at 17°, 12.2; at 54°, 9.55; at 156°, 4.66; at 181°, 3.60; at 252°, 2.01; and at 262°, 1.65. K. Houda and R. Yamada studied the abrasive hardness. M. Georgieff and E. Schmid found that the breaking strain of bismuth crystals by a force perpendicular to the plane of splitting is 324 grms. per sq. mm. It is independent of temp. between –80° and +20°. The plastic deformation begins at a definite critical tension which diminishes with rising temp. up to 200°, and then remains about constant until the m.p. is reached. Whether a crystal is ductile or brittle depends on its orientation in the bismuth wire. E. Grüneisen found the **elastic modulus** or **Young's modulus** of cast bismuth of sp. gr. 9.78 to be 3250 kgrms. per sq. mm., and for the **transverse modulus**, 3390 kgrms. per sq. mm. F. A. Schulze, and W. Voigt found 3200 kgrms. per sq. mm. for the elastic modulus; 1240–1372 kgrms. per sq. mm. for the **torsion modulus**; and **Poisson's ratio**, 0.33. E. von Gomperz found the elastic limit is lower with wires of single crystals than in wires of crystal aggregates. B. MacNutt and A. Concilio measured the load at which a noise is heard in the stressed metal. P. W. Bridgman found 2.29×10^{11} and 2.45×10^{11} for Young's modulus in c.g.s. units for bismuth wires, and if the compressibility be 2.8×10^{-12} c.g.s. units, Poisson's ratio becomes 0.39. W. Voigt, and F. A. Schulze gave for the **compressibility**, 0.3×10^{-5} kgrm. per sq. cm. P. W. Bridgman measured the elastic constants of single crystals of bismuth; and he also found the initial compressibility of extruded bismuth to be 31.8×10^{-7} at 30°, and $\delta v/v_0 = -(35.35 - 28.0 \times 10^{-5}p)p \times 10^{-7}$; and at 75°, $\delta v/v_0 = -(35.94 - 28.7 \times 10^{-5}p)p \times 10^{-7}$; and for a cast cylinder the initial value at 30° was 25.6×10^{-7} at 30°, and $\delta v/v_0 = -(22.02 - 9.0 \times 10^{-5}p)p \times 10^{-7}$; and at 75°, $\delta v/v_0 = -(22.11 - 9.0 \times 10^{-5}p)p \times 10^{-7}$. He also found the cubic compressibility of single crystals over the range $p = 12,000$ kgrms. per sq. cm. to be $29.17 \times 10^{-7}p - 22.43 \times 10^{-12}p^2$ at 30°, and $29.89 \times 10^{-7}p - 31.13 \times 10^{-12}p^2$ at 75°. P. W. Bridgman gave for the compressibility, β , for samples of cast and extruded bismuth at 30° respectively $\beta = 0.0_52202$ and 0.0_53535 ; $\delta\beta/\delta p = 0.0_582$ and 0.0_4158 ; and $-\delta\alpha/\alpha\delta p = 0.0_550$ and 0.0_433 . T. W. Richards gave 3.0×10^{-6} for the average compressibility at 20° between 100 and 500 megabars. L. H. Adams

and co-workers obtained 3.00×10^{-6} per megabar at zero press. and 2.57×10^{-6} at 10,000 kgrms. per sq. cm. press. They also gave for the change in volume $\delta v = 0.9 \times 10^{-4} + 2.923 \times 10^{-6}(p-p_0) - 2.38 \times 10^{-11}(p-p_0)^2$. L. H. Adams gave for $\delta\beta = -0.47$. E. Jänecke found a break at about 112° in the press.-temp. curve of bismuth. J. H. Hildebrand and co-workers measured the **internal pressure** of bismuth. N. S. Kurnakoff and S. F. Schamtschuschny gave for the plasticity or **pressure of flow**, 21.0 kgrms. per sq. mm. with a piece of metal of diameter 8.66 mm. M. Georgieff and E. Schmid, O. Hasse and E. Schmid also measured the flow of the metal under press. D. C. Stockbarger prepared wires by the extrusion process. H. Siedentopf found the **surface tension** of bismuth at its m.p. to be 43.78 mgrms. per mm., and the temp. coeff. was 0.000233; the **specific cohesion**, $a^2 = 8.755$ per sq. mm.; and the temp. coeff. 0.000117; and the mol. **surface energy**, 0.50. W. Hagemann gave $\sigma = 300$ dynes per cm. for the surface tension; H. Siedentopf, 430 dynes per cm.; G. Quincke gave $\sigma = 464.9$ dynes per cm.; and $a^2 = 9.76$ per sq. mm.; and T. R. Hogness gave 375 dynes per cm. at 320° ; 371 at 365° ; 367 at 426° ; and 365 at 472° . F. Sauerwald and G. Drath found at 583° , $\sigma = 353.9$ dynes per cm.; at 770° , $\sigma = 344.0$ dynes per cm.; and at 779° , $\sigma = 343.9$ dynes per cm. The temp. coeff. is $\delta\sigma/\alpha T = 0.060$. L. L. Bircumshaw gave 388 dynes per cm. at 300° ; 380° at 400° ; 367 at 600° ; 353 at 802° ; and 340 at 962° ; and for the sp. cohesion, a^2 per sq. cm., 0.0779 at 300° ; 0.0782 at 400° ; 0.0775 at 600° ; 0.0767 at 802° ; and 0.0754 at 962° . For the temp. coeff. of the surface tension, L. L. Bircumshaw gave -0.27 ; and for the surface energy, 3176 ergs per sq. cm. at 300° ; 3224 at 400° ; 3279 at 600° ; 3332 at 802° ; and 3359 at 962° . Observations were also made by Y. Matuyama. R. von Dallwitz-Wegner found the **cohesion pressure** to be 112,535 atm. at 0° , and 90,372 atm. at 100° . C. E. Fawsitt found the **viscosity** of bismuth at 360° to be 0.0167; M. Plüss gave 0.01620 at 283° ; 0.01609 at 288° ; 0.01525 at 330° ; 0.01494 at 350° ; 0.01473 at 355° ; 0.014685 at 361° ; 0.01455 at 365° ; R. Arpi, 0.0146 at 280° ; 0.0131 at 355° ; 0.0130 at 366° ; 0.0122 at 390° ; 0.0119 at 452° ; and 0.0114 at 528° ; and F. Sauerwald and K. Töpler, 0.00996 at 600° ; 0.01280 at 451° ; and 0.01662 at 304° . Observations were made by G. Subrahmaniam. W. B. Hardy measured the static **friction** between bismuth and lubricants. The **diffusion** of bismuth in mercury was studied by W. J. Humphreys, and R. Kremann and A. Hrasovic, and of gold in bismuth by W. C. Roberts-Austen. J. Groh measured the rate of diffusion or the rate of exchange of the bismuth in bismuth-amalgam (0.627 grm. Bi per 10 c.c. of mercury) with the bismuth in a soln. of bismuth nitrate and found that in 39, 23, and 14 hrs., respectively with 20 c.c. of a 0.25M-soln., 23 c.c. of a 0.4M-soln., and 20 c.c. of a 4M-soln., the bismuth is exchanged at the respective rates of 0.2×10^{-6} , 0.36×10^{-6} , and 4.7×10^{-6} grm. per sq. cm. of amalgam per sec.

According to H. Kopp,⁴ the coeff. of **thermal expansion**—cubical—between 12° and 41° is 0.000040; and A. Matthiessen found the vol., v , at θ° , to be $v = v_0(1 + 0.043502\theta + 0.07446\theta^2)$, when v_0 is the vol. at 0° . F. Sauerwald and K. Töpler gave 0.00012 for the coeff. of cubical expansion at 300° . G. Vicentini and G. Omodei gave for the coeff. of expansion of (linear) of bismuth at about 270° , 0.04132, and for the mean coeff. of cubical expansion of molten bismuth between 271° and 300° ; A. Hess gave 0.03264 for the liquid and 0.03148 for the solid; and C. Lüdeking, 0.04425 for the interval 270° – 303° . For the coeff. of linear expansion, A. Matthiessen gave 0.041316 between 0° and 100° ; H. G. Dorsey gave for the coeff. of thermal expansion, α , of cast bismuth of sp. gr. 9.84:

	-170°	-150°	-140°	-110°	-90°	-50°	-10°	10°
α	1.041129	0.041136	0.041196	0.041201	0.041230	0.041287	0.041311	0.041280

W. Voigt gave 0.041575, and for the length, l , at θ , $l = l_0(1 + 0.041367\theta + 0.052\theta^2)$, where l_0 is the length at 0° . For the linear expansion of the crystals per degree H. Fizeau gave 0.041621 at 40° and 0.041642 at 50° when parallel to the chief axis;

0.041208 at 40° and 0.041239 at 50°, when perpendicular to the chief axis; and for the average value, 0.041346 at 49°, and 0.041374 at 50°. E. Grüneisen gave for the coeff. of linear expansion, 0.041297 between -140° and 17°; and 0.041345 between 17° and 100°; and G. Vicentini and D. Omodei, 0.04132 at 270°. R. von Dallwitz-Wegner gave for the coeff. of cubical expansion, 0.04351 at 0° and 0.04439 at 100°. J. K. Roberts found that the thermal expansion of crystals of metallic bismuth parallel and perpendicular to the vertical axis, by comparison with that of crystalline quartz, are practically constant from ordinary temp. up to 240°. Bismuth melts at about 270°. The constant expansion coefficients over this range are perpendicular to the axis, 12.0×10^{-6} ; parallel to the axis, 16.2×10^{-6} ; mean, 13.4×10^{-6} . The bending over of the length-temp., curve as the m.p. is approached indicates dissociation of the atoms in the solid. P. W. Bridgman found the linear expansion of single crystals of bismuth at room temp. to be 13.96×10^{-6} parallel and 10.36×10^{-6} perpendicular to the axis. S. Lussana gave 0.041574 for the coeff. of linear expansion between 8° and 180° at 1 atm. press.; 0.041294 at 1000 atm. press.; and 0.041146 at 2000 atm. press. E. Grüneisen discussed the relation between the thermal expansion, compressibility, and at. vol.; and A. Schrauf, the relation between the coeff. of expansion and crystallographic axes.

G. Wiedemann and R. Franz,⁵ and A. von Ettingshausen and W. Nernst found bismuth a bad conductor. The former showed that if the conductivity of silver be 100, that of bismuth is 1.8. L. Lorenz gave for the **heat conductivity** in absolute units 0.0177 at 0° and 0.0164 at 100°; W. Jäger and H. Diesselhorst, 0.0194 at 18°, and 0.0161 at 100°; and E. Giebe, 0.0558 at -186°, 0.0252 at -79°, and 0.0192 at 18°. G. Gehlhoff and F. Neumeier found for electrolytic bismuth, cast, 0.0623 at -190°; 0.0257 at -77°; 0.0244 at 0°; and 0.0231 at 100°. For the pressed powder, 0.0498 at -190°; 0.0194 at 0°; and 0.0121 at 100°. L. Lorenz gave for the temp. coeff. of the conductivity $a = -0.037343$, and W. Jäger and H. Diesselhorst, -0.02197 . S. Konno interpolated the following values for the thermal conductivity, k , from his observations:

	0°	100°	200°	300°	400°	500°	600°	700°
k	0.020	0.018	0.017	0.041*	0.037*	0.037	0.037*	0.037*

The values marked with an asterisk refer to the liquid. If k_α be the thermal conductivity in the direction of the chief axis, and k_γ that in the direction of the base, the square root of the ratio $k_\alpha : k_\gamma$ was found by F. L. Perrot to be 1.170; by L. Lownds, 1.19; and by F. M. Jäger, 1.22. This subject was discussed by E. Jannetaz, C. Cailler, and F. T. Trouton. G. W. C. Kaye and J. K. Roberts found the thermal conductivity of bismuth, in C.G.S. units, at 18°, is 0.0159 when parallel to the trigonal axis; 0.0221, when perpendicular to that axis; and the ratio of these two conductivities is 1.39. For the effect of a magnetic field on the thermal conductivity, *vide infra*, electrical conductivity. H. Kronauer found the so-called temperature conductivity in absolute units to be 0.037 at 2.8°; W. Jäger and H. Diesselhorst, 0.0679 at 18°; and 0.0546 at 100° with the temp. coeff. -0.0023; and E. Giebe, 0.0655 at 18°; 0.0847 at -79°; and 0.1884 at -186°. P. W. Bridgman found that the effect of press. on the thermal conductivity is to reduce the conductivity 37.8 per cent. per 12,000 kgrms. per sq. cm. The press. coeff. is -0.0431, which is negative and numerically high. He also measured the thermal conductivity of single crystals.

The **specific heat** was found by H. V. Regnault⁶ to be 0.03084 between 15° and 98°; E. Bède gave 0.02979 between 9° and 102°, or for temp. up to about 200°, $c = 0.0269 + 0.000020$; and for commercial bismuth 0.02889 between 13° and 106°; 0.03036 between 15° and 175°; and 0.03085 between 13° and 205°. H. Kopp gave 0.0292 and 0.0318; G. W. Kahlbaum, 0.0305; L. Lorenz, 0.03013 at 0°; 0.03066 at 50°; 0.03090 at 75°; and 0.03116 at 100°. F. A. Waterman gave 0.03055; O. Richter, 0.029928 between 0° and 108°; and W. Jäger and H. Diesselhorst, 0.0292 at 18°, and 0.0303 at 100°. E. Giebe gave 0.0303 at 18°, 0.0296 at 79°, and

0.0284 at -186° , or 0.0295 between 18° and -186° ; A. Classen, 0.0318 between 21.7° and 61.6° ; A. Levi, 0.03080 between 22° and 99° ; A. Magnus, 0.300 at 17° to 100° ; and 0.0307 at 16° to 248° ; P. Schübel, 0.0299 at 18° to 100° ; and 0.0305 at 18° to 200° ; and S. Umino gave:

Sp. ht.	75° 0.0296	150° 0.0332	200° 0.0360	300° 0.0373	400° 0.0373	500° 0.0373	600° 0.0373
---------	----------------------	-----------------------	-----------------------	-----------------------	-----------------------	-----------------------	-----------------------

H. Schimpf gave 0.03031 for the sp. ht. between 17° and 100° ; 0.02854 between 17° and -79° ; and 0.02752 between 17° and -190° ; and for the value at 0° , he gave 0.0291. R. Ewald gave 0.0251 at -135° ; 0.0279 at -38° ; and 0.0295 at 28° ; T. W. Richards and F. G. Jackson gave 0.0284 between 18.7° and -188.5° . J. Dewar gave 0.0218 at -223° . N. Stücker gave for the sp. ht., c , at θ , between 60° and 125° , $c=0.0302+0.000054(\theta-60)$; and between 60° and 225° , $c=0.0302+0.000101(\theta-60)$; between 125° and 175° , $c=0.0338+0.000162(\theta-12)$, and between 125° and 225° , $c=0.0338+0.000192(\theta-125)+0.000006(\theta-125)^2$. At 60° the sp. ht. is thus 0.03024; at 125° , 0.03375; at 175° , 0.04185; and at 225° , 0.04695. H. John represented the mean sp. ht. between 22° and θ° , by $c=0.02956327+0.0_5304501124(\theta-22)-0.0_311519898(\theta-22)^2+0.0_945607(\theta-22)^3$; and for the true sp. ht. at θ° , $c=0.02956327+0.0_5609(\theta-22)-0.0_83456(\theta-22)^2+0.0_818243(\theta-22)^3$. This subject was discussed by W. Voigt, L. Schütz, J. H. Awbery and E. Griffiths, E. Horn, and K. Schulz. I. Iitaka gave 0.0338 at 271° for the solid, and 0.0356 at 291° for the liquid; and C. C. Person gave 0.0363 for the sp. ht. of the liquid at 280° - 380° . N. Stücker gave 0.03024 for the true sp. ht. at 60° ; 0.03375 at 125° ; 0.04185 at 175° ; and 0.04695 at 225° . For the mean sp. ht. between 60° and 225° , $c=0.0302+0.000101(\theta-60)$. For the **atomic heat** at 0° , H. Schimpf gave 6.38, and T. W. Richards and F. G. Jackson, 5.91; and at -223° , J. Dewar gave 4.54. G. N. Lewis gave $C_p=6.3$, and $C_v=6.2$ at 20° ; and E. D. Eastman and co-workers examined the effect of temp. on the relation C_p-C_v .

J. Dalton⁷ gave 249° for the **melting point** of bismuth. These results refer to the impure metal; and the results of A. Ermann, 265° ; L. B. G. de Morveau, 246° ; J. Crichton, 249° ; F. Rudberg, 264° - 268.3° ; C. C. Person, 266.8° - 270.5° ; and A. D. van Riemsdyk, 268.3° , represent metals of a higher degree of purity. Later results with bismuth supposed to be purified gave W. Guertler and M. von Pirani 270° ; L. I. Dana and P. D. Foote, 271° ; G. Vicentini, 268.3° ; J. H. Awbery and E. Griffiths, 269° ; A. Classen, 264° ; C. T. Heycock and F. H. Neville, 267.54° ; H. Siedentopf, 264° ; H. L. Callendar, 269.2° ; B. G. Eggink, 271.5° ; H. S. van Klooster, 272° ; F. Mylius and E. Groschuff, $271^\circ \pm 0.15^\circ$; and J. Johnston and L. H. Adams, $270.95^\circ \pm 0.05$. The f.p. of the metal given by C. Lüdeking is 260° - 261° ; G. Grube, and R. S. Williams, 268° ; W. R. Mott, 268° ; G. J. Petrenko, D. P. Smith, K. Hüttner and G. Tammann, and H. G. Mathewson, 273° . The effect of press. is to lower the m.p. of bismuth as is the case with water. According to G. Tammann, the effect of a press. p kgrms. per sq. cm., is to lower the m.p. $d\theta = -0.00386(p-1)$; while J. Johnston and L. H. Adams found that the m.p. is lowered by 3.56° per 1000 atm. press.; and that at

p	1	500	1000	1550	2010 atm.
M.p.	270.7°	267.71°	265.67°	264.04°	262.18°

J. Johnston represented the press., p atm., in atm. necessary to melt the substance at a temp. θ° by $p=95.1QD \log(T_m/\theta)$, where Q denotes the heat of fusion per gram, 12.5 cal.; and T_m , the absolute temp. of the m.p. Hence at 27° , $p=3000$ atm. Some relations between the m.p. and other physical constants were discussed by H. Crompton, P. W. Robertson, N. F. Deerr, and R. de Forcrand. H. Carlsohn said that the m.p. of bismuth compounds does not follow the addition rule. A. D. van Riemsdyk said that at a clear red-heat, the volatilization of bismuth is very small. J. Mensching and V. Meyer observed that at 1450° , volatilization

is appreciable, and H. Biltz and V. Meyer said that volatilization occurs between 1600° and 1700°. According to C. Barus, the **vapour pressure** at 1199° is 32 mm.; and at 1211°, 86 mm. O. Ruff and B. Bergdahl gave 126 mm. at 1290°; 300 mm. at 1385°; 406 mm. at 1410°; and 657 mm. at 1490°; while J. N. Greenwood gave for the vap. press., p mm., at

	1200°	1310°	1420°	1740°	1950°	2060°
p	102	25·7	760°	6·3 × 760°	11·7 × 760	16·5 × 760

From these results, J. A. M. van Liempt gave $\log_{10} p = 5·50 - 9786T^{-1}$; and for the sublimation curve $\log_{10} p = 6·54 - 10360T^{-1}$. J. Johnston gave $\log p = -9010T^{-1} + 8·12$. T. Carnelley and W. C. Williams observed that the **boiling point** lies between 1090° and 1450°. T. Carnelley and W. C. Williams found 1390°–1450°, when H. F. Wiebe's relation furnished 1580°. W. R. Mott gave 1420°; J. N. Greenwood, 1420°; C. Barus, 1450°; J. A. M. van Liempt, 1506° at 760 mm.; and O. Ruff and B. Bergdahl, 1490° at 760 mm. E. Demarçay said that considerable vaporization occurs in vacuo at 292°; and A. Schuller distilled the metal in vacuo and observed that at dull redness the vapour condensed into drops. F. Krafft said that the b.p., in the vacuum of the cathode light, is 1050°; and F. Krafft and L. Bergfeld gave 1000°. F. Krafft and P. Lehmann gave for the b.p. at 50 mm. press. 993°; at 90 mm., 1002°; and at 140 mm., 1009°. J. Johnston gave 540° for the b.p. at 10⁻³ mm.; 620° at 10⁻² mm.; 720° at 0·1 mm.; 840° at 1 mm.; 990° at 10 mm.; 1130° at 50 mm.; 1200° at 100 mm.; and 1440° at 760 mm. W. Herz found that the constant c in the equation $\theta_1/\theta_2 = T_1/T_2 + c(\theta_1 - T_1)$ varies from -0·0004273 to +0·0005562, where θ_1 and θ_2 denote the b.p. of two liquids at a definite press., and T_1 and T_2 , the b.p. at another press. Some relations of the transition temp. were studied by R. Lorenz and W. Herz. W. G. Duffield made estimates of the **rate of vaporization** of liquid bismuth.

C. C. Person found the **heat of fusion** at 266·8° to be 12·6 cal. per gram, or 2·6 Cals. per gram-atom; F. Wüst and co-workers, 10·23 cal.; P. W. Robertson, 12·64 cal.; I. Iitaka, 12·24 cal.; S. Umino, 14·10 cal.; W. Herz, 12·2 cal.; J. H. Awbery and E. Griffiths, 13·0 cal. per gram; and D. Mazotto, and J. Johnston and L. H. Adams, obtained similar results. J. Tate gave 188·6 cal. per gram at 920° for the **heat of vaporization**; J. Johnston, 41·3 Cals.; and J. A. M. van Liempt gave 44·8 Cals. per gram-atom, and for **Trouton's constant**, 25·19. F. A. Henglein discussed the heat of vaporization. This subject was also investigated by R. de Forcrand, E. van Aubel, and A. Wehnelt and C. Musceleanu. C. M. Guldberg estimated the **critical temperature** to be 4600°. G. Tammann and E. Ohler found the at. **heat of solution** of bismuth in gold-amalgam to be -3730 cal., which is nearly the same as in mercury—2730 cal. M. Kawakami studied the heat developed on mixing bismuth with some other metals. E. Kordes gave 4·65 (cals.) for the **entropy**; and B. Bruzs gave 15·2 entropy units at 25°, and 19·4 at the m.p.

S. Haughton⁸ gave 1·17 for the **index of refraction** of bismuth for the *C*-line; G. Quincke gave 1·824 for the *C*-line; 1·315 for the *D*-line; 1·155 for the *E*-line; 1·079 for the *F*-line; and 0·9671 for the *G*-line; A. Kundt gave 2·61 for red-light, and 2·13 for blue-light; P. Drude, 2·07 for red-light, and 1·90 for the *D*-ray; G. Horn, 1·841 for *C*-line; 1·670 for *D*-line; 1·563 for *E*-line; 1·466 for *F*-line; and 1·385 for *G*-line; and P. A. Ross gave 1·78 for red-light, 1·92–1·98 for yellow-light, and 2·20–2·30 for blue-light. The coefficient of absorption of bismuth for the *C*-line was found by S. Haughton to be $k=2·5$; G. Quincke gave 2·119 for the *C*-line; 2·605 for the *D*-line; 2·679 for the *E*-line; 2·656 for the *F*-line; and 2·651 for the *G*-line; P. Drude gave 1·9 for red-light, and 1·93 for *D*-line; G. Horn gave 2·493 for *C*-line; 2·492 for *D*-line; 2·459 for *E*-line; 2·418 for *F*-line; and 2·640 for *G*-line. W. Meyer found for the

index of refraction, μ , and the coeff. of absorption, k , for light of wave-length λ in $\mu\mu$:

λ	.	.	.	441.3	467.8	508	589.3	668
μ	.	.	.	1.38	1.47	1.55	1.78	1.96
k	.	.	.	2.26	2.42	2.54	2.80	3.09

E. Hagen and H. Rubens, P. Drude, G. Quincke, and W. Meyer obtained values for the **reflecting power**, R , of bismuth :

λ	.	.	431	508	630	668	3000	7000	11,000	14,000
R	.	.	58.5	52.2	66.9	57.2	71.7	79.5	83.2	81.6

H. Buisson, and C. W. Heaps observed no change in the emissivity of bismuth when its electrical resistance is increased by a magnetic field. The optical constants were also studied by A. K. Aster, and L. H. Rowse. F. E. Dix and L. H. Rowse measured the index of refraction, μ ; the extinction coeff., k ; and the reflecting power, R , for single crystals with light travelling parallel to the optic axis for wave-lengths $670\mu\mu$ to $350\mu\mu$. The reflecting power is nearly constant at 70 per cent.; while both the index of refraction and extinction coeff. have a maximum at $460\mu\mu$, which is taken to represent the photoelectric threshold of a cleavage surface. J. H. Gladstone gave 0.154 for the **specific refraction**, and 32.0 for the **atom-refraction** of bismuth; E. van Aubel gave 39.2. According to M. Hurion, a beam of light passing through a hole bored in a bismuth plate is deflected when the bismuth is in a magnetic field. S. Procopiu studied the **electro-optical effect**, and the **magneto-optical effect** with powdered bismuth suspended in toluene; and B. Pogany, with thin films of bismuth. O. Wiedeburg investigated the radiation of heat by bismuth. C. W. Heaps found that the emissivity of bismuth at 100° was not affected by a magnetic field of 4900 gauss—probably on account of the absence of magnetic resistance in the surface layers of metal.

J. Piccard and E. Thomas⁹ discussed the colour of bismuth ions. R. Bunsen¹⁰ said that bismuth changes the colourless gas-flame blue. According to R. Böttger, the **flame spectrum** of bismuth chloride in the colourless gas flame shows lines in the red and blue. There are bands due to the oxide. The flame-spectrum is not studied for spectral analysis; it was examined by A. Gouy, J. N. Lockyer, and C. de Wateville; the spectrum with the oxy-coal gas flame, or oxy-hydrogen flame was examined by O. Vogel, W. N. Hartley, and J. Meunier. The **spark spectrum** was observed more or less qualitatively by C. Wheatstone, A. Masson, D. Alter, and T. R. Robinson. The first measurements were made by W. Huggins, and since then numerous observations have been made—notably by W. A. Miller, R. Thalén,

FIG. 2.—The Spark Spectrum of Bismuth.

L. de Boisbaudran, M. C. W. Buffam and H. J. C. Ireton, R. Capron, G. Ciamician, J. Parry and A. E. Tucker, E. O. Hulburt, W. N. Hartley and co-workers, A. de Gramont, E. Demarçay, A. Schuster and co-workers, F. Exner and E. Haschek, O. Lohse, L. and E. Bloch, J. Hartmann, A. Hagenbach and H. Konen, W. Schwetz, R. J. Lang, S. R. Milner, T. Royds, J. M. Eder and E. Valenta, A. Mitscherlich, H. Rausch von Traubenberg, J. H. Pollock, G. A. Hemsalech, E. Diacon, B. Reissmann, and J. Offermann. The principal lines in the visible spectrum are illustrated by Fig. 2. There are the two weak lines, 6129 and 6048, in the orange-yellow; the weak yellow line, 5717; the green lines, 5552(β), 5271, 5209(γ), 5144(ϵ), and 5124; the blue line, 4724(α); the indigo-blue lines, 4302(ζ) and 4259; and the violet line, 4118. F. Brasack was able to detect 0.000166 mgrm. of bismuth by means of the

spark spectrum. *Les raies ultimes* were examined by A. de Gramont, and W. N. Hartley and H. W. Moss; the spark spectrum in aq. soln. of salts by E. O. Hulburt; the spectral analysis of bismuth-lead alloys by E. Schweitzer; and the spectral detection of bismuth in gold, by A. Reis. G. Balasse observed the continuous emission spectrum produced by an electrodeless discharge. The **arc spectrum** was examined by R. Capron, J. C. McLennan and co-workers, T. Royds, M. Kimura, B. E. Moore, A. Sellerio, H. Kayser and C. Runge, J. Hartmann, F. Exner and E. Haschek, A. Hagenbach and H. Konen, J. Stark and R. K uch, W. Schwetz, J. M. Eder and E. Valenta, F. M. Walters, G. R. Tshniwal, and J. Offermann. The intermittent arc spectrum was observed by M. Kimura. The **ultra-red spectrum** was examined by H. Becquerel, H. M. Randall, H. Lehmann, V. P. Lubovich and E. M. Pearen, and F. M. Walters; and the **ultra-violet spectrum**, by W. A. Miller, G. D. Liveing and J. Dewar, R. J. Lang, L. and E. Bloch, V. Schumann, and J. M. Eder. The **absorption spectrum** was studied by J. N. Lockyer and co-workers, W. Grotrian, A. L. Narayan and K. R. Rao, R. Mecke, M. Kimura, R. V. Zumstein, W. Friederichs, J. C. McLennan and A. B. McLay, H. Sponer, J. J. Dobbie and J. J. Fox, and J. G. Frayne and A. W. Smith. A. L. Narayan and K. R. Rao found that the fluorescence of the vapour of bismuth, excited by radiations from 6000 A. to 3500 A., consisted of a banded spectrum in the orange-yellow; when excited by the ultra-violet rays from a bismuth arc, the fluorescence became bluish in colour and had lines at 4722 A. and 3068 A. J. C. McLennan and co-workers studied the fluorescence spectrum of bismuth vapour. Bismuth salts are colourless, according to J. Formanek. The soln. show no absorption effect after treatment with alkanna. C. R. Crymble found an absorption band, with a head at 2852, as the ultra-violet spectrum of bismuth chloride soln. (1 : 1000). He also compared the absorption spectra of the family group—P, As, Sb, and Bi. The absorption spectrum was studied by K. Sch afer and F. Hein, and A. E. Ruark and co-workers. A. L. Narayan and K. R. Rao found that bismuth vapour at 1300° yields an absorption spectrum composed of a very great number of bands shading off towards the red, and presenting a fine structure, they extend from 6500 to 4500 A. The vapour emits an orange-yellow fluorescence, the spectrum of which contains 24 bands from 6600 to 5050 A. A. Terenin, and K. R. Rao studied the resonance and fluorescence spectra of bismuth vapour. The effect of *pressure* on the spectral lines was examined by W. J. Humphreys; and the effect of a *magnetic field*, or the **Zeeman effect**, by J. E. Purvis, P. A. van der Harst, H. Luneland, S. Goudsmit and E. Back, and C. Wali-Mohammed; and the influence of an *electric field*—the **Stark effect** by H. Nagaoka and Y. Sugiura. The *self-induction* effect was examined by G. A. Hemsalech, E. N eul e a, and D. Huber; the *dispersion*, by O. von Baeyer, and H. Geisler; and the *enhanced lines*, by J. N. Lockyer, M. Miyanishi, and J. Steinhhausen. The *structure of the lines* and the **series spectrum** were investigated by A. Ditte, H. Kayser and C. Runge, G. Joos, J. C. McLennan and A. B. McLay, S. Goudsmit and E. Back, E. Gehrcke and O. von Baeyer, A. E. Ruark and R. L. Chenault, C. Wali-Mohammed, V. Thorsen, H. Nagaoka and T. Mishima, L. Aronberg, and K. Sch afer and F. Hein. H. Nagaoka and Y. Sugiura pointed out a number of frequency differences in a few bismuth lines, but, according to A. E. Ruark and R. L. Chenault, some of these are spurious, and C. Runge said that the connection between the satellites of mercury 2536, and bismuth 4722, and the isotopes of these elements described by H. Nagaoka and co-workers is a mere chance effect. E. T. Wherry found that the crystals are poor **radio-detectors**.

The *K-series* of the **X-ray spectrum** was examined by W. Duane¹¹ and co-workers, J. M. Cork and co-workers, E. Friman, H. R. Robinson and A. M. Cassie, G. R echou, and M. Siegbahn and E. J onsson; the *L-series* was found by H. Hirata, D. Coster, M. de Broglie, H. R. Robinson, E. Friman, C. E. Eddy and L. H. Turner, K. Lang, W. Duane and R. A. Patterson, S. J. M. Allen,

and M. Siegbahn to have the lines $\alpha_2\alpha$, 1.1533; $\alpha_1\alpha$, 1.14115; $\beta_1\beta$, 0.94930; $\beta_2\gamma$, 0.95293; $\gamma_1\delta$, 0.83708; ϵ , 1.31295; η , 1.057; $\beta_5\zeta$, 0.9223; $\gamma_2\theta$, 0.7929; $\beta_4\nu$, 0.9754; $\beta_3\phi$, 0.9357; $\gamma_3\chi$, 0.7874; and $\gamma_4\psi$, 0.761. J. C. Karcher, E. Hjalmer, W. Stenström, G. Wentzel, D. Coster, and M. Siegbahn gave for the *M*-series, α , 5.124; β_1 , 4.915; β_3 , 4.604; γ_1 , 4.534; γ_2 , 3.932; γ_3 , 3.840; α' , 3.916; α , 3.9014; β , 3.7083; γ , 3.4714; δ , 2.943; ϵ , 2.813; *M*, 5.124; *M*₂, 3.326; and *M*₃, 2.873. V. Dolejšek gave for the *N*-series, $N_7P_1=13.040$, and $N_7P_2=13.140$ for the *N*-series, N_7P_1 , 13.040; and K_7P_2 , 13.140. J. C. Chapman¹² found that the **X-rays** have a fluorescent effect. H. Whiddington observed the effect of X-rays on the ejection of high-speed electrons from bismuth (oxide). A. L. Foley observed no definite change occurs when bismuth is exposed for a long time to X-rays. S. J. M. Allen studied the absorption of X-rays by bismuth; and T. E. Aurén found the absorption coeff. to be 677 when that of hydrogen is unity. J. Stark and G. Wendt observed that the surface perpendicular to the crystals is attacked by **canal rays** three times as fast as the basal surface. A. E. Ruark and co-workers gave 8.0 volts for the **ionizing potential**, and 1.9, 3.9, and 5.7 volts for the inelastic collision potential of bismuth. G. Shearer examined the emission of electrons from bismuth exposed to X-rays. K. H. Kingdon gave 8 volts for the **ionizing potential** of bismuth vapour; and G. Riccardi, 8.48 volts. B. Rosen discussed this subject. J. E. P. Wagstaff gave 1.63×10^{12} for the **vibration frequency**; and W. Herz, 1.62×10^{12} . W. P. Jorissen and J. A. Vollgraff thought that the proportion of thallium spectroscopically perceptible in bismuth was increased by exposing the metal to **cathode rays**. M. Kimura and G. Nakamura found the cathode ray spectrum closely resembled the spark spectrum. L. Meitner showed that the **α -ray** activity of bismuth from Joachimsthal pitchblende residues is due to ionium, and not to a new element as supposed by K. Fajans and E. Towara. A. G. Shenstone concluded that the passage of an electric current through a plate of bismuth augmented the **photoelectric effect**; but F. Horton attributed the result to the evolution of gases owing to the warming of the apparatus by the current. T. J. Parmley found the photoelectric threshold of single crystals lies between 2804 Å. and 2894 Å. B. Gudden¹³ and R. Pohl, R. Hamer, R. S. Bartlett, and M. Hake studied the photoelectric effect with submicroscopic particles of bismuth; F. Gross, the effect with films of bismuth; and A. T. Waterman, the effect of temp. on the emission of electrons. The **radioactivity** of bismuth—*vide* polonium—was examined by F. Giesel, W. Marckwald, etc. The effect of bismuth compounds on the **luminescence** of calcium sulphide, etc., was studied by A. Forster, L. de Boisbaudran, H. Becquerel, A. Verneuil, V. Klatt and P. Lenard, etc. H. Kopfermann found that the fluorescence of bismuth vapours at 950° gave the spectral lines 4722.72 Å. and 3067.81 Å. The glowing of bismuth wires was shown by W. B. Pietenpol and H. A. Miley to be due to a film of oxide. The optical resonance of bismuth was measured by G. Mie. E. Adinolfi found that **X-rays** have an effect on the arrangement of bismuth during solidification, varying in nature with the hardness of the rays. H. R. Robinson, and R. Whiddington studied the liberation of electrons by X-rays from bismuth oxide; S. J. M. Allen, R. A. Houstoun and N. Ahmad, the absorption of X-rays; and A. L. Foley, the effect of exposure to X-rays, or to ultra-violet light on the spectrum.

P. E. Shaw and C. S. Jex¹⁴ found that bismuth does not show a negative charge by frictional electricity with glass. The **electrical conductivity** of bismuth is good. K. F. Herzfeld, and A. Günther-Schulze studied the metallic conduction of bismuth. L. Lorenz gave 9290 mhos at 0° and 6300 mhos at 100°; E. van Aubel, at 0°, 9200 mhos for hard bismuth and 9260 mhos for soft bismuth; F. A. Schulze, 8300 mhos at room temp.; W. Jäger and H. Diesselhorst, 8400 mhos at 18°, and 6240 mhos at 100°; E. Giebe, 8610 mhos at 18°, 11,960 mhos at -79°, and 24,520 mhos at -186°; and J. A. Fleming and J. Dewar, 7500 mhos at 60°, 8840 mhos at 19°, 11,970 mhos at -58.6°,

and 24,570 mhos at -187.5° . The **electrical resistance**, the reciprocal of the conductivity, is 0.000088 when at 19° , according to J. Dewar and J. A. Fleming; E. Giebe gave 0.000086 ohm at 18° ; W. Jäger and H. Diesselhorst, 0.000084 ohm at 18° ; and A. Werner, 0.000083 ohm at 22° . P. Lenard gave 0.000092 ohm at 155° for pressed wire, and 0.000087 ohm at 230° . For the effect of *temperature* on the resistance, R_0 , between 0° and 100° , E. van Aubel gave $R=R_0(1+0.04429\theta)$ for soft bismuth, and $R=R_0(1+0.00422\theta)$ for hard bismuth; for the same range of temp., W. Jäger and H. Diesselhorst gave for the temp. coeff., 0.0045; P. Lenard, 0.00458; F. Streintz, 0.0045; L. Holborn, 0.00446; and G. Vicentini and D. Omodei, from 0° to 271° , $R=R_0(1+0.001176\theta+0.05532\theta^2+0.071289\theta^3)$. W. E. Williams made observations on this subject. P. Lenard and J. L. Howard gave the high value 0.0052. Whilst P. Lenard, and E. van Aubel said that the temp. coeff. is constant between 0° and 100° , the latter observed 0.00412 between 0° and 19.5° and 0.00450 between 0° and 99.7° . W. Tuijn and H. K. Onnes found that the metal is not supraconducting at 1.24° K. P. W. Bridgman gave a negative coeff., -0.00039 , between 0° and 100° for an impure sample, while for electrolytic bismuth, of a high degree of purity, he found the average coeff. was 0.00438 from 0° to 100° , and 0.00381 at 0° —*vide infra*. He also found the sp. resistance of single crystals to be 13.8×10^{-6} ohms parallel and 10.9×10^{-6} ohms when perpendicular to the chief axis. R. S. Bartlett found the resistance of a thin film of bismuth exposed to ultra-violet light was reduced to 0.0014 at 0° to nearly zero at -185° . For the ratio of the electrical conductivities taken vertical and parallel to the axes of the crystals, C. Matteucci gave 1.6, and E. von Everdingen, 1.68. According to A. Matthiessen and M. von Bose, when a bismuth wire has been heated for a long time at 100° , its conductivity increases so that if the conductivity measured at 0° be 1.2517, the conductivity at 0° after heating for a day at 100° is 1.4494, a longer heating made very little difference to the result. This is taken to support E. Cohen and A. T. L. Moesveld's view as to the allotropy of bismuth—*vide supra*.

The various observations on electrical conductivity were reviewed by A. Schulze. E. F. Northrup and V. A. Suydam's measurements of the electrical resistance of bismuth over a range of temp. covering the fusion of the metal, are:

	17.5°	100°	200°	300°	400°	600°	750°
R . . .	120.00	156.50	214.50	128.90	134.20	145.25	153.55

The data are plotted in Fig. 3. Y. Matsuyama gave 126.7×10^{-6} ohm for the sp. resistance of molten bismuth. G. Vassura gave 3640 mhos for the solid at 271° , and 7810 mhos for the liquid at the same temp.

L. de la Rive gave 7370 mhos for the liquid at 358° , and 6220 at 860° . H. Tsutsumi found that the electrical resistance of metals usually increases during fusion, but with bismuth and antimony the contrary is true. The ratio of the resistance of the liquid to that of the solid is 0.43. H. Perltz studied the relation between the crystal lattice and the change of resistance on fusion. This phenomenon is attributed to a transformation of the molecules during fusion as exemplified by the abnormally high heat of fusion of bismuth. While the sp. resistance of the metals in the liquid and solid states at the m.p. approximates 2, the ratio for antimony and bismuth is roughly 0.5—actually, 0.43 for bismuth. G. Bretano, and P. W. Bridgman found the effect of *pressure* on antimony and bismuth, and the latter showed that, unlike the result with most metals, the effect is large and positive. Expressing the press. p , in kilograms per sq. cm., and the resistance, R , relative to unity at 0° :

FIG. 3.—The Effect of Temperature on the Resistance of Bismuth.

p	0	2,000	4,000	6,000	8,000	10,000	12,000
R $\left\{ \begin{array}{l} 0^\circ \\ 25^\circ \\ 50^\circ \\ 75^\circ \end{array} \right.$	1.0000	1.0336	1.0726	1.1163	1.1638	1.2143	1.2672
	1.0969	1.1333	1.1748	1.2204	1.2698	1.3225	1.3779
	1.1996	1.2389	1.2830	1.3316	1.3841	1.4498	1.4980
	1.3115	1.3540	1.4013	1.4527	1.5078	1.5664	1.6279

and for the press. coeff. with 0, 6000, and 12,000 kgrms. press. per sq. cm., he found respectively at 0° , 0.0_4153 , 0.0_4195 , and 0.0_4212 —average 0.0_42027 ; at 25° , 0.0_4155 , 0.0_4198 , and 0.0_4202 —average 0.0_42142 ; at 50° , 0.0_4155 , 0.0_4192 , and 0.0_4199 —average 0.0_42076 ; and at 75° , 0.0_4154 , 0.0_4185 , and 0.0_4194 —average 0.0_42023 . W. E. Williams obtained 0.0_4191 for the press. coeff. between 0 and 300 kgrms. per sq. cm., at 0° . P. W. Bridgman summarized his observations by saying that the average press. coeff. is positive, increasing in numerical value with increasing press., and decreasing with increasing temp.; the instantaneous coeff. at zero press. is nearly independent of the temp., but at higher press., it decreases at the higher temp. This means that as the press. increases, the temp. coeff. of the resistance decreases. He also found that taking the electrical resistance of liquid bismuth at 271° as unity, the resistance at

p	0	2,000	4,000	6,000	8,000	10,000	12,000
R $\left\{ \begin{array}{l} 275^\circ \\ 260^\circ \\ 240^\circ \end{array} \right.$	1.0019	0.9789	0.9584	0.9400	—	—	—
	—	—	0.9520	0.9336	0.9167	—	—
	—	—	—	0.9253	0.9088	0.8931	0.0783

The press. coeff. of the resistance of the liquid is negative like normal metals so that the positive coeff. with the solid is an effect of the crystalline structure. The press. coeff. is little affected by temp., and the temp. coeff. is little affected by press. within the observed ranges. The initial press. coeff. for the sp. resistance is -0.0_4132 ; and the temp. coeff. 0.00048 . This is about five times less than for a normal solid at the same temp. At a press. of 7000 kgrms. per sq. cm., the resistance of the liquid is approximately 45 per cent. of that of the solid—E. F. Northrup and R. G. Sherwood observed 43 per cent. E. D. Williamson gave 1.2672 for the ratio of the resistance at 12,000 kgrms. per sq. cm. press. to the resistance at 1 kgrm. per sq. cm. E. Zavattiero, and P. W. Bridgman found that *tension* decreased the electrical resistance of all samples of bismuth. The effect is comparatively large with a range of tension of 100 grms., the tension coeff. was -0.0_4292 ; with less pure samples, the tension coeff. was -0.0_4520 at 0° , and 0.0_4427 at 31.1° . Beyond the elastic limit the electrical resistance increases with tension as in the case of other metals. A. Schulze found that bismuth has a higher resistance for alternating than for direct currents; but that the metal is electrically anisotropic. The resistance of thin films is disproportionately high. This subject was also studied by E. H. Hall, and P. Kapitza. L. Tiere and V. Ricca studied the resistance of bismuth solidified in a *magnetic field*. G. W. Schneider studied the resistance in a longitudinal magnetic field. According to R. Paillot, the electrical resistance of a spiral of bismuth wire is considerably diminished when the latter is placed in the neighbourhood of *radium radiations*. A wire of resistance 15.103×10^{-4} ohms was placed 0.5 mm. distant from 0.03 gm. of radium bromide (activity=500,000); in these circumstances, the resistance of the bismuth spiral was reduced considerably. The action of the radium salt is instantaneous, and remains constant as long as the distance from the wire is unaltered.

A. E. Malinovsky obtained negative results in an attempt to find if the random motion of the conductivity electrons is affected by the self-induction of the metal. The relation between the thermal and electrical conductivities was examined by A. Eucken and O. Neumann¹⁵—*vide* antimony. L. Lownds found that while the ratio of the thermal conductivities of bismuth perpendicular and parallel to the chief axis is 1.42, this ratio becomes 1.80 when the bismuth is in a *magnetic field* with $H=4980$ C.G.S. units. The corresponding values for the electrical conductivities are respectively 1.78 and 1.87. A. Righi, however, found that the ratio of the thermal conductivity inside and outside a magnetic field is very nearly the same

as the ratio of corresponding values for the electrical conductivity. In the former case the ratio was 0.878, and in the latter, 0.886. A. Leduc obtained similar results; but A. von Ettingshausen said that the decrease in the thermal conductivity in a magnetic field is less than is the case with the electrical conductivity, being in the one case 4 per cent. and in the other 28 per cent. L. Lownds found that the sp. resistance of bismuth parallel and vertical to the principal axis is respectively 269,000 and 151,000 at 0° ; 379,000 and 135,000 at -79° ; and 243,000 and 86,000 at -186° . At 255° , -79° , and -186° , the percentage increase in the electrical resistance, parallel to the chief axis, is respectively 5.0, 22.5, and 33.5 for $H=2120$ C.G.S. units; 9.2, 37.7, and 44.2 for $H=3120$; 12.1, 43.1, and 47.4 for $H=3500$, and 19.8, 62.1, and 56.5 for $H=4980$. At 14° , -79° , and -186° , vertical to the chief axis, the percentages increases are respectively 3.9, 9.6, and 6.1 for $H=2120$; 7.3, 14.2, and 9.7 for $H=3120$; 8.6, 15.7, and 10.6 for $H=3500$; and 14.3, 21.5, and 11.4 for $H=4980$. According to C. Carpinì, the variation of the electrical resistance of bismuth in both feeble and strong magnetic fields is a hyperbolic function of the strength of field, and it is also a sine function of the angle made by the coil of bismuth with the lines of force. No hysteresis phenomena were observed on changing the strength of field. When an alternating current is employed, the change of resistance is far smaller than with the corresponding direct current. The curves appear to depend in a very complicated manner on the amplitude and period of the alternating current. C. W. Heaps, and P. Lenard found that for small transverse fields, the relation between the resistance R and the strength H of the field is $dR/R=12000 \times 10^{-12} H^2$; and for longitudinal fields, $dR/R=3200 \times 10^{-12} h^2$. F. A. Ward found that the decrease in the thermal conductivity of bismuth is 3.22 per cent. in a transverse magnetic field of 5370 C.G.S. units, and 5 per cent. in a field of 6260 C.G.S. units. The subject was also examined by E. von Everdingen, J. Dewar and J. A. Fleming, P. Lenard, L. F. Curtiss, F. A. Ward, G. C. Trabaschi, P. le Rossi, G. W. Schneider, G. Berndt, E. J. Williams, F. P. König, F. C. Blake, R. Geipel, and R. Seidler. The periodic relation between the electrical conductivities was studied by Z. A. Epstein; E. Horn, and C. Drucker, the relation between the sp. ht. and the temp. coeff. of the resistance; and the theory of electronic conduction, by A. T. Waterman. G. A. Rogers studied the effect of X-rays on the resistance of thin films of bismuth, but observed no perceptible change. P. Fischer found cylinders from compressed mixtures of bismuth and 50 per cent. cupric oxide are non-conducting.

If an electric current flows between two points, P and Q , in a thin metal plate, the lines of flow diverge on passing from P and converge at Q , while the equipotential lines are everywhere at right angles to the current. If the plate be in a magnetic field, with its plane at right angles to the field, the lines of flow and the equipotential lines are distorted so that looking along the lines of force, the system of lines is deformed as if twisted to the right (positive) with zinc, antimony, tellurium, and iron, and to the left (negative) with gold, bismuth, and nickel. This is the so-called **Hall effect**. It is very large with bismuth and tellurium. This subject was studied by A. von Ettingshausen and W. Nernst,¹⁶ E. von Everdingen, L. Lownds, L. Tieri and E. Persico, G. Polvani, P. la Rossi, E. H. Hall, C. W. Heaps, P. H. Craig, F. Kläiber, W. van B. Roberts, O. M. Carbino, D. Goldhammer, A. Righi, G. P. Grimaldi, and P. Senepa. L. J. Neuman measured the influence of the crystalline texture on the Hall effect; and T. F. Hargitt, the Hall effect in spluttered films. H. Rausch von Traubenberg found that the rotation effect decreases with temp. so that the fall is rapid at first, then slow up to about 260° , and thereafter rapid up to the m.p.; and E. Adinolfi showed that the Hall effect varies linearly with the strength of the magnetic field, and exponentially with the temp. P. W. Bridgman investigated the relation between the four transverse electro- and thermo-magnetic effects. According to G. P. Grimaldi, if two bismuth plates be dipped in the same soln., and one only be in a strong magnetic field, a feeble current flows from the magnetized to the

unmagnetized bismuth. G. Polvani observed a lag with respect to the magnetic field of the Hall effect in bismuth. J. Beattie, G. C. Trabacchi, and C. W. Heaps studied the relation between the thermoelectric power and the Hall effect with bismuth.

According to A. L. Hughes,¹⁷ bismuth free from air is electronegative to platinum, but in air, the contact difference of potential increases so that the metal becomes more electropositive, reaches a maximum, and then decreases to a stationary value. R. D. Kleeman and W. Frederickson found that bismuth assumes a positive charge in distilled water; and R. Saxon noted that when a piece of bismuth is placed between, but without touching, two electrodes immersed in water, and a current passed between the electrodes, the surface of the metal remains bright on the cathode side, and is oxidized on the anode side. R. Saxon observed a grey oxide forms on the anode when water is electrolyzed with bismuth electrodes. According to A. Classen, in the electrolysis of a nitric acid soln. of bismuth, at first some bismuth peroxide deposits on the anode, but this gradually disappears, and elemental bismuth is deposited on the cathode. The reaction has been employed in quantitative analysis by E. F. Smith and co-workers, O. Steen, D. Balachowsky, K. Wimmenauer, O. Brunck, A. Hollard and L. Bertiaux, H. J. S. Sand, F. F. Exner, S. C. Schmucker, L. G. Kollock, F. Rüdorff, T. Moore, C. Luckow, L. Schucht, A. Brand, A. Jilek and J. Lukas, A. Fischer and R. J. Boddaert, S. Eliasberg, J. Wieland, H. Kammerer, etc. B. Neumann gave for the absolute **electrode potential** of bismuth in normal soln. of the sulphate, -0.490 volt; in normal chloride, -0.315 volt; and in normal nitrate, -0.500 volt. D. F. Smith measured the e.m.f. of cells of the type $H_2 | HClO_4 | HClO_4 + BiOClO_4 | Bi$, and calculated for the electrode potential $Bi | BiO^+ + H^+$, -0.314 volt, and E. H. Swift, -0.318 volt; while the latter obtained for $Bi | Bi(OH)^+ + H^+$, -0.310 volt, and the former -0.298 volt. F. H. Smith gave for the electrode potential of bismuth against a normal soln. of hydrogen chloride in the presence of solid oxychloride $0.022-0.090$ volt against the calomel electrode; and A. A. Noyes and M. Chow gave for the specific potential of the $Bi | BOCl$ -electrode, -0.1635 volt at 15° ; -0.1599 volt at 25° ; and -0.1563 volt at 35° . J. Tafel studied the over-voltage, and polarization effects of a bismuth cathode in $2N-H_2SO_4$ at 12° . The initial potential with the $Hg_2SO_4 | Hg$ -electrode was 1.640 volts, and in 20 mins., about 1.670 volts, and thereafter a drop to the initial value when it remains constant. The over-voltage is about one volt. W. Isbekoff studied the decomposition voltages of a number of metal bromides, and hence deduced the **electrochemical series**: Al, Zn, Cd, Ag, Hg, Sb, **Bi**. F. W. Bergstrom found in liquid ammonia soln. the order Pb, **Bi**, Sn, Sb, As, P, Te, Se, S, I. M. Bose found that the anodic decomposition curve of bismuth nitrate soln. exhibits a decomposition point with about 1.86 volts, a bright yellow oxide is produced at higher voltages, and ozonized oxygen is evolved in considerable quantity from the surface of the oxide. N. W. Taylor studied the activity of bismuth in binary liquid metals. A. Thiel and W. Hammerschmidt found the **over-voltage** in $2N-H_2SO_4$ at 25° to be 0.388 volt. E. Newberry observed a white thick coating is formed in acidic soln., but a slight bronze film in alkaline soln. A. Günther-Schulze studied the **cathodic spluttering** of bismuth. T. Andrews, and G. C. Schmidt studied the **passivity** of the metal. A. Günther-Schulze and W. Winter found that bismuth exhibits the **electrolytic valve action** in nearly all electrolytes. The effect is due to the formation of a layer of oxide on the surface of the anode. C. Bellia utilized the Hall effect to obtain the rectification of alternating to direct current. The **electrolytic solution pressure** of bismuth is 2.4×10^{-27} . K. Elbs and H. Thümmel found that an anode of bismuth dissolves in soln. of sodium chloride or hydrochloric acid entirely in the trivalent form. V. Bayerle found the normal deposition potential is 0 volts (calomel electrode), and in acidic soln. the deposition proceeds reversibly; while in alkaline soln., the action resembles metallic deposition from zincates or plumbates in accord with the metallic nature of bismuth, and in contrast with arsenic and antimony. The **solubility**

product $[\text{Bi}^{+++}][\text{OH}]^3$ is 4.3×10^{-31} . The **anodic corrosion** of bismuth in nitric acid, and soln. of sodium nitrate, was studied by E. B. R. Prideaux and H. W. Hewis. With 10 per cent. soln. of sodium nitrate and a current density of 12.5 amps. per sq. dm., there was an average of 4.6 volts; the current efficiency was 100 per cent., and 1.76 kilowatt-hours were consumed per kilogram of bismuth dissolved. The product was a white oxynitrate. A negligibly small amount of bismuth remained in soln. With sat. soln. of sodium nitrate, the oxynitrate was formed as a loose precipitate, but three-fourths of the bismuth remained in soln. and was precipitated by water. G. Grube and F. Schweigardt found that, like antimony, bismuth dissolves anodically in soln. of potassium or sodium hydroxide in the trivalent form. A gram of bismuth can be dissolved in a litre of the conc. alkali-lye, forming the bismuthite. The anode then becomes passive and covered with the higher oxide. F. Paneth found that the ratio of cathodic to anodic dissolution of bismuth (thorium-C) in dil. soln. of potassium hydroxide is 1 : 1.2 and 1 : 3.0 for 0.0004*N*- and 0.001*N*-soln. respectively.

According to J. Svanberg,¹⁸ rods cut parallel to the chief axis are more negative, and those cut perpendicular to that axis are more positive in the thermoelectrical series than rods cut in any other direction. There is a marked **thermoelectric force** between rods cut in each of these two directions. Rods cut in other directions are negative towards rods cut perpendicular to the chief axis, and positive with rods cut parallel to the chief axis. This subject was examined by R. Franz, H. Zahn, H. Pélabon, C. W. Heaps, C. Matteucci, and A. Matthiessen. E. Wagner obtained at 300 kgrms. press. between 0° and 100°, 707×10^{-12} volts per degree per kgrm. P. W. Bridgman measured the thermoelectric power of single crystals. According to P. W. Bridgman, the thermal e.m.f. E in volts $\times 10^{-6}$, of couples composed of uncompressed and of metal compressed by a press. p kgrms. per sq. cm., when the cold junctions were at 0°, are :

p	2,000	4,000	6,000	8,000	10,000	12,000
E $\left\{ \begin{array}{l} 10^\circ \\ 20^\circ \\ 40^\circ \\ 60^\circ \\ 80^\circ \end{array} \right.$	$\left. \begin{array}{l} \cdot \\ \cdot \\ \cdot \\ \cdot \\ \cdot \end{array} \right\} \begin{array}{l} 11 \\ 21 \\ 42 \\ 64 \\ 85 \end{array}$	$\left. \begin{array}{l} \cdot \\ \cdot \\ \cdot \\ \cdot \\ \cdot \end{array} \right\} \begin{array}{l} 21 \\ 42 \\ 87 \\ 134 \\ 185 \end{array}$	$\left. \begin{array}{l} \cdot \\ \cdot \\ \cdot \\ \cdot \\ \cdot \end{array} \right\} \begin{array}{l} 38 \\ 73 \\ 141 \\ 218 \\ 302 \end{array}$	$\left. \begin{array}{l} \cdot \\ \cdot \\ \cdot \\ \cdot \\ \cdot \end{array} \right\} \begin{array}{l} 54 \\ 106 \\ 205 \\ 308 \\ 425 \end{array}$	$\left. \begin{array}{l} \cdot \\ \cdot \\ \cdot \\ \cdot \\ \cdot \end{array} \right\} \begin{array}{l} 74 \\ 145 \\ 281 \\ 416 \\ 560 \end{array}$	$\left. \begin{array}{l} \cdot \\ \cdot \\ \cdot \\ \cdot \\ \cdot \end{array} \right\} \begin{array}{l} 93 \\ 183 \\ 364 \\ 539 \\ 710 \end{array}$

The effect is large and positive, increasing regularly with press. and temp. up to 710×10^{-6} volts at 100° and 12,000 kgrms. per sq. cm. press. E. Siegel found the effect of press. on the thermal e.m.f. of molten bismuth is very much smaller than with solid bismuth. P. H. Dowling found the contact potential between solid and liquid bismuth to be of the order of -0.020 volt. T. Todesco obtained a thermoelectric effect with two specimens of single crystals of bismuth, the crystals in contact were asymmetrically oriented; T. Terada and T. Tsutui, with single crystals of bismuth with *cadmium*; and R. W. Boydston, with *constantan*. A. Matthiessen found the thermoelectric power of the *lead-bismuth* thermo-couple, with commercial pressed bismuth wire, to be -97.0 microvolts at 20°; with pure pressed bismuth wire, -89.0 microvolts; with crystalline bismuth parallel with the chief axis, -65.0 microvolts; and perpendicular to that axis, -45.0 microvolts. P. W. Bridgman gave for the effect with the lead-bismuth couple, $E = (-74.42\theta + 0.0160\theta^2) \times 10^{-6}$ volts. F. L. Perrot found that the thermal effect of a *copper-bismuth* couple, with the bismuth parallel and perpendicular to the (0001)-face, is :

	30°	50°	70°	95°
Bi parallel to (0001)	0.00190	0.00396	0.00610	0.00899 volt.
Bi perpendicular to (0001)	0.00084	0.00185	0.00299	0.00447 „

Different values were obtained using prisms cast from the molten metal, and E. Cohen and T. Moesveld attributed this to the presence of different proportions of α - and β -bismuth. L. Lownds gave for the thermal e.m.f., E millivolts, of the copper-bismuth couple when the two junctions were at θ° , and θ_2° ,

$E=48.32(\theta_1 - \theta_2) + 0.2988(\theta_1^2 - \theta_2^2)$ when the bismuth is taken perpendicular to the chief axis, and $E=130.2(\theta_1 - \theta_2) + 0.3504(\theta_1^2 - \theta_2^2)$ when taken parallel to that axis. P. W. Bridgman made observations on this subject. W. B. Burnie noticed the very great drop in the thermoelectric force of this couple when the bismuth melts. W. W. Coblentz gave 80 millivolts per degree for the thermal e.m.f. of a *silver-bismuth* couple; and K. Bädeler, 100 millivolts per degree between 20° and 22° for the *antimony-bismuth* couple. J. Dewar and J. A. Fleming gave for the *platinum-bismuth* couple, at 100° when the cold junction is at 0°, -7.25 millivolts; W. Jäger and H. Desselhorst, -6.52 millivolts; E. Wagner, -7.39 millivolts; E. Rudolfi, -6.31 millivolts; and G. Borelius and A. E. Lindh, -5.2 millivolts when taken perpendicular, and 7.7 millivolts when taken parallel to the chief axis of bismuth. H. Pélabon studied the effect of temp. on the thermoelectric power of bismuth. G. Spadavecchia, and G. P. Grimaldi observed that a strong magnetic field lessens the thermoelectric power of bismuth. C. R. Darling and R. H. Rinaldi found marked breaks in the e.m.f.-temp. curves of the alloys of bismuth which expand on solidification, but not when there is contraction. T. Todesco examined the effect of light on the thermoelectric current.

F. P. le Roux found that when an electric current flows from the copper through a copper-bismuth couple to the bismuth, 25.8 cal. are produced per ampère-hour with bismuth containing 10 per cent. of antimony, and 19.1 cal. with purified bismuth—the **Peltier effect**. Expressing the Peltier effect in millivolts, F. P. le Roux gave 22.3; E. Edlund, 17.7; and A. E. Caswell, 16.1. P. W. Bridgman gave for the Peltier effect, P volts with the lead-bismuth couple $P=(-74.2+0.0320\theta)\theta+273)\times 10^{-6}$ volt; and with a couple of bismuth uncompressed and compressed at p kgrms. per sq. cm., the Peltier effect, p in joules per coulomb $\times 10^6$:

p		2,000	4,000	6,000	8,000	10,000	12,000
P	0°	289	574	1070	1530	2080	2580
	20°	311	644	1020	1490	2050	2670
	40°	332	720	1090	1530	2070	2760
	60°	353	800	1330	1790	2309	2860
	80°	374	950	1580	2180	2600	2960

The Peltier effect is thus positive and, in general, it increases with rising press. and temp., but at the middle of the range passes through a flat minimum with rising temp. The **Thompson effect** in joules per coulomb per degree $\times 10^8$, using the same couple is zero at 2000 kgrms. per sq. cm. press.; at 4000 kgrms. press., it is negative; and at higher press. it is initially negative, rising to positive values:

p		2,000	4,000	6,000	8,000	10,000	12,000
σ	0°	0	0	+1150	-1150	-1250	-520
	20°	0	117	-290	-500	-760	-470
	40°	0	250	+500	+250	-160	-440
	60°	0	430	+800	+1000	+530	-370
	80°	0	600	+460	+1660	+1270	-280

Also, M. O'Day measured the Thompson effect with bismuth. In Table VI, 9. 51, 5, N. C. Little has compared the thermomagnetic effect and the galvanomagnetic effect of bismuth, antimony, and arsenic. W. B. Nottingham¹⁹ studied the characteristic curves of the bismuth arc; and E. Blechschmidt, T. Baum, and A. Günther-Schulze, the cathodic spluttering of bismuth.

In 1778, A. Brugman,²⁰ and in 1827, M. le Baillif, observed that bismuth is repelled by a magnet. M. Faraday showed that bismuth is strongly diamagnetic, so that if a metal rod cut parallel to the chief axis be suspended so that it is free to rotate in a horizontal axis, between the poles of an electromagnet, it will rotate in a direction so that the chief axis makes an angle ϕ with the lines of force. This subject was studied by J. Tyndall, H. Knoblauch, and G. W. Hankel. T. Collodi found that the Corbino effect decreases rapidly with rise of temp. and reaches a minimum at the m.p., and thereafter remains constant. W. W. Jaques found the magnetization

coeff. to be -12554×10^{-12} when parallel to the principal axis, and -14323×10^{-12} when vertical thereto. A. Leduc allowed small spherical glass bulbs of 2 cms. diameter to be filled with molten bismuth, and the metal to solidify, whilst the bulbs were under the influence of a strong magnetic field. If the crystalline spheres of bismuth are then suspended freely in the same magnetic field, they take up the same orientation as that which they had at the moment of solidification of the metal. If the magnetic field is cut off and the bulbs are made to rotate about the axis of suspension, the motion is at once stopped when the magnetic field is established, and the bulbs are found to be orientated as at the time of crystallization. J. Dewar and J. A. Fleming gave for the **magnetic susceptibility** at 15° , -14×10^{-6} vol. units and at -182° , -16×10^{-6} vol. units. A. von Ettinghausen gave for the susceptibility at ordinary temp., -14×10^{-6} vol. units; L. Lombardi, -13×10^{-6} vol. units; and A. P. Wills, -12×10^{-6} vol. units. P. Curie obtained at 20° , -1.4×10^{-6} mass units, at 273° , -1.0×10^{-6} and at $273^\circ-405^\circ$, -0.04×10^{-6} mass units. K. Honda gave at 18° , -1.4×10^{-6} mass units; at 260° , -1.0×10^{-6} mass units; and at 270° for the molten metal, -0.01×10^{-6} mass units. G. Meslin gave -1.39×10^{-6} mass units for the crystalline, and -1.42×10^{-6} mass units for the cast metal. H. Isnardi and R. Gans gave -1.346×10^{-6} mass units for field of strength $H=1029$ to 13,680 gauss. C. Nusbaum studied the effect with single crystals; and found 1.13×10^{-6} dyne cm. when parallel to the principal axis, and 1.32×10^{-6} when vertical thereto; H. K. Onnes and A. Perrier, and M. Owen, the effect of low temp. on the susceptibility, and found that between -170° and 268° , the higher the temp. the lower the value of the magnetic susceptibility. S. Meyer gave -5.25×10^{-6} for the magnetization number of powdered bismuth, and P. Pascal gave -406×10^{-7} for the atomic susceptibility of trivalent bismuth, and -698×10^{-7} for that of quinquevalent bismuth. J. Forrest studied the parallel and transverse components of magnetization of bismuth crystals. W. Gerlach studied the atomic susceptibility of bismuth vapour; J. A. Becker and L. F. Curtiss, and F. K. Richtmyer, the magnetic properties of thin films. J. F. Spencer and M. E. John measured the magnetic susceptibility of bismuth-tin alloys, finding for bismuth alone -1.24×10^{-6} mass units. E. H. Williams found compounds of bismuth with an odd mol. number are paramagnetic, and those with an even mol. number are diamagnetic. M. Pierucci measured the effect of abrupt variations of temp. on the diamagnetic properties of bismuth; and P. Ehrenfest tried to explain the high magnetic susceptibility of bismuth by an electronic structure in which electrons have orbits crystallographically defined and enclosing several atomic nuclei.

§ 5. The Chemical Properties of Bismuth

H. von Wartenberg¹ observed no sign of a combination between heated bismuth and argon, nor did F. Fischer and co-workers obtain any evidence of chemical action when bismuth is sparked beneath liquid argon. W. Ramsay and J. N. Collie observed no reaction with helium at a red-heat. F. H. Newman studied the adsorption of hydrogen in discharge tubes. There is no sign of interaction when hydrogen is passed over heated bismuth, and, according to F. Paneth, M. Matthies and E. Schmidt-Hebbel, no identifiable quantity of bismuth hydride formed when activated hydrogen is passed over bismuth powder. According to R. L. Richland, if water be electrolyzed with a bismuth cathode, this metal is blackened, and covered with black dendrites once thought to be a bismuth hydride. F. Meurer believed that a hydride is produced when zinc acts on dil. hydrochloric or sulphuric acid containing a bismuth salt in soln., but J. Schlossberger and C. R. Fresenius were unable to confirm this. Organic derivatives of a bismuthine, BiH₃, are known with the hydrogen atoms replaced by methyl, ethyl, phenyl, and other radicles. E. J. Weeks and J. G. F. Druce failed to make a bismuth hydride analogous to that of arsenic, but they obtained bismuth dihydride, Bi₂H₂, as a grey flocculent precipitate by adding bismuth chloride to a mixture of zinc and conc. hydrochloric acid; and by reducing a bismuth salt with aluminium and potassium hydroxide. The dihydride deposits bismuth when heated, and is rapidly oxidized by fused potassium nitrate. A. C. Vournasos reported an unstable hydride to be formed by treating alkali bismuthide with hydrogen at 350°, and digesting the product with water. L. Vanino and E. Zumbusch reported the following unsuccessful

attempts to make bismuth hydride: Hydrogen passed over alloys of lead, tin, and bismuth, or of one of these three metals with cadmium, heated to their m.p. Aluminium, zinc, iron, cadmium, or lead added to an acid or neutral soln. of a bismuth compound. Bismuth-magnesium or bismuth-zinc alloys placed in dil. acid. Calcium hydride mixed with bismuth compounds moistened with water or aq. soln. of bismuth chloride. Hydrogen passed over mixtures of bismuth or bismuth oxide with platinum black, nickel-asbestos, or reduced nickel. Palladium sat. with hydrogen placed in a soln. of bismuth sulphate, or an electric current passed through a cell containing bismuth sulphate in soln., and having an anode of palladium sat. with hydrogen and a cathode of platinum or a cathode of bismuth and anode of platinum. Activated aluminium when allowed to remain in bismuth-mannitol soln. or with a mixture of bismuth and bismuth oxide, or in soln. of bismuth salts in alcohol. Hypophosphorous acid added to bismuth sulphate or to bismuth nitrate in soln. gave only a precipitate of metallic bismuth. The presence of bismuth hindered the preparation of copper hydride by this method. P. Sachs also obtained negative results with sodium formate and bismuth. F. Paneth reported that a gaseous bismuth hydride can be formed and that it is comparatively stable at ordinary temp., but it is decomposed at an elevated temp. The gas can be condensed by cooling in liquid air. He said:

Bismuth hydride is obtained by dissolving an alloy of magnesium with thorium-*C* or radium-*C* in 0.2*N*-hydrochloric or sulphuric acid. The alloy is prepared by exposing magnesium foil to the radiations of a radiothorium preparation contained in a glass capsule covered with silk paper, which is impermeable to thorium-*X*; shortly after its removal, in consequence of the rapid decay of thorium emanation and thorium-*A*, the deposit consists entirely of thorium-*B* and thorium-*C*. The alloy is placed in a weighing bottle connected with an electroscope in such a manner that a regular current of nitrogen can be sent through the apparatus. After the determination of the natural leak of the electroscope, 0.2*N*-hydrochloric acid is dropped on to the alloy; the electroscope soon indicates an activity, which becomes feebler after a few minutes. The results of this and similar experiments show that when magnesium superficially alloyed with bismuth and lead is dissolved in dil. hydrochloric acid, a small fraction of the bismuth is converted into such a state that it can be carried by a gas current through a cotton wool filter, and that a similar reaction does not occur with lead. The observed effects are actually due to a volatile compound of bismuth, and not to the liberation of thorium-*C*, to the selective action of the filter, or to the relatively greater volatility of thorium-*C* chloride.

F. Paneth and E. Winternitz obtained the hydride from a bismuth-magnesium alloy prepared by heating equal weights of powdered bismuth and magnesium (as free from silicon as possible) in an iron crucible in a rapid stream of dry hydrogen. The alloy is dissolved in approximately 4*N*-hydrochloric or sulphuric acid (or in some cases nitric acid). Bismuth hydride is thus obtained in sufficient quantity to permit its detection either by the formation of a mirror or by luminescence tests. The bismuth mirror is obtained in the usual Marsh's apparatus, and very closely resembles the antimony mirror. As generally obtained, it consists of a strong brown ring in front of and a fainter ring behind the heated spot. The former deposit appears to be frequently burnt into the glass and to be unsuitable for further experiments. This drawback can be overcome by placing a pierced clay disk on the tube and allowing the flame to play against this, and also by increasing the velocity of the gas current. Attempts to estimate the yield of bismuth hydride by weighing the bismuth mirrors show that about 5×10^{-5} of the bismuth used is converted into the hydride, or that the yield is only about one-twentieth of that obtained from thorium-*C*. The absorption of bismuth hydride by various reagents has been examined; the most suitable for this purpose appears to be 0.4*N*-silver nitrate soln. Water absorbs the gas to some degree, and 4*N*-sulphuric acid to about the same extent. 0.5*N*-sodium carbonate soln. and *N*-potassium hydroxide soln. are more active, whilst the gas is also absorbed by desiccating agents, such as calcium chloride or soda-lime. It is completely decomposed by concentrated sulphuric acid. An aq. soln. of hydrogen sulphide is no more efficient than pure water.

F. Paneth and co-workers found that small quantities of the hydride are produced when bismuth electrodes are used in the preparation of active hydrogen and are so arranged that the bases are rapidly removed from the zone of the discharge. According to E. J. Weeks and J. G. F. Druce, when bismuth dihydride is heated in vacuo, it furnishes **bismuthine** or **bismuth trihydride**, BiH_3 , thus: $3\text{Bi}_2\text{H}_2 = 4\text{Bi} + 2\text{BiH}_3$; and the same product is obtained by reducing the dihydride with hot hydrogen: $2\text{Bi}_2\text{H}_2 + \text{H}_2 = 2\text{Bi} + 2\text{BiH}_3$. The gas burns with a steel-grey flame producing thin clouds of bismuth oxide. It gives a precipitate of silver tritabimuthide with silver nitrate. W. Strecker and W. Daniel were unable to verify these results.

When bismuth is heated in **air**, until it boils, it burns with a faint, bluish-white flame, and the fumes of bismuth trioxide so formed condense as *flowers of bismuth*, or *flores bismuthi*, on cold surfaces. According to P. A. von Bonsdorff,² T. Thomson, and W. Heintz, bismuth at ordinary temp. does not oxidize in dry or moist air, but if heated in air, it acquires a thin film; if the film be skimmed from the molten metal as it is formed, the dark brown product is the so-called *bismuth ash*, which may be a mixture of metal and trioxide, or it may contain a suboxide (*q.v.*). Bismuth precipitated by zinc was found by W. Heintz to be rapidly oxidized in air at 200° – 220° ; and a mixture of bismuth and aluminium hydroxides co-precipitated, and reduced by hydrogen at 170° – 210° is spontaneously inflammable at ordinary temp. C. F. Schönbein found that **ozone** slowly oxidizes bismuth to the pentoxide. P. A. von Bonsdorff showed that if bismuth be partially covered with **water**, and exposed to air freed from carbon dioxide, hydrated bismuth oxide is first formed, and afterwards crystals of the yellow oxide are produced. If the air is not freed from carbon dioxide, white scales of bismuth carbonate are produced, and the surface of the metal acquires first a reddish-brown, and then a blue film. H. V. Regnault found that bismuth at a red-heat slowly decomposes water, forming bismuth trioxide. L. J. Thénard found that **hydrogen dioxide** is slowly decomposed by powdered bismuth, which itself suffers no appreciable change—C. F. Schönbein said that a brown oxide is formed—a mixture or compound of bismuth tri- and penta-oxides. W. R. Dunstan observed a well-marked reaction for hydrogen dioxide when the metal is shaken up with dil. sulphuric acid and air.

H. Moissan³ found that bismuth is only superficially attacked by **fluorine** at a red-heat. J. Davy, and R. Weber found that finely-divided bismuth unites with **chlorine**, forming the trichloride; but, according to R. Weber, P. P. Dehérain, W. Heintz, and R. Schneider, if the chlorine is brought closely in contact with the bismuth, the dichloride or both the di- and tri-chlorides are formed. J. Thomsen said that finely-divided bismuth may or may not inflame when projected into chlorine gas, and V. Thomas and P. Dupais found that chlorine at its b.p. has no action on bismuth. R. Cowper said that thoroughly dried chlorine attacks bismuth only at the surface. Bismuth was found by C. Willgerodt and A. G. Page to be a very poor catalyst in the chlorination of organic compounds. R. Weber, G. S. Sérullas, and M. M. P. Muir found that when bismuth is heated in the vapour of **bromine**, yellow bismuth tribromide, and grey dibromide may be formed. W. Heintz, R. Schneider, and R. Weber observed that **iodine** unites directly with heated bismuth, forming the triiodide. Dry **hydrogen chloride** was found by W. Heintz to attack red-hot bismuth to a small extent, forming traces of the trichloride. W. Heintz, and G. Gore observed no reaction between liquid hydrogen chloride and bismuth. A. Ditte and R. Metzner showed that if air be excluded, hydrogen chloride, and **hydrochloric acid** have no action on bismuth, but if oxygen be present in the acid, an amount of bismuth is dissolved eq. to the oxygen in soln.—no hydrogen is developed: $4\text{Bi} + 3\text{O}_2 + 12\text{HCl} = 4\text{BiCl}_3 + 6\text{H}_2\text{O}$. R. Schneider also noted the solvent action of aerated hydrochloric acid on bismuth. C. F. Schönbein observed that aq. soln. of **hypochlorites** act slowly on bismuth, forming the higher oxide; W. S. Hendrixson, that **chloric acid** oxidizes bismuth slowly, and only

a small proportion passes into soln.; and M. M. P. Muir, that **perchloric acid** forms bismuthyl perchlorate.

D. Lagerhjelm,⁴ and R. Schneider observed that when bismuth is melted with **sulphur** in the absence of air, bismuth trisulphide is formed (*q.v.*), and, according to W. Spring, union occurs when the powdered elements are highly compressed. L. Moser and E. Neusser said that **hydrogen sulphide** converts heated bismuth completely into sulphide. N. Domanicky found that **sulphur monochloride** in the presence of ether forms bismuth chloride. J. Uhl, and H. Schiff observed that bismuth suffers no change when heated in a current of **sulphur dioxide**, and C. Geitner, that when heated with an aq. soln. of sulphur dioxide in a sealed tube at 200°, bismuth trisulphide is formed. Dil. **sulphuric acid** is without action on bismuth, but when warmed with the conc. acid bismuth sulphate and sulphur dioxide are formed. R. H. Adie found that when bismuth is heated with sulphuric acid, sulphur dioxide appears at about 90°, but no hydrogen sulphide. According to M. Websky, when heated with **potassium hydrosulphate**, below the m.p. of the metal, bismuth sulphate is formed; but at a higher temp., a basic sulphate is produced. M. G. Levi and co-workers observed the formation of a basic sulphate by the action of a soln. of **alkali persulphate**. J. J. Berzelius, and F. Rössler observed that when bismuth is fused with **selenium**, a selenide is formed, and J. J. Berzelius said that bismuth and **tellurium** are completely miscible in the fused state. E. B. Hutchins found that hot conc. soln. of **telluric acid** attack bismuth.

P. Vigier⁵ observed no evidence of the direct union of **nitrogen** and bismuth—*vide supra*, F. Hérard, amorphous bismuth. F. H. Newman studied the adsorption of nitrogen in discharge tubes. According to G. Gore, liquefied **ammonia** does not dissolve the metal; and the gas, or the aq. soln., has no action on bismuth. C. A. Kraus observed complex-ion formation with bismuth in ammonia soln. E. Müller and H. Barck found that bismuth decomposes **nitric oxide** at 400°, forming bismuth trioxide. J. J. Berzelius found that at ordinary temp., **nitric acid** is transformed into the nitrate; if fuming nitric acid be poured over powdered bismuth, the metal becomes red-hot; and J. L. Proust added that an explosion occurs when nitric acid is added to molten bismuth. N. A. E. Millon showed that the presence of nitrous acid is necessary for the nitric acid to attack the bismuth. Bismuth assumes the **passive state** in nitric acid of sp. gr. 1.54. According to T. Andrews:

Bismuth in nitric acid of sp. gr. 1.4, was rapidly acted upon, but this action immediately ceased when the bar was touched by platinum. On removing the platinum from the liquor, the bismuth will sometimes begin again to dissolve; at other times, its surface will become covered with a black crust, which is soon removed by the acid; but the metal, though now exhibiting a beautifully polished surface, is no longer acted upon by the acid, or, at least, is dissolved only with extreme slowness. Thus, a slip of metal, which, in its ordinary state, will require only a few seconds to complete its soln., will, when thus slightly modified, resist for many hours the action of the same acid.

According to C. Montemartini, the action of nitric acid of 27.5 or 70 per cent. HNO_3 yields with bismuth no ammonia, nitrogen, or nitrous oxide. More nitric oxide is obtained with the dil. than with the conc. acid, and it is produced by the secondary reaction. With the 27.5 per cent. acid, no nitrogen peroxide is produced, but with the 70 per cent. acid, this gas is the main product. C. C. Palit and N. R. Dhar observed only a slight action, and no nitrous acid was formed when 13 or 26 per cent. nitric acid acted on bismuth for 3 hrs. at ordinary temp. A. Quararoli studied the period of induction; and found that nitric acid freed from nitrous acid by urea does not attack bismuth. J. H. Stansbie found that when bismuth is treated with nitric acid of sp. gr. 1.2 at 65° in an atm. of hydrogen, nitric oxide, nitrogen peroxide, and nitrogen are evolved, and nitrous acid accumulates in the soln.—probably as nitrite. The reaction closely resembles those with copper and silver under similar conditions (*q.v.*). G. Tammann found that cold work makes the metal less noble, and it dissolves more quickly in acid. N. R. Dhar

said that when nitric acid acts on bismuth, only nitrous and hyponitrous acids are formed, and not hydroxylamine, hydrazine, or ammonia, which require the hydrogenation of nitric acid. Aqua regia readily dissolves bismuth, forming the trichloride. According to J. J. Sudborough, **nitrosyl chloride** acts on bismuth at ordinary temp., forming the trichloride, which in turn forms a complex salt with the excess of nitrosyl chloride. F. W. Bergstrom found that **potassium amide** reacts slowly with bismuth. B. Pelletier, and C. M. Marx, found that bismuth takes up very little **phosphorus** when the two elements are heated together. A. Michaelis observed that when bismuth is heated with **phosphorus trichloride** in a sealed tube some bismuth trichloride and phosphorus are formed. C. Braun said that when bismuth is heated to redness with **metaphosphoric acid**, some bismuth is projected away as fine rain, and some bismuth phosphate is formed. Both **arsenic** and **antimony** mix in all proportions in the molten state—*vide* arsenides and antimonides. Bismuth was found by W. Finkelstein to precipitate arsenic from a soln. of **arsenic trichloride** in nitrobenzene; and A. Mazzucchelli and A. Vercillo observed no alloy is formed by the action of bismuth on **antimony trichloride**. F. E. Brown and J. E. Snyder found that **vanadium oxytrichloride** has no action on bismuth. H. Giebelhausen found that **amorphous boron** is scarcely wetted by molten bismuth. H. Moissan found that **carbon** does not dissolve in molten bismuth. W. Fränkel studied the action of bismuth on **carbon dioxide**: $\text{Bi}_2\text{O}_3 + 3\text{CO} \rightleftharpoons 3\text{CO}_2 + 2\text{Bi}$, and found that at 400°, 500°, and 600°, equilibrium is attained respectively in 16, 5, and 2½ hrs. Y. Shibata and H. Kaneko studied the oxidizing action of the colloidal metal on pyrogallol soln. C. B. Gates found that 0.5 c.c. of **oleic acid** dissolves 0.0091 grm. of bismuth in 6 days. A. Korczynsky studied the catalytic action of bismuth in the halogenization of hydrocarbons. E. Vigouroux said that **silicon** dissolves in molten bismuth, but is rejected as the metal solidifies without forming a silicide.

The action of bismuth on the **metals** is discussed in a separate section; and for the fusible alloys, *vide* tin, and lead. W. Guertler⁶ discussed the affinity of bismuth for some of the metals. K. Jellinek and J. Wolff studied the equilibrium of bismuth with chlorides of sodium, potassium, calcium, and barium. A. Joannis found that a soln. of **sodium** in liquid ammonia forms sodium tritabismuthide. According to M. Kohn, bismuth reduces soln. of **copper salts** to the cuprous state: $\text{Bi} + 3\text{CuCl}_2 = \text{BiCl}_3 + 3\text{CuCl}$; while alkaline soln. of cupric salts are reduced to copper. N. W. Fischer, and J. B. Senderens observed that bismuth incompletely precipitates copper from a boiling soln. of cupric nitrate, and with a soln. of cupric chloride, cuprous chloride, and bismuth oxychloride are formed. H. Rose found that bismuth decomposes **silver hydroxide**; and N. W. Fischer observed that an alcoholic soln. of **silver nitrate** deposits silver. He also noticed that bismuth completely precipitates the gold from a soln. of **gold chloride** in a few hours. R. Boyle observed that when bismuth is heated with an excess of **mercuric chloride**, bismuth trichloride is formed, but if stoichiometrical proportions are used, both **mercurous chloride** and mercuric chloride furnish bismuth dichloride.

The physiological action of bismuth.—Soluble bismuth compounds are toxic. L. F. Meyer,⁷ and W. Steinfeld observed that when bismuth salts are injected subcutaneously into mammals or birds, or if large doses are given them through the mouth, effects as severe as those due to antimony may be produced. Death follows in 24–48 hrs., and the fatal issue is preceded by convulsions. After death, the organs are blackened—presumably by hydrogen sulphide in the parenchyma—but the small intestine and stomach are healthy unless sulphur compounds have been eaten. P. Dalché mentioned symptoms of poisoning in cases where wounds have been treated with bismuth preparations. The symptoms resembled mercurial poisoning. Bismuth leaves the rectum as sulphide and colours the fæces black; it may cause a purplish line on the gums; and the breath may have a garlic odour due to the contamination of bismuth with tellurium. Bismuth is slowly absorbed and excreted chiefly in the urine, and it may be found in the liver, kidney, spleen,

and nervous system. P. Lemay and L. Jaloustre found comparatively large amounts in the brains of two individuals to whom bismuth hydroxide had been administered. Bismuth salts are dusted on sores as protectives and mild astringents. The salts are also used in relieving gastric pains; and as astringents in diarrhoea. The oxynitrate, carbonate, and salicylate are used medicinally. G. Fuchs studied the effect of bismuth salts on the secretion of mucus, and C. Levaditi and co-workers, on trypanosomiasis and spirillosis. The physiological action of bismuth was studied by C. S. Lenard.

Some reactions of bismuth of analytical importance.—Bismuth salts are nearly all hydrolyzed by water, forming compounds containing the univalent radicle *bismuthyl*, BiO; thus, bismuth trichloride forms the oxychloride BiOCl, which, unlike the corresponding antimony oxychloride, is insoluble in tartaric acid. The soln. of bismuth salts do not give a precipitate with **hydrochloric acid**; and **hydrogen sulphide** precipitates brown bismuth trisulphide from neutral or dil. acidic soln.; the precipitate is insoluble in cold dil. mineral acids and alkali sulphide soln., but soluble in hot, dil. nitric acid, and boiling, conc. hydrochloric acid. The precipitate from alkaline soln., or that produced by **alkaline sulphides** is soluble in an excess of the alkali sulphide. Cold acidic soln. are partially precipitated by **ammonium thioacetate**, and completely when the soln. is boiling. Bismuth trisulphide is also precipitated when a soln. of a bismuth salt is treated with **sodium thiosulphate**. When cold soln. of bismuth are treated with **potassium hydroxide**, white bismuth hydroxide, Bi(OH)₃, is precipitated; this becomes yellow on boiling owing to the formation of bismuthyl hydroxide, BiO(OH). Bismuth hydroxide is soluble in boiling, conc. alkali-lye, but on cooling part is reprecipitated, and all is precipitated by dilution. Both hydroxides are insoluble in the cold in an excess of the precipitant, and are readily soluble in acids. Water containing the hydroxides in suspension gave a yellow or brown precipitate of metabismuth acid, HBiO₃, when treated with oxidizing agents like chlorine, bromine, hypochlorites, or hydrogen dioxide. Aq. **ammonia** precipitated a white basic salt from soln. of bismuth salts. According to F. Jackson,⁸ the sensitiveness of the reactions with ammonia and with alkali-lye is 1 : 8000. Soln. of **alkali carbonate** also precipitate basic carbonates from soln. of bismuth salts. F. Jackson said that the sensitiveness of the reaction is 1 : 32000. The hydrated oxide was found by J. von Liebig to be completely precipitated, even in the cold, by calcium carbonate; H. Demarçay added that barium, strontium, and magnesium carbonates act in an analogous way. Black bismuth triiodide is precipitated by **potassium iodide**, and the precipitate is soluble in excess, forming a yellow or orange soln. of KBiI₄. According to F. B. Stone, the yellow colour with potassium iodide is a soln. of a bismuth salt feebly acidified with sulphuric acid, is perceptible with a dilution 1 : 1,000,000. A soln. of **sodium phosphate** gives a white, granular precipitate of BiPO₄, insoluble in dil. nitric acid, and sparingly soluble in conc. hydrochloric acid. With **potassium cyanide**, the whole precipitate of the cyanide is instantly hydrolyzed to Bi(OH)₃; **potassium thiocyanate** precipitates bismuth monosulphide; **potassium ferrocyanide** gives a white precipitate soluble in hydrochloric acid; **potassium ferricyanide**, a yellow precipitate soluble in hydrochloric acid; and **potassium cobalticyanide**, a white precipitate. With **potassium dichromate or chromate**, yellow bismuthyl chromate is precipitated, soluble in mineral acids, and insoluble in alkali-lye. F. Jackson said that the sensitiveness of the chromate reaction is 1 : 4000. An alkaline soln. of stannous chloride, *i.e.* an **alkali stannite**, was shown by L. Vanino and F. Treubert to give a black precipitate of bismuth. If too much alkali-lye be present, metallic tin, or black stannous oxide may be precipitated. M. M. P. Muir said that with tartaric acid soln. of stannous oxide and of bismuth oxide, one part of bismuth can be detected in 210,000 parts of soln. Dil. **sulphuric acid** gives no precipitate with a dil. soln. of bismuth nitrate; H. Herzog⁹ found that a boiling neutral soln. gives a precipitate of basic acetate; M. M. P. Muir, that **sodium acetate** gives a white precipitate soluble in an excess of

acetic acid : H. Rose, and R. Schneider, that **oxalic acid** gives a white precipitate, and **ammonium acetate**, a white precipitate soluble in excess ; and C. Reichard, that a conc. soln. of **brucine** gives an intense red coloration.

The metallic precipitation of bismuth.—N. W. Fischer¹⁰ said that **copper** has no action on bismuth salt soln., but V. A. Jacquelin said that copper precipitates bismuth slowly and incompletely, and H. Reinsch added that a soln. of bismuth nitrate in 500 parts of dil. hydrochloric acid immediately forms a grey film on copper. The effect is obtained with soln. even more dilute. R. Schneider said that bismuth dissolves in a boiling soln. of cupric chloride—the soln. is decolorized, presumably owing to the formation of cuprous chloride. A. Commaille, and F. J. Faktor observed that **magnesium** precipitates bismuth from soln. of its salts, but K. Seubert and A. Schmidt said that precipitation is not complete in hydrochloric acid soln. N. W. Fischer said that **zinc and cadmium** precipitate bismuth rapidly and completely with the evolution of some gas, and a rise of temp. After the free acid has been neutralized, a basic salt of bismuth is precipitated, but this is also slowly reduced to the metal. K. Seubert and A. Schmidt found that the precipitation by zinc is not complete in hydrochloric acid soln. N. W. Fischer said that the precipitation by **lead** is incomplete, ceases after a time, and no gas is evolved ; A. Patera found the action with lead is incomplete in the presence of nitric acid ; and C. Ullgren, in acetic acid soln. O. Prelinger observed that **manganese** precipitates bismuth from soln. of its salts. N. W. Fischer said that **arsenic**, and **antimony** do not do so. The precipitation of bismuth by **iron** was found by N. W. Fischer to be rapid and complete, without the evolution of gas. J. Clark, J. G. Gallety and G. C. Henderson, and A. T. Starting also said that the precipitation with iron is complete. H. Cousin discussed the precipitation of bismuth by an alkaline soln. of dextrose.

The uses of bismuth.¹¹—Metallic bismuth is largely employed in the preparation of fusible alloys—*vide tin*, 7. 46, 5—used in automatic sprinklers and other apparatus for the prevention of fires ; electric fuses ; safety plugs in boilers ; in dentistry for making dies for plaster casts ; for special solders ; as crystals in the detectors of radiophone receiving apparatus ; etc. A. Lassieur¹² gave the following *fusible alloys* : with Sn : Pb : Bi : Cd = 2 : 4 : 7·5 : 1·5, m.p. 75°–76° ; 19 : 33·1 : 33·6 : 14·3, m.p. 94°–95° ; 2 : 4 : 10 : 1·5, m.p. 74°–75° ; 4 : 4 : 7·5 : 1·5, m.p. 75° ; 2 : 2 : 7·5 : 1·5, soft at 75°, molten at 80° ; 1 : 2 : 4 : 1, m.p. 74°–75° ; and 2 : 4 : 5 : 2, pasty at 77°, molten at 80°. Some of these alloys melt in hot water. The increased resistance of bismuth in a magnetic field is utilized in making instruments for determining the strength of magnetic fields. Bismuth salts—chiefly the oxycarbonate, or oxynitrate, oxysalicylate, oxygallate, oxylactate—are used medicinally for indigestion ; they are used in surgery dressings for wounds—some mixtures have trade names as *dermatol*, *airol*, *iodogallicine*, etc. An insoluble bismuth salt given with a meal distributes itself in the alimentary canal and allows an X-ray photograph to be taken which shows the digestive tract in clear outline. The oxychloride, and oxynitrate were formerly used as a cosmetic for toilet purposes, but have given way to the cheaper zinc oxide. Bismuth oxide has been used as a constituent of certain optical glasses ; in making enamels for cast-iron ; in porcelain painting and enamelling ; bismuth antimonate is used in making certain yellow colours ; the oxychloride and oxynitrate have been used as white pigments in painting—*blanc d'espagne*, and *blanc de perle* ; bismuth along with gold appears in some recipes for gilding porcelain ; and the oxynitrate, ground with an essential oil, is used in imparting an iridescent surface—*mother-of-pearl lustre*—to pottery. Some inflammable materials—*e.g.* tar, creosote, asphalt, and oils used for waterproofing cloth, wood, and paper—are rendered much less inflammable by admixture with 5–20 per cent. of bismuth chloride with or without a solvent like amyl acetate, etc.

§ 6. The Atomic Weight and Valency of Bismuth

According to J. Dalton,¹ 1810, the atomic weight of bismuth is 68. J. J. Berzelius at first supposed that ordinary bismuth oxide is analogous to lead oxide, and he assigned to both the same formula, RO_2 —this made the at. wt. of bismuth 284 (oxygen 16); and in 1826, he represented the formula RO , which made the at. wt. of bismuth 142 (oxygen 16). In 1817, J. J. G. Meinecke represented the eq. wt. of bismuth as 72; L. Gmelin gave 71; C. G. Bischof, T. Thomson, and C. M. Despretz, 72. In 1826, L. B. Thénard, gave 213 for the at. wt. of bismuth; then followed P. T. Meissner, O. B. Kühn with 71; and P. F. Cauchy with 142. P. L. Dulong and A. T. Petit's observation in 1869 on the sp. ht. correspond with the at. wt. 213 (oxygen 16); but J. J. Berzelius did not accept this value. A. E. Arppe, A. Stromeyer, W. Heintz, and W. Wiluëef showed that the formula of the ordinary oxide is probably Bi_2O_3 , and that of the higher oxide Bi_2O_5 , and the at. wt. of bismuth approximating 212.86 (oxygen 16) was then generally accepted. This is in agreement with the vapour densities of the volatile compounds of bismuth; with the sp. ht. rule, the isomorphous rule, and the periodic table.

Usually, bismuth acts as a trivalent element, and its halides are typified by BiCl_3 . A. Marquerdt prepared bismuth trimethide, $\text{Bi}(\text{CH}_3)_3$, and triethide, $\text{Bi}(\text{C}_2\text{H}_5)_3$; and A. Michaelis and A. Marquerdt, the triphenylide, $\text{Bi}(\text{C}_6\text{H}_5)_3$. Bismuth trimethide yields the trichloride with hydrochloric acid; and the triethide, with iodine yields $\text{Bi}(\text{C}_2\text{H}_5)_2\text{I}$, and with mercuric chloride, $\text{Bi}(\text{C}_2\text{H}_5)_2\text{Cl}_2$. E. B. Hutchins and V. Lenher were unable to make bismuth pentachloride, BiCl_5 ; but O. Ruff and co-workers obtained evidence of the formation of the pentafluoride, BiF_5 , by the action of fluorine on the trifluoride at -80° . In bismuth oxytrifluoride, BiOF_3 , the bismuth is probably quinquevalent, as is also the case with bismuth pentoxide, Bi_2O_5 . The quinquevalency of bismuth is supported by the existence of the complexes $\text{Bi}(\text{OH}_3)_3\text{Br}_2$, $\text{Bi}(\text{C}_6\text{H}_5)_3\text{Br}_2$, and $\text{Bi}(\text{C}_6\text{H}_5)_3\text{Cl}_2$ prepared by A. Michaelis, and A. Gillmeister. The evidence for bivalent bismuth turns on the existence of bismuth monoxide, and of the dihalides (*q.v.*). E. Neusser doubted the existence of bivalent bismuth.

D. Lagerhjelm calculated the at. wt. of bismuth to be 210.9–212.9 from the ratio $2\text{Bi} : \text{B}_2\text{O}_3$; R. Schneider, 208.00–208.04; L. Birckenbach, 208.05; A. Classen, 208.90; and J. Löwe, 207.83, from the same ratio; J. C. G. de Marignac obtained 208.6 from the ratio $\text{Bi}_2\text{O}_3 : 2\text{Bi}$. D. Lagerhjelm obtained 215.2 from the ratio $2\text{Bi} : \text{Bi}_2\text{S}_3$; and 212.4 from the ratio $2\text{Bi} : \text{Bi}_2(\text{SO}_4)_3$; R. L. Janssen, 208.07, from

the same ratio. J. C. G. de Marignac obtained 208.16 and B. Kuzma 208.0 from the ratio $\text{Bi}_2\text{O}_3 : \text{Bi}_2(\text{SO}_4)_3$. G. H. Bailey obtained 208.9 from an analysis of the sulphate. J. B. A. Dumas calculated 210.89 from the ratio $\text{BiCl}_3 : 3\text{Ag}$; and H. Mehler, 208.05 from the ratio $\text{BiBr}_3 : 3\text{AgBr}(\text{Ag}, 107.934)$.

In 1907, B. Brauner gave 208.0 for the best representative value, and in 1910, F. W. Clarke gave 208.062. G. D. Hinrichs favoured the whole number. R. H. Adie attributed the difference between the high and the low results to the presence of silicon, and he obtained 208.8 for the at. wt. Since then, W. O. de Coninck and P. Gérard obtained 208.50 from the ratio $\text{BiCl}_3 : \text{Bi}$; O. Hönigschmid and L. Birckenbach, 209.024 from the ratio $\text{BiCl}_3 : 3\text{AgCl}$, and 209.026 from the ratio $\text{BiCl}_3 : 3\text{Ag}$, and they favour the round value 209.00. They criticize A. Classen and O. Ney's value 208.9967, calculated from the ratio $2\text{Bi}(\text{C}_6\text{H}_5)_3 : \text{Bi}_2\text{O}_3$; in confirmation thereof, A. Classen and G. Strauch gave for the same ratio 208.989.

The **atomic number** of bismuth is 83. F. W. Aston² found that bismuth has no **isotopes**, being a simple element of at. mass 209. H. Müller obtained negative evidence of **atomic disintegration** when bismuth is exposed to intense α -radiation. G. Kirsch and H. Pettersson investigated the action of the α -particle on the atoms of bismuth. W. P. Jorissen and J. A. Vollgraff attempted to transform bismuth into thallium by the cathode rays, but without success. Bismuth commonly contains a trace of thallium which can be detected spectroscopically. A. Holmes and R. W. Lawson discussed bismuth as a possible end-product in the radioactive thorium compounds. K. A. Hofmann found bismuth in two samples of brögerite, but F. Soddy found none in Singalese thorite. The **electronic structure**, according to N. Bohr's scheme, is (2) (4, 4) (6, 6, 6) (8, 8, 8, 8) ⁷(6, 6, 6) (4, 1). The electronic structure was discussed by C. D. Niven, R. N. Ghosh, M. L. Huggins, E. C. Stoner, H. G. Grimm and A. Sommerfeld, G. Runge, and H. Nagaoka and co-workers. H. Collins has made some speculations on this subject.

§ 7. The Bismuthides

J. L. Gay Lussac and L. J. Thénard,¹ C. M. Marx, and H. Caron obtained alloys of sodium and bismuth by melting together a mixture of the two elements. The combination starts below the m.p. of bismuth and is attended by vivid combustion. G. S. Sérullas made the alloy by heating a mixture of bismuth and charred soap. A. Joannis, and P. Lebeau obtained an alloy approximating Na_3Bi by the action of sodammonium on bismuth. C. A. Kraus and H. F. Kurtz observed that by reducing soln. of bismuth salts in liquid ammonia by sodium, alloys are formed. C. T. Heycock and F. H. Neville found that the lowering of the f.p. of bismuth by sodium agrees with the assumption that the sodium is monatomic. N. S. Kurnakoff found that an alloy with 75 per cent. of bismuth, Na_3Bi , has a m.p. of 720° . E. Kordes studied the eutectic mixtures. C. T. Heycock and F. H. Neville, and C. H. Matthiesson measured the f.p. of the alloys and the curve, Fig. 4, has a

FIG. 4.—Freezing-point Curves of Sodium-Bismuth Alloys.

FIG. 5.—Freezing-point Curves of Potassium-Bismuth Alloys.

maximum at 775° and 75 at. per cent. of bismuth corresponding with **sodium tritribismuthide**, Na_3Bi . A Joannis obtained the tritribismuthide by the action of a soln. of sodium in liquid ammonia on the metal. F. Paneth and co-workers observed the formation of no bismuth hydride when the alloy is treated with acid. The tritribismuthide is bluish-violet in colour, brittle, and rapidly oxidizes in moist air. There is a eutectic in the curve at 218° and 22 at. per cent. of sodium; and a break in the curve at 445° and 47 at. per cent. of sodium. This corresponds with **sodium monobismuthide**, NaBi . This substance is brittle. Both compounds are about as hard as bismuth. R. Kremann and co-workers measured the electrode potential of sodium-bismuth alloys in a pyridine soln. of sodium iodide or in an aq. soln. of sodium sulphate with alloys having less than 5 per cent. of sodium against a bismuth electrode. Concordant results were not obtained, but with alloys having 10 to 80 at. per cent. of bismuth, the e.m.f. was constant at about 1.6 or 1.7 volts. J. L. Gay Lussac and L. J. Thénard, and C. M. Marx prepared alloys of potassium and bismuth, by melting a mixture of the two elements. Union is attended by incandescence. L. N. Vauquelin made an alloy by heating a mixture of bismuth and potassium tartrate covered with lamp-black; and G. S. Sérullas, by heating a mixture of bismuth with half its weight of carbonized potassium tartrate, and about half per cent. of nitre. C. Méhu also studied these alloys; and E. Kordes, the eutectic mixtures. D. P. Smith measured the f.p. of the potassium-bismuth alloys, and the

results are illustrated by Fig. 5. The metals in the fused state are miscible in all proportions. The f.p. curve has a maximum at 540° and 35 at. per cent. of potassium corresponding with **potassium dibismuthide**, KBi_2 ; and a maximum at 671° and 75 at. per cent. of potassium corresponding with **potassium tritabismuthide**, K_3Bi . This compound has a transition temp. at 280° . The break in the f.p. curve at 420° indicates the formation of **potassium tritadibismuthide**, K_3Bi_2 . There are two eutectics at 260° and 3 at. per cent., and at 335° and 50 at. per cent. of potassium respectively. The tritadibismuthide reacts with the fused mass near 373° , forming what is probably *potassium heptaennitabismuthide*, K_9Bi_7 . N. Parravano thinks that this compound is more likely to be **potassium monobismuthide**, KBi , because it results from a peritectic reaction, and the duration of the reaction cannot furnish an absolute criterion of the composition. R. Kremann and co-workers measured the electrode potential of potassium-bismuth alloys in a pyridine soln. of potassium chloride against bismuth. The e.m.f. showed two sharp steps corresponding with K_3Bi at 1.6 volts, and KBi_2 at about 0.80 volt. T. Seebeck studied the thermoelectric properties of the alloys. G. Bredig and F. Haber made colloidal soln. of sodium and potassium bismuthides by the submerged arc process.

C. M. Marx² made *copper-bismuth alloys* by fusing mixtures of the elements; E. Vigouroux obtained pale yellow lamellæ of the alloy as a by-product in the preparation of copper silicide. H. Gautier and R. Gosselin said that the f.p. curve shows a maximum corresponding with *copper monobismuthide*, CuBi . Alloys were made by R. H. Thurston, C. R. A. Wright, A. Gibb, and W. Hampe; the microstructure was studied by M. Merle, and J. E. Stead; and the hardness by A. Mallock. The f.p. curve has been measured by H. Gautier, A. H. Hiorns, K. Jeriomin, W. C. Roberts-Austen, C. T. Heycock and F. H. Neville, E. A. Lewis, K. L. Meissner, and A. Portevin. The results are shown in Fig. 20, 3, 21, 6. There are no compounds, and no solid soln. F. C. Calvert and R. Johnson studied the sp. gr. of the copper-bismuth alloys; F. C. Calvert and R. Johnson, the electrical conductivity; T. Seebeck, and A. Battelli, the thermoelectric properties. The general properties of the alloys, and the effect of bismuth on the mechanical properties of copper—C. M. Marx, E. A. Lewis, A. Portevin, D. Hanson and G. W. Ford, C. J. B. Karsten, F. C. Calvert and R. Johnson, W. C. Roberts-Austen, M. Knoerzer, C. T. Heycock and F. H. Neville, J. Arnold and J. Jefferson, F. Johnson, H. N. Lawrie, N. Parravano, P. Jolibois and P. Thomas, etc.—are described 3, 21, 6. E. Matthey observed that copper can be removed from an alloy with a low proportion of bismuth by fusion with bismuth sulphide, and from one with a high proportion of bismuth, by fusion with sodium sulphide. J. H. Stansbie measured the rate of dissolution of the copper-bismuth alloys in nitric acid.

The *silver-bismuth alloys* have been discussed in connection with silver—3, 22, 7. No definite compounds are formed. Alloys were made by P. Berthier,³ C. R. A. Wright, C. W. Kayser, A. Matthiessen, R. Schneider, and C. M. Marx. The mutual solubility of the elements was studied by W. Alexejeff. The sp. gr., by P. von Muschenbrock, A. Matthiessen and M. Holzmann, and E. Maey; the hardness, elongation, and tensile strength, by L. Jordan and co-workers; D. H. Andrews and J. Johnston, the solubility of silver in bismuth; the mixture rule, J. Dejmek; the diffusion by W. C. Roberts-Austen; the f.p. curves, by C. T. Heycock and F. H. Neville, and C. I. Petrenko; the electrical conductivity, by A. Matthiessen, and R. Kremann and K. Bayer; the thermoelectric properties, by A. Battelli; the e.m.f. by W. N. Lacey, A. P. Laurie, and H. le Chatelier. I. Domeyko⁴ described naturally occurring *silver bismuthide*, in Corpinpo, Chile. He called the mineral *aleacion de plata con bismuto*, and J. D. Dana, **chilenite**. Analyses by I. Domeyko, and D. Forbes correspond with Ag_{10}Bi to Ag_{12}Bi . It occurs in silver-white amorphous grains, which soon acquire a yellow tarnish. The mineral is soluble in nitric acid. H. E. McKinstry observed no action when the mineral is exposed to the light of an electric arc. The *bismuth-gold alloys* were discussed in connection with gold—3, 23, 6. No compounds are formed.

The alloys were prepared by C. Hatchett,⁵ A. Matthiessen, and F. Rössler. No compounds are formed. T. Andrews, F. Osmond and W. C. Roberts-Austen, L. Nowack, and M. Merle, studied the microstructure; J. Arnold and J. Jefferson, the effect of bismuth on the properties of gold; W. C. Roberts-Austen, the diffusion; A. Matthiessen, and E. Maey, the sp. gr. of the alloys; C. T. Heycock and F. H. Neville, and R. Vogel, the f.p. curve; A. Matthiessen, the electrical conductivity; A. P. Laurie, and H. le Chatelier, the e.m.f. F. Rössler found the alloy to be insoluble in a mixture of equal parts of nitric and tartaric acids. C. U. Shepard⁶ mentioned *bismuthic gold* occurring in North Carolina; and he called it **bismuthaurite**. It was not mentioned by F. A. Genth. It is thought that bismuthaurite was an artificial product. The *black gold* of the Australian miners occurs in Maldon, Victoria, and G. H. F. Ulrich⁷ called it **maldonite**. Analyses reported by G. H. F. Ulrich, and R. W. E. MacIvor correspond with *gold hemibismuthide*, Au_2Bi . The colour is silver-white with a pink tinge; the sp. gr. 8.2-9.7; and the hardness 1-2. W. Vernadsky made some observations on the mineral.

H. Caron⁸ melted a sodium-bismuth alloy with barium chloride and obtained an alloy of bismuth with 28 per cent. of barium free from sodium. The crystalline *barium-bismuth alloy* loses only a little weight when heated in a carbon crucible. It oxidizes rapidly in air, and if it contains more than 5 per cent. of barium, it is decomposed by water with the evolution of hydrogen, and the separation of bismuth. He obtained a *bismuth-calcium alloy* in a similar manner. L. Donsky could prepare alloys with only up to 10 per cent. of calcium. The f.p. of bismuth is lowered about 5° by the addition of calcium; and the eutectic contains less than one per cent. The f.p. curve, Fig. 6, rises from the eutectic to 502°, with 4.5 per cent. of calcium, and then runs horizontally as far as it could be followed. Acicular crystals of a **calcium bismuthide** are formed, but the formula could not be determined. P. Kremann and co-workers examined the e.m.f. of the Ca-Bi-alloys. The compound is decomposed rapidly in moist air, and even in vacuo over sulphuric acid. O. Ruff and H. Hartmann studied the velocity of absorption of nitrogen by the alloys at 400°-520°.

J. Parkinsom⁹ made alloys with magnesium. E. Kordes studied the eutectic mixtures. The f.p. curve of magnesium-bismuth alloys was examined by C. T. Heycock and F. H. Neville. G. Grube's curve is shown in Fig. 5, of 4. 29, 5. The curve consists of three branches. There is a well-defined maximum at 710° and 85.09 per cent. of bismuth corresponding with the steel-grey, brittle **magnesium ditribismuthide**, Mg_3Bi_2 , which is slowly oxidized in moist air. The compound is practically insoluble in bismuth. There is a eutectic at 552° and 65 per cent. of bismuth. No mixed crystals are formed. The *zinc-bismuth alloys*, and the *cadmium-bismuth alloys* have been previously discussed—*vide* Figs. 21 and 22 of 4. 30, 6. D. H. Andrews and J. Johnston studied the solubility of bismuth in cadmium; M. Kawakami, the heat of admixture; and E. Kordes, the eutectic mixtures. G. J. Petrenko and A. S. Fedoroff observed that the amount of each metal in solid soln. with the other cannot exceed 0.1 per cent. The eutectic has 40 per cent. bismuth. K. Houda and T. Ishigaki studied this subject; P. Fischer, and N. W. Taylor, the e.m.f.; A. W. Smith, and M. Naumann, the electrical conductivity; M. Naumann, the thermoelectric force; R. Kremann and A. Tröster, the electrolysis of these alloys; C. di Capua and M. Arnone, and M. Naumann, the hardness; C. H. Mathewson and W. M. Scott, the ternary system, Zn-Cd-Bi; D. H. Andrews and J. Johnston the ternary system, Sn-Cd-Bi. No compounds have been observed. *Mercury-bismuth* alloys, or *bismuth amalgams*, have been prepared, though V. Rothmund,¹⁰ and A. Gouy found the solubility of bismuth in mercury to be very small. J. Groh measured

FIG. 6.—The Freezing Point of Alloys of Calcium and Bismuth.

that rate of dissolution of bismuth in mercury. R. Böttger obtained an amalgam by the action of sodium amalgam on bismuth nitrate; and G. Vortmann electrolyzed a soln. obtained by dissolving bismuth trioxide and mercuric chloride in hydrochloric acid, and adding potassium iodide until the precipitate has all dissolved; or an alcoholic hydrochloric acid soln. of bismuth and mercuric chlorides; a soln. of the two nitrates in nitric and tartaric acids; and an ammoniacal soln. of the two chlorides. The f.p. of soln. of bismuth in mercury were determined by C. T. Heycock and F. H. Neville, and G. Tammann.

N. A. Puschin's observations are summarized in Fig. 7. G. Tammann, G. McP. Smith, E. Kordes, N. A. Puschin, K. Bornemann, and D. Mazzotto made observations on this subject, and failed to establish the existence of any definite compound, or solid soln. Hence. P. I. Bachmetjeff and J. V. Washaroff's Hg_{23}Bi , shown by a maximum on the sp. ht. curve, is probably not a chemical individual; and a similar remark applies to J. H. Croockewit's HgBi_2 , obtained by pouring molten bismuth into warm mercury, and squeezing out the excess of mercury through chamois-leather. Amalgams were also made by C. M. Marx, V. Merz and W. Weith, J. Regnaud, J. Schumann.

FIG. 7.—Freezing-point Curve of Mercury-Bismuth Alloys.

A. Battelli found that amalgams with more mercury than $\text{Hg}:\text{Bi}=9:1$ are liquid; those with less mercury than $\text{Hg}:\text{Bi}=2:1$ are solid; the solid amalgams are very brittle. D. H. Andrews and J. Johnston measured the solubility of bismuth in mercury; H. Feninger, the viscosity; F. C. Calvert and R. Johnson gave 11.208 for the sp. gr. of $\text{Hg}:\text{Bi}$; 10.693 for $\text{Hg}:\text{Bi}_2$; 10.474 for $\text{Hg}:\text{Bi}_4$; 10.350 for $\text{Hg}:\text{Bi}_4$; and 10.240 for $\text{Hg}:\text{Bi}_5$. G. Vicentini and C. Cattaneo measured the contraction coeff. G. Tammann and W. Jander, and J. Würschmidt found anomalies in the change of vol. with temp. indicating a transition point between the allotropic forms of bismuth at 75° . The change is attended by a considerable contraction. W. J. Humphreys studied the diffusion; C. Cattaneo, the thermal expansion; P. I. Bachmetjeff and J. V. Washaroff, the sp. ht.; and W. Ramsay, and E. D. Eastman and J. H. Hildebrand made some observations on the vap. press. The electrical conductivity or the electrical resistance was measured by A. Matthiessen, A. Matthiessen and C. Vogt, H. Feninger, A. Lohr, C. Michaelis, E. Lassen, G. Vicentini and C. Cattaneo, C. L. Weber, and A. Battelli; E. J. Williams, the change in the electrical resistance of the amalgam when placed in a magnetic field; T. Seebeck, and W. Rollmann, the thermoelectric process; V. Rothmund, R. Sabine, N. A. Puschin, A. Oberbeck and J. Edler, and G. Gore measured the electrode potential of the amalgams; and R. Kremann and A. Kapaun, the electrolysis of the amalgams. The amalgams are stable in air, but H. Lucas found that mercury with one eight-thousandth part of bismuth forms a black powder when shaken in air; and G. S. Sérullas said that water and potassium-amalgam will reveal as a black powder, one part of bismuth in 1,200,000 parts of mercury. V. Merz and W. Weith said that the mercury is all expelled by heating the amalgam to the temp. of boiling sulphur, mercury, or diphenylamine. C. F. Schöbein found that hydrogen dioxide is formed when the amalgam is shaken with water or dil. sulphuric acid. K. Someya found that bismuth amalgam reduces ferric to ferrous salts; quinquevalent to quadrivalent vanadium; stannic to stannous salts; cupric to cuprous salts; and titanous to titanous salts. K. Someya found that bismuth amalgam reduces vanadates to hypovanadates; ferric to ferrous salts; titanous to titanous salts; and molybdic acid to quinquevalent molybdenum. A. S. Russell and D. C. Evans studied the reducing efficiency of amalgams of bismuth on ferric sulphate, potassium permanganate, and uranyl sulphate, and expressed the results in terms of the overvoltages.

According to C. R. A. Wright,¹¹ *aluminium-bismuth alloys* separate into two layers—the lower layer is a soln. of about 0.28 per cent. aluminium in bismuth; and the upper one a soln. of about 2.02 per cent. bismuth in aluminium. C. and A. Tissier, and E. Self prepared alloys of the two elements. A. G. C. Gwyer also found that the reciprocal solubility of these two elements is small. The f.p. curve is shown in Fig. 8. The sat. soln. of bismuth in aluminium contains about 0.5 at. per cent. of the former metal and solidifies at 652°, about 5° below the m.p. of aluminium. At the same temp., the layer rich in bismuth contains about 8 at. per cent. of aluminium, but the solubility diminishes with decrease of temp., and is practically zero at the m.p. of bismuth. The two metals show no sign of chemical combination, even on heating for some time at 1200°. W. Campbell and J. Mathews studied the micro-structure; C. T. Heycock and F. H. Neville, the f.p. of the alloys; and H. Schirmeister, the tensile strength and elongation. H. Pécheux found that the alloys with

FIG. 8.—Freezing-point Curve of Alloys of Aluminium and Bismuth.

Aluminium 75 85 88 94 per cent.
 Specific gravity (20°) 2.857 2.79 2.776 2.74
 Melting point 719°–720° 674°–680° 663°–664° 650°–655°

The alloys are stable in moist and dry air; but they are attacked readily by conc. acids, or dil. or conc. alkali-lye. The powdered alloy decomposes water especially in the presence of copper sulphate. C. R. A. Wright studied the ternary systems, Bi–Al–Sb; Bi–Al–Sn; and Bi–Al–Ag.

E. Carstanjen,¹² and E. J. Chapman found that thallium forms alloys with bismuth. N. S. Kurnakoff and N. A. Puschin, and C. T. Heycock and F. H. Neville studied the f.p. of alloys of these two elements, and M. Chikashigé's results are summarized in Fig. 4 of 5. 36, 4. The f.p. curve has three maxima. The one at 211.7° and 37 per cent. of thallium corresponds with **thallium pentatritabismuthide**, Tl_3Bi_5 . This maximum was not observed by C. T. Heycock and F. H. Neville. The pentatritabismuthide forms a series of mixed crystals with 35.5–38.5 per cent. of thallium, and another series with 66.3–88.75 per cent. of thallium. There is a transition point at 90° indicating that the mixed crystals react to form **thallium tritabismuthide**, Tl_3Bi . The pentatritabismuthide is soft, and difficult to polish; the freshly cut surface is light grey, but rapidly becomes yellow. The compound is oxidized by long contact with air. The alloys in the region of the maxima of 303.5° and 88.7 per cent. of thallium, and at 302° and 99.2 per cent. of thallium behave as mixed crystals and not as chemical compounds. The three eutectics are at 197° and 20 per cent., 186° and 53 per cent., and 297° and 93 per cent. of thallium respectively. W. Guertler and A. Schulze measured the electrical conductivity of the alloys; and W. Jenge, the electrode potential. The observations of R. Kremann and A. Lobinger on the e.m.f. of cells with these alloys as one electrode agreed with the existence of the trita- and the pentatrita-bismuthides; but N. S. Kurnakoff and co-workers observed no evidence of the latter in their study of the f.p. of these alloys. D. Omodei studied the thermal expansion of these alloys; and E. van Aubel, the thermoelectric properties. The electrical conductivities by A. E. Whitford, and the magnetic susceptibilities by C. E. Medenhall and W. E. Lent are illustrated by Fig. 9. R. Vogel's observations¹³ on **cerium tritabismuthide**, Ce_3Bi , formed at about 1400°; **cerium tritetritabismuthide**, Ce_4Bi_3 , m.p. 1630°; **cerium monobismuthide**, $CeBi$, formed at 1525°;

Aluminium	75	85	88	94 per cent.
Specific gravity (20°)	2.857	2.79	2.776	2.74
Melting point	719°–720°	674°–680°	663°–664°	650°–655°

FIG. 9.—Properties of Thallium-Bismuth Alloys.

cerium tritabismuthide, Ce_3Bi , formed at about 1400°; **cerium tritetritabismuthide**, Ce_4Bi_3 , m.p. 1630°; **cerium monobismuthide**, $CeBi$, formed at 1525°;

and **cerium dibismuthide**, CeBi_2 , formed at 882° are indicated in connection with cerium—5. 38, 10.

The *silicon-bismuth alloys* are discussed in connection with bismuth silicides—6. 40, 12; the *tin-bismuth alloys*, in connection with tin—7. 46, 5; and the *lead-bismuth alloys*, in connection with lead—7. 47, 5. No *tin bismuthides* or *lead bismuthides* have been isolated. R. S. Williams¹⁴ found that *chromium and bismuth* are immiscible in the fused state so that the f.p. curves appear as in Fig. 10. No compounds are formed. S. Hilpert and T. Dieckmann examined the magnetic properties of the alloys. C. Sargent prepared a *molybdenum-bismuth alloy* and a *tungsten-bismuth alloy* in the electric furnace. J. J. and F. de Elhuyar also made bismuth-tungsten alloys. Observations on the *manganese-bismuth alloys* were made by E. Bekier, N. Parravano and U. Perret, and P. Siebe. The two metals are not completely miscible. The f.p. diagram is shown in Fig. 11. When more than 23 per cent. of manganese has been determined by the cooling curve method, the two metals are not completely miscible. When more than 23 per cent. of manganese is present, two layers are formed, the upper consisting of practically pure manganese, whilst the lower is a 23 per cent. soln. of manganese

FIG. 10.—Freezing-point Curves of Chromium-Bismuth Alloys.

FIG. 11.—Freezing-point Curve of Manganese-Bismuth Alloys.

in bismuth. Five arrest points were found, corresponding with five crystalline phases. The eutectic horizontal is at 259° , and the other four horizontals, corresponding with the arrest points, are at 442° , 1043° , and 1252° . The last represents a eutectic containing at most 0.5 per cent. bismuth, which lowers the m.p. of manganese 13° . From alloys containing up to 0.5 per cent. of manganese, pure bismuth first separates; with 0.5–9 per cent. of manganese, the first compound separates; from 9 per cent. to 11 per cent. a second compound, and from 11 per cent. to 20 per cent., a third. The nature of the compounds has not been determined. Between 23 per cent. and 99.5 per cent. of manganese there is a complete gap. The hardness of the alloys increases with the manganese content. They are ferromagnetic, and this property is peculiar to the first compound, crystallizing from alloys containing between 0.5 per cent. and 9 per cent. of manganese. E. Wedekind and T. Veit prepared **manganese bismuthide**, MnBi , by the interaction of manganese thermite and bismuth. It forms octahedral and eight-sided columnar crystals which are strongly magnetic; it is very sensitive towards acids, with the exception of conc. hydrochloric acid, which reacts very slowly and may be used for its purification. The same compound was also obtained, but with difficulty, by the direct fusion of the components in an atm. of hydrogen. S. Hilpert and T. Dieckmann prepared the same compound by heating manganese amalgam with the necessary amount of bismuth in an atm. of hydrogen, and then distilling off the mercury. The grey substance burns in air giving non-magnetic products; it is soluble in nitric acid and in hot hydrochloric acid. The magnetic bismuthide loses

its magnetic properties at 360° and regains them at 380° on cooling. P. Martin studied the magneto-optical effect with manganese bismuthide.

E. Isaac and G. Tammann¹⁵ studied the *iron-bismuth alloy*, and found that iron is not miscible with bismuth in the solid or fused state, and no compounds are formed. The f.p. curves thus appear as in Fig. 12.

FIG. 12.—Freezing-point Curve of Iron-Bismuth Alloys.

C. J. B. Karsten said that he could prepare iron with only 0.081 per cent. of bismuth. C. M. Marx could not obtain an alloy of the two metals although J. F. Henkel reported a brittle alloy with 25 per cent. of iron; and C. E. Gellert made observations on the sp. gr. of these alloys. S. Hilpert and T. Dieckmann examined the magnetic properties of the alloys. K. Lewkonja studied the *cobalt-bismuth alloys* and found that the two elements are partially miscible in the liquid state—the limits of miscibility being 6 and 93 per cent. of cobalt—Fig. 13. G. Voss examined the *nickel-bismuth alloys* and found that the two elements are completely miscible in the fused state. The f.p. curve, Fig. 14, consists of three branches without maxima or minima.

There is one series of mixed crystals with up to 0.5 per cent. of bismuth. At 638°, the sat. solid soln. reacts with the fused mass containing 32 per cent. of nickel to form **nickel monobismuthide**, NiBi; and this, in turn, reacts with the fused mass containing 11 per cent. of nickel to form **nickel tribismuthide**, NiBi₃. These compounds could not be prepared in a pure state. The transition temp. of magnetic to non-magnetic nickel is lowered 20° by the addition of sufficient bismuth to form the sat. solid soln., and then remains constant at 325° up to a composition of 32 per cent nickel, beyond which the alloys are no longer magnetic. F. Rössler made some nickel-bismuth alloys. G. Tammann

FIG. 13.—Freezing-point Curve of Cobalt-Bismuth Alloys.

FIG. 14.—Freezing-point Curves of Nickel-Bismuth Alloys.

and K. Dahl studied the brittleness of the NiBi- and the NiBi₃-alloys. W. Meissner partially studied the ternary system: Bi-Cu-Ni.

A. F. Gehlen¹⁶ said that *platinum-bismuth alloys* can be readily obtained of a bluish-grey colour, brittle, and readily fusible. They were also made by C. Barus, J. Murray, R. W. Fox, and C. Winkler. C. T. Heycock and F. H. Neville found that the f.p. of platinum is lowered 2.09° and 2.16° respectively by the addition of 0.206 and 0.939 at. per cent. of bismuth. The f.p. curve was surmised by W. Guertler to be similar to that of platinum and lead. C. Barus found the sp. resistance of an alloy of sp. gr. 21.33 at 0° to be 15.83 with the temp. coeff. of 0.0721 between 0°

and 100°. R. W. Fox found that when calcined in air, most of the bismuth is oxidized to the trioxide. A. B. von der Ropp, and C. Winkler examined the solvent action of nitric acid on these alloys. According to F. Rössler, **platinum dibismuthide**, $PtBi_2$, is formed when 10 grms. of platinum and 400 grms. of bismuth are fused together under glass in a coke furnace. The product is slowly cooled and washed with dil. nitric acid. The dark grey plates are slightly attacked by nitric acid. R. Chenevix¹⁷ prepared a grey-coloured *palladium-bismuth alloy* with a sp. gr. 12.587. F. Rössler found the alloy to be insoluble in a mixture of nitric and tartaric acids. T. Graham said that it absorbs no hydrogen. C. T. Heycock and F. H. Neville studied the effect of bismuth on the f.p. of palladium. W. H. Wollaston made a *rhodium-bismuth alloy* soluble in nitric acid. F. Rössler found the alloy to be insoluble in a mixture of nitric and tartaric acids.

§ 8. Bismuth Monoxide, and Trioxide

The brownish-grey film of oxide which can be skimmed from molten bismuth was considered by T. Thomson to be a suboxide; so also did W. Heintz believe that the bismuth precipitated by zinc absorbs rather more oxygen than corresponds with the formula BiO. It is probable that in these cases a mixture of bismuth trioxide and bismuth is involved. S. M. Tanatar heated the basic oxalate, $\text{Bi}_2\text{O}(\text{C}_2\text{O}_4)_2$, in a current of dry carbon dioxide and obtained a product with the ultimate composition, *bismuth suboxide, or hemioxide*, Bi_2O . Its sp. gr. at 19° is 8.356; and the supposed compound gives the same chemical reactions as bismuth monoxide. This fact, and the heat of dissolution in acids, agrees with the assumption that the hemioxide is a mixture of the monoxide and metal.

Another oxide, also referred to as a suboxide, is regarded as **bismuth monoxide**, BiO, from the analyses of R. Schneider, and H. Schiff. It was made by A. Vogel by heating bismuth trioxide or the basic nitrate with stannous chloride. It forms a black powder, which, after washing and drying, glows with a yellowish-green light

when heated, forming the trioxide. It turns yellow in air at ordinary temp., and is soluble in hydrochloric acid. J. J. Berzelius, and A. E. Arppe said that A. Vogel's suboxide always contains some tin which cannot be removed by washing. H. Schiff obtained this oxide by the action of a soln. of an alkali stannite on bismuth trioxide or hydroxide; R. Bunsen treated a neutral or feebly alkaline soln. of bismuth tartrate with a neutral or feebly alkaline soln. of stannous chloride and tartaric acid. R. Schneider, F. Hartl, and M. M. P. Muir prepared the oxide by an analogous process—pouring a soln. of bismuth trichloride into a soln. of alkali stannite. R. Schneider recommended pouring slowly, with constant stirring, a soln. of bismuth trioxide in nitric acid into an excess of dil. potash-lye, washing the precipitated bismuth hydroxide, and suspending it in a capacious flask containing a 2 per cent. soln. of potassium hydroxide. A freshly prepared soln. of stannous chloride was slowly added to the flask, which was then completely filled with air-free water, tightly closed, and the contents well shaken. The product is a light homogeneous black powder which, on exposure to air, forms ordinary bismuth hydroxide. A Jaworosky warmed a gram of bismuth oxynitrate with a soln. of 3 grms. of ferrous sulphate, 4 of sodium antimonate, 5 of sodium hydroxide, and 40 of water, and obtained the monoxide as a dark brown powder. E. Zumbusch employed a similar process.

L. Vanino and F. Treubert maintained that bismuth monoxide is never formed by the action of stannous chloride on bismuth trichloride in alkaline soln. If the bismuth trichloride is in excess, the precipitate consists of a mixture of metallic bismuth with metahydroxide or the oxychloride. Three mol. proportions of stannous chloride suffice to reduce completely bismuth trioxide, Bi_2O_3 , to metallic bismuth. A. Lottermoser also held that the reaction progresses: $\text{Bi}_2\text{O}_3 + 3\text{SnO} = 3\text{SnO}_2 + 2\text{Bi}$. R. Schneider replied that L. Vanino and F. Treubert did not keep the bismuth soln. always in excess, but added the latter gradually to the soln. of the stannous salt. Under these conditions, the bismuth salt is completely reduced to the metal. W. Herz and A. Guttman confirmed R. Schneider's observation that the reaction progresses $\text{Bi}_2\text{O}_3 + \text{SnO} = \text{SnO}_2 + 2\text{BiO}$; and showed that the product is identical with that obtained by S. M. Tanatar by heating the oxalate, $(\text{BiO})_2\text{C}_2\text{O}_4$, in a current of carbon dioxide: $(\text{BiO})_2\text{C}_2\text{O}_4 = 2\text{BiO} + 2\text{CO}_2$. W. Herz and A. Guttman found that in an evacuated tube, the decomposition of the oxalate begins at 18° and 15 mm. press., and is completed at 245° – 250° . If the temp. be too high, the oxalate furnishes a mixture of bismuth and its trioxide, not the monoxide. M. M. P. Muir said that the monoxide is formed when bismuth trioxide is heated to 265° in a current of hydrogen; C. F. Schlagdenhauffen and C. Pagel obtained a similar result with carbon monoxide at 400° . F. J. Brislee observed a break in the reduction curve of bismuth by carbon monoxide at 300° trioxide at different intervals of time.

Time in hours	0	3	4.5	6	9	12	15
Weight of oxide	3.00	2.934	2.920	2.890	2.868	2.850	2.831

R. Schneider reduced potassium bismuth sulphate with hydrogen and obtained the monoxide above 300° ; below that temp., only water and sulphuric acid are given off. The brownish monoxide is mixed with some trisulphide. A. Hilger and P. A. von Scherpenberg said that the monoxide is probably formed by the action of warm potassium cyanide on bismuth hydroxide.

J. J. Berzelius said that a suboxide is formed when bismuth is heated with microcosmic salt on charcoal in the reducing flame of the blowpipe. The clear glass becomes black on cooling. J. L. Proust, and H. Davy believe that J. J. Berzelius' oxide is a mixture of bismuth and bismuth trioxide. A. E. Arppe's attempt to make the suboxide by reducing an alkaline soln. of bismuth trioxide with glucose gives according to R. Schneider, and J. Löwe, a precipitate of bismuth; W. Heintz reduced bismuth phosphate in hydrogen, and obtained bismuth phosphide; and R. Schneider obtained but a small yield of bismuth monoxide by heating potassium bismuth tartrate and similar compounds in a current of hydrogen.

R. Schneider said that the dark grey or black powder appears more or less crystalline under the microscope, and gives no metallic streak on polished steel. When prepared by the wet process, and kept in vacuo, or at 100° , it contains about one per cent. of water— $8\text{BiO}\cdot\text{H}_2\text{O}$; but, according to W. Herz and A. Guttman, when heated in a current of carbon dioxide, it is free from water, has a pale grey colour, and is somewhat hygroscopic. The sp. gr. of the monoxide, prepared by the wet process, is 7.88–7.90 at room temp.; 7.24–7.28 when dried over sulphuric acid; and 7.55–7.60 when quite dehydrated. S. M. Tanatar gave 7.153–7.201 for the sp. gr. at 19° of the product obtained by the dry process. These results do not agree with the assumption that the monoxide is a mechanical mixture of bismuth and its trioxide; and W. Herz and A. Guttman obtained 8.9 for the sp. gr. of a mixture of colloidal bismuth and bismuth trioxide. S. M. Tanatar's observations on the heat of soln. of the monoxide in acids agree with the chemical individuality of the monoxide; the heat of formation of 3 mols of the monoxide from a mol of bismuth trioxide and a gram-atom of bismuth is 11.814 Cals. If the monoxide be heated above the m.p. of bismuth in carbon dioxide, W. Herz and A. Guttman, and S. M. Tanatar found that it decomposes into a mixture of bismuth and its trioxide. R. Schneider said that when dried in vacuo, the monoxide is only slightly oxidized by exposure to air; while M. M. P. Muir, and S. M. Tanatar said that it is stable in dry air, but in moist air, R. Schneider, and H. Schiff noticed that it quickly acquires a film of ordinary bismuth hydroxide, and, added M. M. P. Muir, heat is at the same time evolved. If the oxide has been dried, and afterwards moistened, oxidation occurs only slowly. When heated in air, oxidation occurs without glowing—but A. Vogel, R. Schneider, and S. M. Tanatar observed a glow. The monoxide prepared from the oxalate oxidizes only slowly when heated in air. M. M. P. Muir found that oxidation in air begins at 180° , and proceeds slowly up to 220° , when it is not completed; in oxygen, oxidation begins at 140° , and is completed at 240° ; hydrogen reduces it at 300° – 310° ; and carbon monoxide at 250° . R. Schneider, and S. M. Tanatar found that the monoxide slowly decomposes under cold and rapidly under boiling water; and under hot dil. acids, forming bismuth and bismuth salts: $3\text{BiO} + 6\text{HCl} = 2\text{BiCl}_3 + 3\text{H}_2\text{O} + \text{Bi}$. D. L. Hammick found that when heated in sulphur dioxide, it gives a reddish-brown sublimate (as does bismuth trioxide to a much less extent), which blackens on heating, contains oxygen, and may be bismuth monoxide, a lower oxide, free bismuth, or a mixture. The ultimate product is $4\text{Bi}_2\text{O}_3\cdot 3\text{SO}_3$, and no sulphide or free sulphur is formed, but a trace of sulphur trioxide is produced. Some evidence of the volatilization of the monoxide in sulphur dioxide was obtained. S. M. Tanatar found that the monoxide reduces Fehling's soln., and a soln. of potassium permanganate. M. M. P. Muir also found that alkaline permanganate oxidizes the monoxide to tetra- and pentoxides; and a soln. of bromine in alkali-lye oxidizes it to the trioxide and then to the pentoxide. Bismuth monoxide appears to be a feeble base in that it forms a corresponding sulphide, and also halides. R. Schneider, and M. M. P. Muir showed that bismuth separates out when the monoxide is boiled with a conc. aq. soln. of potassium hydroxide, or with an alkaline soln. of tartaric acid or glycerol.

E. Neusser doubted if the alleged monoxide really exists as a chemical individual. Metallic bismuth can be extracted from the substance by shaking with mercury. When heated for 16–18 hours in dry hydrogen sulphide, the suboxide behaves as a mixture of metal trioxide, and hydroxide, each of which is attacked by the gas at a different rate. The presence of hydroxide explains the variable composition of the suboxide and also the low density (7.16 at 22° when freshly prepared) compared with that calculated for a mixture of bismuth metal and trioxide. He was unable to accept S. M. Tanatar's observations on the thermochemistry of the monoxide since he found that the heat of the reaction with hydrochloric acid, the solubility in aq. soln. of sodium hydroxide, and the sp. magnetic susceptibility are indistinguishable from those of a mixture of a mol of the trioxide and a gram-atom of the metal. He therefore concluded that *there is no satisfactory proof of the existence*

of bivalent bismuth, and that the so-called compounds of bivalent bismuth are only mixtures of the metal and the trioxide.

According to G. Agricola,² yellow bismuth oxide—**bismuth trioxide**, Bi_2O_3 , or *bismuthous oxide*—was used as a pigment in the Middle Ages. The impure trioxide occurs in nature as the mineral *bismuth ochre*. J. G. Wallerius called the yellow pulverulent earth *ochra wismuthi*; J. B. L. Romé de l'Isle, *mine de bismuth calciforme*; L. A. Emmerling, *Wismuthokker*; and J. D. Dana, **bismite**.

As indicated in connection with bismuth, the trioxide is produced when bismuth is heated in air, then, when the molten metal is continuously stirred in air, it forms a yellowish-brown powder of the trioxide; and when bismuth is heated to its b.p. in air it forms *flowers of bismuth* or *flores bismuthi* as a lemon-yellow, flocculent powder. The trioxide is also formed when the monoxide is heated in air. The most convenient process is to heat the basic nitrate in air until it no longer loses weight. This method was used by D. Lagerhjelm,³ R. Schneider, F. Chemnitz, and A. Classen. A similar result is obtained by heating the carbonate or sulphate. V. A. Jacquelin, and A. E. Nordenskjöld fused the hydroxide with an excess of potassium hydroxide and obtained crystals of bismuth trioxide. L. Vanino and E. Zumbusch obtained the hydroxide by dissolving bismuth nitrate (20 grms.) in water (100 c.c.) containing mannitol (7.5 grms.), adding 50 c.c. of ice-cold potassium hydroxide soln. (22 grms. in 100 c.c. of water), and finally dil. sulphuric acid until the mixture was only slightly alkaline. E. R. Darling fused the metal with sodium nitrate and passed chlorine into the fused mass. P. A. von Bonsdorff covered bismuth with water exposed to air freed from carbon dioxide, and obtained first the hydroxide and then yellow crystals of the trioxide. E. B. R. Prideaux and H. W. Hewis obtained the oxide by the corrosion of bismuth anodes in an anolyte of a sat. soln. of sodium nitrate. From one-fourth to one-half the bismuth is precipitated as oxynitrate, and the remainder in soln. is precipitated as bismuth hydroxide by running the anodic liquor into an equal vol. of $\frac{1}{2}N$ -NaOH diluted about five times; the precipitate is washed by decantation. With a 10 per cent. soln. of sodium nitrate as anodic liquor, the amount of bismuth remaining in soln. is negligible, and the precipitate consists of oxynitrate with about 30 per cent. of bismuth trioxide. The current density used was 12.5 amp. per sq. dcm., and an average of 4.6 volts. Crystals were also obtained by A. Stromeyer, and E. Frémy, by boiling the hydroxide with alkali-lye; and M. M. P. Muir and A. Hutchinson, by boiling for 15 mins. in soln. of 2½–3 parts of potassium cyanide with a soln. of one part of bismuth trioxide in the smallest amount of nitric acid, and repeated by treating the product with boiling potash-lye.

Analyses of bismuth-ochre, by W. A. Lampadius, A. Stelzner, G. A. Suckow, A. Carnot, and W. T. Schaller and F. L. Ransome agree with the assumption that it is an impure bismuth trioxide; but W. T. Schaller does not consider that the evidence is at all satisfactory, and he showed that the bismuth ochres—native bismite—are more probably impure bismuth hydroxides, $\text{Bi}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, or $\text{Bi}(\text{OH})_3$. Those from San Diego Co., California, were described by C. F. Kunz, and W. T. Schaller. According to A. F. Rogers, the crystals of bismite agree with those of artificial bismuth trioxide, but W. T. Schaller and F. L. Ransome could not confirm this statement. Analyses of artificial bismuth trioxide by J. Davy, T. Thomson, D. Lagerhjelm, M. H. Klaproth, C. F. Bucholz, L. J. Proust, L. B. G. de Morveau, J. Löwe, J. C. G. de Marignac, A. Classen, and R. Schneider agree with the formula Bi_2O_3 . The **colour** of bismuth ochre—probably bismuth hydroxide, *vide infra*—is greyish-white, straw-yellow, or greenish-yellow; the artificial product is pale lemon-yellow, and, according to R. Schneider, when heated it becomes first orange-yellow and then reddish-brown. The mineral occurs massive with a conchoidal or earthy fracture; and also as a pulverulent earth. Bismuth trioxide is dimorphous. The greyish-black **crystals** obtained by M. M. P. Muir and A. Hutchinson were small tetrahedra belonging to the cubic system; those prepared by A. E. Nordenskjöld were rhombic with the axial ratios $a : b : c = 0.8166 : 1.0649$.

V. M. Goldschmidt described solid soln. of yttrium and bismuth oxides. W. Guertler observed that when melted bismuth trioxide is allowed to cool, the mass glows after crystallization has commenced. The cooling curve, Fig. 15, shows a break at 820° , then falls to 688° , rises to 704° , and then falls rapidly to the ordinary temp. Hence 704° represents the **transition temperature** of the II-modification to the ordinary or III-modification. This is confirmed by the heating curve, Fig. 15. The II-modification cannot be obtained at ordinary temp. Another form, the I-modification, is produced by heating bismuth trioxide in a porcelain crucible. It melts at a higher temp. than the II-form, and it is more stable, for it dissolves less readily in dil. nitric or sulphuric acid. L. Moser also said that bismuth trioxide exists in several modifications; R. Lorenz and W. Herz made some observations on this subject.

The **specific gravity** of bismuth trioxide which has been obtained by fusing the basic nitrate was found by A. Classen to be 9.044; P. F. G. Boullay, 8.968; by H. G. F. Schröder, 8.855–8.868 at 4° . W. Herapath gave 8.21; C. J. B. Karsten, 8.173; and L. Playfair and J. P. Joule, 8.079; A. le Royer and J. B. A. Dumas gave 8.45 for the glassy trioxide, and M. M. P. Muir and A. Hutchinson gave 8.37 for the rhombic form, and 8.828 for the cubic form. W. Guertler gave 8.20 for the sp. gr. of the II-form, and 8.55 for the III-form. D. Balareff studied the mol. vol. O. Hauser and W. Steger gave for the **specific heat** of bismuth trioxide 0.0568 at 20° – 100° ; 0.0598 at 20° – 204° ; 0.0604 at 20° – 312° ; 0.0616 at 20° – 414° ; and 0.0623 at 20° – 503° . J. N. von Fuchs, and F. W. Schmidt said that the trioxide melts to an amber-yellow liquid, which, on cooling, forms a crystalline mass. T. Carnelley and J. Walker gave for the **melting point**, a temp. between 655° and 710° . W. Hempel said that **volatilization** of the trioxide occurs at a very high temp. as when it is heated by the gas-blowpipe flame. According to G. H. Bailey, if the temp. of bismuth sulphate be high enough to ensure complete decomposition, some bismuth oxide is lost by volatilization. J. Joly found that no volatilization occurs except at a very high temp.; and A. A. Read observed no change in the composition of bismuth trioxide when heated to 1750° in an oxidizing atmosphere. E. L. Nichols and D. T. Wilber sublimed the oxide in an electric arc. W. R. Mott calculated 900° for the **boiling point**. A. Ditte and R. Metzner gave for the **heat of formation** of bismuth trioxide ($2\text{Bi}_2\text{O}_3$) = 137.8 Cals., and W. G. Mixter, 136 Cals. C. Renz found that bismuth trioxide is **photosensitive**, for, when exposed to light in the presence of glycerol, benzaldehyde, or tartaric acid dissolved in alcohol, it becomes grey and ultimately black. Reduction to a lower oxide or the metal occurs. A. Kundt gave 1.91 for the **index of refraction** of bismuth trioxide for white light. E. L. Nichols and D. T. Wilber observed no flame luminescence with the oxide. J. O. Perrine observed no ultra-violet fluorescence with bismuth oxide. A. Karl found that the oxide is triboluminescent. H. R. Robinson and A. M. Cassie studied the line spectra of secondary and tertiary X-rays produced by primary K-rays. F. Beijerinck found that the **electrical conductivity** of bismuth trioxide in compact masses is zero; but at elevated temp., it is a conductor. F. Horton measured the effect of temp. on the electrical resistance in ohms, and the electrical conductivity in mhos of bismuth oxide melted and cast into slabs:

	225°	315°	376°	487°	535°	645°
Ohms .	8×10^7	255×10^4	259,000	15,300	7,150	2,050
Mhos .	4.27×10^{-9}	1.34×10^{-7}	1.32×10^{-6}	2.23×10^{-5}	4.77×10^{-5}	1.66×10^{-4}

The electrolysis of the oxide can be detected at 200° . T. W. Case found that

FIG. 15.—Heating and Cooling Curves of Bismuth Trioxide.

light has no appreciable influence on the non-conductivity of bismuth trioxide. J. Dewar and J. A. Fleming found the **dielectric constant** was only slightly changed by cooling the oxide to -185° . The **magnetic susceptibilities** of bismuth trioxide and hydroxide given by K. Honda, and G. Meslin are -0.188×10^{-6} , and -0.129×10^{-6} respectively; and by S. Meyer, -0.150×10^{-6} , and -0.103×10^{-6} respectively.

A. K. Sanyal and N. R. Dhar found that the hydrated oxide is discoloured by exposure to tropical sunlight for 20 hrs. R. Schneider observed that when bismuth trioxide is heated in **hydrogen** it is reduced to metal; as J. C. G. de Marignac also observed, the reduction proceeds with difficulty and at a temp. at which some of the oxide is volatilized; and M. M. P. Muir said that at 300° , less oxygen is given off than corresponds with the formation of the monoxide. E. S. Meunier found that when heated in air in contact with alkali a bismuthate is formed. A. Mailfert said that **ozone** transforms the trioxide into pentoxide, and if alkalis be present, the alkali bismuthate is formed. Various other oxidizing agents—*e.g.* chlorine-water, and bromine-water—in the presence of alkali transform the trioxide into the tetroxide, or pentoxide; and T. Poleck obtained bismuth pentoxide by the action of **sodium dioxide**. For the action of **water**, *vide infra*. M. M. P. Muir found that when heated in **chlorine**, bismuth trichloride and a little oxychloride, $\text{Bi}_3\text{O}_2\text{Cl}_3$, are formed; with **bromine** vapour, the oxybromide, $\text{Bi}_{11}\text{O}_{13}\text{Br}_7$, and a little tribromide are produced. J. L. Gay Lussac found that **iodine** transforms the trioxide into triiodide. The equilibrium between the halogen acids—**hydrochloric and hydriodic acids**—was studied by M. M. P. Muir. W. Jacobs studied the action of hydrochloric acid. E. A. Atkinson found that **hydrobromic acid** converts heated bismuth trioxide into tribromide. When the trioxide is heated with **sulphur**, some trisulphide is formed, and when heated in a current of **hydrogen sulphide**, O. Schumann said that the sulphide, Bi_4S_3 , is produced (*q.v.*). L. Moser and E. Neusser said that the reaction is not complete. D. L. Hammick observed that when heated in **sulphur dioxide**, bismuth trioxide yields first a black powder, which contains sulphate and gives bismuth on treatment with hydrochloric acid; it is a mixture of a bismuth sulphate with either bismuth monoxide, free bismuth, or both oxide and bismuth. The ultimate product is $4\text{Bi}_2\text{O}_3 \cdot 3\text{SO}_3$; and no sulphide or free sulphur is formed, and only a trace of sulphur trioxide. G. Oddo and E. Serra found that **sulphur chloride** converts the heated trioxide into trichloride. Hydrated bismuth trioxide readily transforms a number of metal **sulphides** into oxides—*e.g.* arsenic trisulphide. G. Gore said that bismuth trioxide, or rather the hydroxide, is insoluble in liquid **ammonia**. M. M. P. Muir showed that when heated with ammonia the trioxide is reduced to the metal, and, added A. Gutbier and L. Birckenbach, particularly if silver and quartz-sand be present. A similar result occurs with **ammonium chloride**; and R. H. Brett said that the freshly precipitated hydroxide is soluble in a soln. of ammonium chloride, but not in one of **ammonium nitrate**. A. Michaelis observed that when the trioxide is heated with **phosphorus trichloride** in a sealed tube, at 160° , bismuth phosphate, and phosphoryl and bismuthyl chlorides are formed. W. R. Schoeller found that **bismuth trisulphide** readily reacts with the trioxide at 965° —either in a current of carbon dioxide, or below molten sodium chloride in a crucible. Sulphur dioxide is evolved at a comparatively low temp., and globules of bismuth are formed. The yield of bismuth is 90 per cent., and a little basic bismuth sulphate is formed. The trioxide is readily reduced to the metal by **carbon**, and M. M. P. Muir found that the reduction with **carbon monoxide** begins at 200° ; F. Schlagdenhauffen and C. Pagel found that dry bismuth trioxide is not altered by carbon monoxide at 230° , but at 400° is reduced to the monoxide without forming the metal—*vide bismuth*. R. H. Purcell found that by the intensive drying of carbon monoxide, the temp. of reduction was increased from 175° to 430° . F. J. Brislee also studied the reaction—*vide bismuth suboxide*. W. Müller observed that the trioxide is slowly but completely reduced by **methane**.

H. Rose found that fused **potassium cyanide** reduces the trioxide to metal; J. Milbauer, that molten **potassium thiocyanate** furnishes microcrystalline bismuth trisulphide and potassium metasulphobismuthate; and J. N. Pring, that **aluminium carbide** reduces it to metal. N. Tarugi, and H. Moissan observed that **calcium carbide** reduces the trioxide to bismuth free from calcium. W. Eidmann found that the trioxide is insoluble in **acetone**. Combinations with **organic compounds** have been obtained. Thus, P. Thibault prepared complexes with gallic acid; and L. Lévy observed coloured products with morphine, codeine, and other alkaloids. J. Spiller found that bismuth hydroxide is not precipitated in the presence of **sodium nitrate**. L. Kahlenberg and W. J. Trautmann observed a slow reaction when the trioxide is heated with **silicon**. W. Hempel showed that the molten trioxide decomposes **silicates**; and G. Rauter, that at 270°–280° in a sealed tube with **silicon tetrachloride** part of the trioxide is decomposed, forming silica and bismuth trichloride. F. Kuwa examined the colouring effect on glass.

J. L. Gay Lussac and L. J. Thénard observed that **potassium** reduces the heated trioxide to the metal. The reaction is accompanied by incandescence. Similar results were obtained with **sodium**. A. Stavenhagen and E. Schuchard observed that when the trioxide is heated with powdered **aluminium**, the reduction occurs with explosive violence. F. W. Schmidt found that the trioxide is reduced to black bismuth monoxide by **alkali stannites**. This reaction has been previously indicated; if an excess of reducing agent is used, bismuth itself is formed. M. M. P. Muir said that **potassium permanganate** in alkaline soln. oxidizes the trioxide slowly; and conversely, R. Schneider observed that manganese oxide is converted by bismuth tetroxide and nitric acid into permanganate. J. Knox found that when bismuth trioxide is shaken for 2–3 weeks with soln. of **sodium hydroxide**, colourless soln. are obtained free from opalescence. The amount of trioxide dissolved is proportional to the conc. of the alkali-lye; thus, 100 c.c. of soln. with 1.0, 2.0, and 3.0 mols of sodium hydroxide per litre, dissolved respectively 0.0013, 0.0026, and 0.0049 grm. of bismuth trioxide. According to L. Moser, freshly precipitated bismuth hydroxide is practically insoluble in soln. of sodium hydroxide up to *N*-NaOH at 20°; slightly soluble in soln. up to 4*N*-NaOH; and markedly so in more conc. soln. At 100°, the solubility is greater, but still small in dil. soln. Thus, for the solubility of freshly precipitated bismuth hydroxide (grams of Bi per litre) a soln. of sodium hydroxide (grams per litre), L. Moser gave:

NaOH	400	320	240	200	160	120	80	40	20
Bi { 20°	0.16	0.11	0.11	0.10	0.08	0.07	0.04	trace	0
Bi { 100°	1.70	1.20	—	0.50	0.50	—	0.35	0.20	0.15

J. Knox obtained similar results with soln. of **potassium hydroxide**. Expressing conc. as before, L. Moser gave:

KOH	560	448	336	280	224	168	112	56	28
Bi { 20°	0.14	0.11	0.11	0.10	0.08	0.06	0.03	trace	0
Bi { 100°	1.65	1.20	—	0.50	0.50	—	0.3	0.02	0.15

Hence, bismuth trioxide behaves as a weak base, but, in agreement with its more electropositive character, its basic character is weaker than the corresponding oxides of antimony and arsenic. Bismuthyl hydroxide, BiO.OH, or Bi₂O₃.H₂O, is a weak base. According to M. Lebaigue, when hydrated bismuth trioxide is boiled for a quarter of an hour with certain **metal salt** soln., the hydroxides are precipitated—*e.g.* from soln. of aluminium, chromic, or ferric salts—soln. of cupric, zinc, lead, manganese, ferrous, cobalt, or nickel salts. He therefore proposed to employ the process for the separation of metals in analyses, but J. Alog showed that the precipitation of the metals just indicated is complete only under certain conditions, and that other metals are partially precipitated either as oxides or basic salts. E. Laborde and co-workers found that radioactive compounds of radium, mesothorium, or thorium, precipitated with bismuth oxide, enhance its catalytic activity. J. A. Hedvall and N. von Zweigbergk studied the action of **barium**

dioxide on bismuth trioxide; and F. de Carli found that bismuth trioxide reacts when heated with barium oxide, but not with the oxides of calcium, lead, zinc, or cadmium.

N. R. Dhar and S. Gosh found that bismuth hydroxide is peptized by alkali-lye along with starch, glycerol, sugar, etc. According to W. Biltz, if a soln. of bismuth nitrate be diluted with water as long as no precipitation occurs, and the soln. dialyzed, a **colloidal solution** of bismuth trioxide is formed. C. Paal and L. di Pol found sodium protalbate to be an effective protective agent in the preparation of the colloidal soln.—*vide supra*, colloidal bismuth. L. Hugounenq and J. Loiseleur found that bismuth oxide is peptized by glycogen in the cold. Commercial colloidal bismuth hydroxide has the commercial name *bismon*. A. Kuhn and H. Pirsch studied the peptization of bismuth hydroxide with sucrose, mannitol, glycerol, and lactose—*vide infra*, bismuth sulphide. Kalle and Co. also obtained **organosols** of the trioxide—*vide supra*, colloidal bismuth. Bismuth trioxide is considered to be insoluble in water, and M. M. P. Muir and co-workers said that it does not pass into the hydrated oxide when exposed to moist air, or confined under water. G. Almkvist said that a litre of water at 20° dissolves 1.44 mgrms. of bismuthyl hydroxide, BiO.OH . T. Carnelley and J. Walker found that when a soln. of the normal nitrate is precipitated by ammonia in the cold, and the product dried in air, the composition approximates to that of normal **bismuth hydroxide**, Bi(OH)_3 , or *trihydrated bismuth trioxide*, $\text{Bi}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, or *orthobismuthous acid*, H_3BO_3 . M. M. P. Muir and D. Carnegie recommended dissolving bismuth nitrate in the smallest possible quantity of dil. nitric acid, pouring the soln. into an excess of conc. aq. ammonia, and washing the precipitate first with water, then with a dil. soln. of sodium carbonate, and finally with water. L. Moser said that the best way to make the normal hydroxide free from basic salts is to run a glycerol soln. of a bismuth salt into sodium hydroxide and immediately to neutralize the whole excess of alkali with dil. nitric or acetic acid. If sulphuric acid is used, as recommended by P. Thibault, some basic sulphate is formed. The precipitate after washing with a little alcohol, and drying in air, has the composition Bi(OH)_3 . It readily absorbs carbon dioxide from air. The loss of water over sulphuric acid is quite continuous, no arrest occurs at BiO.OH . R. Lorenz found bismuth forms a film of hydroxide when made the anode in the electrolysis of aq. soln. of alkali chlorides, nitrates, or sulphates. T. Carnelley and J. Walker observed that the white powder loses water quite regularly on a rising temp., up to 415°, when the composition approximates $\text{B}_2\text{O}_3 \cdot \text{H}_2\text{O}$; at 400°, all the water is expelled. M. M. P. Muir and co-workers said that all the water is driven off at 100°. J. Thomsen gave for the heat of formation: $2\text{Bi} + 3\text{O}_{\text{gas}} + 3\text{H}_2\text{O}_{\text{liq.}} = 2\text{Bi(OH)}_3 + 2 \times 68.9$. R. Robl observed no perceptible fluorescence with the metabismuthous acid, HBiO_2 , exposed to ultra-violet light. G. Almkvist gave 1.44 mgrm. per litre for the solubility of BiO(OH) in water.

According to W. T. Schaller the bismuth ochres—bismite—are grey, yellow, or green, pulverulent masses which under the microscope appear to be homogeneous and amorphous, but not transparent. The composition corresponds with more or less impure bismuth hydroxide, Bi(OH)_3 , not the trioxide, Bi_2O_3 . The combined water is not given off at 210°, but it is expelled on ignition at a red-heat. F. L. Ransome, and W. T. Schaller described some Nevada bismite as occurring in pearly scales which are probably trigonal.

According to M. M. P. Muir, if a soln. of bismuth pentoxide in hydrochloric acid be treated with sulphur dioxide, and then with potash-lye, and the precipitate exposed under water to sunlight, there is formed a yellowish-white powder, which, when dried over sulphuric acid, in vacuo, has the composition of *dihydrated bismuth trioxide*, $\text{Bi}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$, or *pyrobismuthous acid*, $\text{H}_4\text{Bi}_2\text{O}_5$. T. Carnelley and J. Walker observed no evidence of the formation of this compound on the heating curve of the normal hydroxide. According to A. E. Arppe, if a soln. of bismuth nitrate be poured into potash-lye, and the mixture heated for a time, the precipitate, after

washing with water and drying at 100°, has the composition of *monohydrated bismuth trioxide*, $\text{Bi}_2\text{O}_3 \cdot \text{H}_2\text{O}$; *metabismuthous acid*, HBiO_2 ; or *bismuthyl hydroxide*, $\text{BiO} \cdot \text{OH}$. These products represent different stages in the drying of colloidal hydrated bismuth trioxide. If the temp. of the alkaline liquor be over 70°, the yellow trioxide is formed. A. Stromeyer, and J. Löwe said that if the trichloride be used, some oxychloride is precipitated as well. E. B. R. Prideaux and H. W. Hewis obtained the hydrated oxide by pouring a soln. of bismuth nitrate into dil. alkali-lye; and E. Moles and R. Portillo, by precipitating an acetic soln. of bismuth nitrate with conc. ammonia. H. Meerwein observed no complex formation with alcohol. P. Thibault said that the hydroxide, bismuth oxide, prepared by the addition of an alkali to a soln. of bismuth nitrate or chloride, always contains some basic nitrate or chloride. It may, however, be obtained free from these compounds by taking advantage of the fact that bismuth oxide is soluble in a soln. of potassium hydroxide which contains glycerol. Bismuth nitrate is intimately mixed with glycerol, water is added until the salt is entirely dissolved, and then potassium hydroxide until the precipitated oxide is redissolved. If dil. sulphuric acid is then added, a precipitate of bismuth oxide is produced, which is entirely free from any combined acid, and after drying in air, or in a vacuum over sulphuric acid, or at 100°–105°, has the composition $\text{Bi}_2\text{O}_3 \cdot \text{H}_2\text{O}$. E. Zumbusch prepared the hydroxide by this process. H. Schiff said that this oxide is produced when moist bismuth monoxide is exposed to air, while M. M. P. Muir found that the dihydrated oxide is so formed. T. Carnelley and J. Walker observed a small break in the heating curve, near 415°, corresponding with the formation of the monohydrate. A. K. Sanyal and N. R. Dhar found that the hydroxide is blackened after 20 hrs.' exposure to tropical sunlight.

L. Belladen⁴ studied the f.p. curve of mixtures of lead monoxide and bismuth trioxide. The results are summarized in Fig. 16; they show the existence of an unstable **lead metaoctobismuthite**, $\text{PbO} \cdot 4\text{Bi}_2\text{O}_3$, or $\text{PbBi}_8\text{O}_{13}$, melting with decomposition at 695°; **lead mesohexabismuthite**, $\text{Pb}_2\text{Bi}_6\text{O}_{11}$, or $2\text{PbO} \cdot 3\text{Bi}_2\text{O}_3$, melting at 686°; and **lead pyrobismuthite**, $2\text{PbO} \cdot \text{Bi}_2\text{O}_3$, or $\text{Pb}_2\text{Bi}_2\text{O}_5$, melting at 625°.

C. W. Balke and E. F. Smith⁵ obtained what they regarded as **ammonium bismuthotungstate**, $3(\text{NH}_4)_2\text{O} \cdot 2\text{Bi}_2\text{O}_3 \cdot 11\text{WO}_3 \cdot 10\text{H}_2\text{O}$, from a soln. of bismuth hydroxide in a boiling soln. of ammonium paratungstate. The yellow oil, when dried, forms a yellow, transparent, vitreous mass. The corresponding **potassium bismuthotungstate**, $3\text{K}_2\text{O} \cdot 2\text{Bi}_2\text{O}_3 \cdot 11\text{WO}_3 \cdot 15\text{H}_2\text{O}$, is an oil which dries to a pale yellow, transparent, vitreous mass; and **strontium bismuthotungstate**, $3\text{SrO} \cdot 2\text{Bi}_2\text{O}_3 \cdot 11\text{WO}_3 \cdot 11\text{H}_2\text{O}$, is an oil which solidifies to a wax-like mass; and when dried at 100°, it furnishes a hard yellow, vitreous mass, insoluble in water.

FIG. 16.—Freezing-point Curve of Mixtures, $\text{PbO}-\text{Bi}_2\text{O}_3$.

§ 9. The Higher Oxides of Bismuth

In 1818, C. F. Bucholz and R. Brandes¹ showed that when bismuth trioxide is heated with an excess of an alkali hydroxide in air, the trioxide takes up oxygen, forming what was called *bismuth peroxide*. Subsequent workers were not agreed as to the composition of the oxide remaining after the alkali had been washed away. The end-product of the oxidation is probably **bismuth pentoxide**, Bi_2O_5 , but various intermediate stages of the oxidation have been regarded as definite compounds— Bi_4O_7 of M. M. P. Muir, and G. André; Bi_4O_8 —or $(\text{Bi}_2\text{O}_4)_2$ or $(\text{BiO}_2)_4$ — Bi_4O_9 of A. Stromeyer, C. Hoffmann, and A. E. Arppe as well as G. André's $\text{Bi}_{10}\text{O}_{23}\cdot 6\text{H}_2\text{O}$; and Bi_4O_{10} —or Bi_2O_5 . J. Lorch was unable to wash out all the alkali, and he therefore supposed the product of the operation to be an alkali bismuthate. Later observations, however, have shown that the only stable oxides concerned in the oxidation of the trioxide are **bismuth tetroxide**, Bi_2O_4 , *bismuth dioxide*, BiO_2 , and bismuth pentoxide.

The formation of bismuth tetroxide.—C. F. Schönbein obtained the tetroxide by oxidizing bismuth with ozone; and A. Mailfert, by oxidizing bismuth trioxide with ozone. M. M. P. Muir oxidized bismuth monoxide with potassium permanganate and obtained a mixture of tetra- and penta-oxides. C. F. Bucholz and R. Brandes, V. A. Jacquelin, and E. Frémy obtained the tetroxide by melting the trioxide with an excess of alkali hydroxide while exposed to air; and E. Frémy, and L. Schneider added potassium chlorate as oxidizing agent. I. Meschtschersky heated the trioxide with barium, calcium, or magnesium oxide mixed with potassium chlorate or nitrate; and R. Böttger fused the basic nitrate with the alkali hydroxide. In a number of modes of formation of the tetroxide, bismuth trioxide, the dioxide, oxychloride, or oxynitrate is suspended in alkali-lye and treated with an oxidizing agent—*e.g.*, the processes of G. André, A. E. Arppe, C. Deichler, A. Gutbier and R. Bünz, W. Heintz, A. Hilger and P. A. von Scherpenberg, C. Hoffmann, V. A. Jacquelin, J. Lorch, and M. M. P. Muir. C. Schrader used chlorine or bromine; C. Deichler, and A. Gutbier and R. Bünz, used electrolytic chlorine developed in the presence of the alkali hydroxide; A. E. Arppe, R. Brandes, V. A. Jacquelin, E. Rupp and G. Schaumann, H. Schiff, C. Schrader, and A. Stromeyer boiled the liquor with hypochlorites—C. Schrader said that the oxidation does not occur at ordinary temp.; C. Deichler, A. Gutbier and R. Bünz, and E. Rupp and G. Schaumann used potassium persulphate; J. Lorch used chlorine and sodium dioxide jointly; and L. Vanino

and O. Hauser, and A. Gutbier and R. Bünz, potassium ferricyanide. K. Hasebroek, E. Rupp and G. Schaumann, L. Moser, L. Vanino and O. Hauser, A. Gutbier and R. Bünz, J. Hanus and O. Kallauner, and P. Jannasch oxidized bismuth salt soln. with an ammoniacal soln. of hydrogen dioxide, and obtained a yellow or orange precipitate, but, added J. Lorch, the yield is very small. J. Hanus and O. Kallauner used sodium dioxide for the oxidation. An acid soln. of bismuth trioxide was found by C. F. Schönbein to be more or less oxidized by hydrogen dioxide; J. Lorch, and T. Poleck said that sodium dioxide alone has only a slight oxidizing action on bismuth hydroxide or basic nitrate; and similarly also when sodium dioxide is fused with the trioxide. C. Deichler observed no effect with barium dioxide. The tetroxide was found by W. Wernicke, C. Luckow, J. Lorch, L. Schucht, A. Hollard, M. Bose, A. Classen, and C. Deichler to be deposited on the anode during the electrolysis of neutral or alkaline soln. of a bismuth salt with a feeble current. A. Gutbier and co-workers obtained a light brown amorphous powder containing 97.93 per cent. Bi_2O_3 and about 2 per cent. of active oxygen. C. E. Corfield and E. Woodward obtained bismuth tetroxide by the action of nitric acid on sodium bismuthate. The dihydrate could not be reduced to the monohydrate without simultaneous decomposition—*vide infra*, the preparation of bismuth pentoxide. C. H. D. Bödeker found that the oxidized product is obtained by the action of a soln. of potassium cyanide on bismuth nitrate; W. Foster, by heating bismuth ferrocyanide with sodium hypobromite; and by M. M. P. Muir, by the action of chlorine or bromine on a soln. of bismuth ferricyanide. M. M. P. Muir and co-workers' directions for preparing bismuth tetroxide are:

Bismuth trioxide is suspended in a large excess of potash-lye of about 1.35 sp. gr.; the potash-lye is kept nearly boiling, and chlorine is passed in until the precipitate is homogeneous, and of a dark chocolate-red colour; the precipitate is washed free from potash-lye with hot water, kept in contact with dil. nitric acid (about 1 acid to 20 water) for 12–16 hrs. until the colour of the solid has changed to brownish-yellow, washed free from acid, boiled for about an hour with a strong soln. of sodium, or calcium, hypochlorite (preferably the former), till a perfectly homogeneous yellow-brown, heavy powder is produced, which settles readily. This is washed with hot water till free from chlorine and alkali. When dried at 100° or over sulphuric acid, the composition approximates $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$; and when dried at 180° – 200° for two or three hours, Bi_2O_4 . The prolonged digestion with nitric acid serves to dissolve any bismuth trioxide which may have escaped oxidation, and also to deoxidize the bismuth pentoxide which has been formed; subsequent treatment with the alkaline hypochlorite appears to convert any traces of bismuth trioxide yet present into bismuth tetroxide.

C. Deichler recommended alkali-lye of sp. gr. 1.05–1.35, and at a temp. of 95° – 100° . According to A. Gutbier and R. Bünz, the results obtained by the action of chlorine on bismuth hydroxide suspended in hot, conc. alkali-lye, and the product treated with conc. nitric acid to remove the lower oxide, are greatly influenced by the nature and conc. of the alkali-lye. The best results with chlorine were obtained by the action with a large excess of conc. potash-lye of sp. gr. 1.4. No product of uniform composition could be isolated; and the same remarks apply to the oxidation with potassium persulphate; and ferricyanide as oxidizing agents. R. R. L. Worsley and P. W. Robertson obtained a mixture of $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ and $\text{Bi}_2\text{O}_5 \cdot \text{H}_2\text{O}$ by the action of chlorine on the trioxide suspended in boiling alkali-lye; and a mixture of Bi_2O_4 and $\text{Bi}_2\text{O}_4 \cdot \text{H}_2\text{O}$ with a trace of Bi_2O_6 by the action of ammonium persulphate or potassium ferricyanide on the trioxide suspended in boiling alkali-lye.

The properties of bismuth tetroxide.—Bismuth tetroxide may appear as a dark brown, yellowish-brown, or orange-yellow powder. The products obtained by the action of chlorine, ammonium persulphate, or potassium ferricyanide on dil. alkali-lye are brown or purplish-black anhydrous tetroxides, but the yellow dihydrate, $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$, mixed with the hydrated pentoxide, is produced by the action of chlorine on conc. alkali-lye. It is only sparingly soluble in boiling nitric acid of sp. gr. 1.4, and the hydrated pentoxide is dissolved. The yellow dihydrate loses water and oxygen at 100° . Analyses reported by A. E. Arppe, W. Heintz,

C. Schrader, M. M. P. Muir, and C. Deichler agree with the formula Bi_2O_4 ; and when prepared by wet processes, and dried at 100° or over sulphuric acid, M. M. P. Muir, W. Wernicke, and C. Schrader gave $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$, while L. Vanino and O. Hauser gave $\text{Bi}_2\text{O}_4 \cdot \text{H}_2\text{O}$. M. M. P. Muir gave 5.60 for the sp. gr. of the anhydrous tetroxide at 20° , and 5.80 for the dihydrate—W. Wernicke gave 5.57. When the tetroxide is heated in **hydrogen** at 265° , M. M. P. Muir obtained the monoxide, and in a current of **carbon monoxide** at 245° – 250° it forms the trioxide. When heated in **air** or **oxygen** at 300° , yellow trioxide is formed. M. M. P. Muir said that the dihydrate loses a mol. of water at 110° , and the remainder at 180° – 200° —L. Vanino and O. Hauser said 160° – 170° , and C. Schrader, 150° . R. R. L. Worsley and P. W. Robertson said that the tetroxide decomposes at 160° . The dehydrated tetroxide is brown, and, according to M. M. P. Muir, takes up a mol. of water on exposure to ordinary air, and rather more than 2 mols. in moist air; when kept under water, it gradually forms ordinary bismuth hydroxide. C. F. Schönbein found that it decomposes **hydrogen dioxide** and forms a peroxide. L. Vanino and O. Hauser observed that when heated with the **oxyacids**, the hydrated tetroxide dissolves, forming bismuthous salts, and oxygen is given off; cold dil. **sulphuric acid** does not decompose it; and cold, dil. **nitric acid** attacks it slowly. The cold, conc. acids readily attack the tetroxide; and no trace of hydrogen dioxide is formed by the action of cold, conc. sulphuric acid. Conc. **hydrochloric acid** decomposes it at -15° with the evolution of chlorine, but without forming a chloride of quadrivalent bismuth. **Sulphurous acid** reduces the tetroxide, forming normal bismuth sulphate slowly in the cold, rapidly when heated. M. M. P. Muir, and C. Schrader said that the orange-yellow, hydrated tetroxide is scarcely attacked by dil. nitric acid, but L. Schneider found that most of it is dissolved by nitric acid of sp. gr. 1.2, leaving a dark brown residue which is mainly Bi_2O_4 —ozone oxygen is given off. Aq. **ammonia** has no action on the tetroxide. G. Tammann studied the reducing action of the tetroxide on silver nitrate in light. L. Schneider observed that **manganous salts** in nitric acid soln. are oxidized at ordinary temp. to permanganates. M. M. P. Muir found that the tetroxide is insoluble in a conc. soln. of **potassium hydroxide**; L. Vanino and O. Hauser added that the hydrated tetroxide has a feeble acidic character in that when digested with hot alkali-lye, some alkali is taken up by the tetroxide, and this is not removed by washing; they supposed that definite *hypobismuthates* could be formed which form the hydrated tetroxide when treated with dil. nitric acid. A. Gutbier and R. Bünz do not agree that hypobismuthates are formed. R. R. L. Worsley and P. W. Robertson said that an unstable per-salt is formed when the tetroxide dissolves in conc. alkali-lye.

The preparation of bismuth pentoxide.—M. M. P. Muir and D. Carnegie showed that **hydrated bismuth pentoxide**, $\text{Bi}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or **metabismuthic acid**, HBiO_3 , is the final product of the reaction between chlorine and bismuth hydroxide or oxychloride suspended in a large excess of a very conc. soln. of potassium hydroxide, when washed for a long time with water nearly boiling. M. M. P. Muir recommended the following mode of preparation:

Bismuth trioxide is suspended in a large excess of very conc. potash-lye of sp. gr. 1.37–1.38. The liquid is kept nearly boiling, and chlorine is passed in until the precipitate is quite homogeneous, and of a dark-red colour; the precipitate is then washed with hot water, until free from potash, and then with cold water, until every trace of chloride is removed; if any chloride is allowed to remain it is decomposed by the nitric acid subsequently added with formation of hydrochloric acid, which acts on the bismuthic oxide. The product is then boiled for a very few minutes with conc. nitric acid (whereby any remaining bismuth tetroxide or hypobismuthic oxide is removed) until all is distinctly scarlet, washed repeatedly and quickly with boiling dil. nitric acid, each quantity of acid being more dil. than the preceding, and finally the acid is completely removed by washing with cold water; the scarlet precipitate is then dried at 125° for three or four hours.

The composition of the product is HBiO_3 , and when dried at 120° it forms reddish-brown bismuth pentoxide, Bi_2O_5 . W. Heintz, and C. Deichler used a similar

process; and the latter obtained the monohydrate mixed with a little dihydrate. C. E. Corfield and E. Woodward were unable to prepare bismuthic acid or bismuth pentoxide by decomposing sodium bismuthate with nitric acid—bismuth tetroxide was always produced. A. Gutbier and R. Bünz were unable to prepare *ein einheitlich zusammengesetztes Produkt*, or to isolate *eine wohldefinierte chemische Verbindung* by the oxidation of the bismuth trioxide suspended in potash-lye. A. E. Arppe used only a moderate excess of the conc. alkali-lye, but M. M. P. Muir, and C. Schrader were then unable to prepare the hydrated pentoxide. R. R. L. Worsley and P. W. Robertson said that the product is a mixture of $\text{Bi}_2\text{O}_5 \cdot \text{H}_2\text{O}$ and $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$, which cannot be separated. That obtained by oxidizing the trioxide suspended in dil. alkali-lye gives a mixture of $\text{Bi}_2\text{O}_5 \cdot \text{H}_2\text{O}$ and $\text{Bi}_2\text{O}_4 \cdot \text{H}_2\text{O}$, which can be separated by the solvent action of hot nitric acid of sp. gr. 1.2. A brown variety is produced by the action of glacial acetic acid on commercial sodium bismuthate. C. Hoffmann reported that potassium bismuthates united with different proportions of bismuth tri- or penta-oxide are the solid products first deposited. M. M. P. Muir was unable to confirm this, but he noted the extreme slowness with which the alkali is removed from the precipitate, and that hot water continues to dissolve out alkali after cold water has ceased to affect the product. According to C. Deichler, impure bismuth pentoxide can be prepared by an electrolytic process:

Bismuth trioxide (10 gms.) is mixed with potassium hydroxide (150 grms. of sp. gr. 1.42–1.45) and potassium chloride (15 grms.), and the soln. electrolyzed in a platinum dish, using the dish as anode and a platinum plate as cathode, the latter being protected by a porous diaphragm in order to prevent the deposition of bismuth. A current density of 2–3 ampères per sq. cm. is employed, and the temp. is kept just below that of the b.p. of the soln. Potassium bismuthate is deposited as a dense red precipitate which adheres firmly to the dish and is easily washed with water, the excess of bismuth trioxide remaining in suspension. When the potassium bismuthate is treated for a short time with hot conc. nitric acid and then washed with water, a mixture of bismuthic acid and the hydrate $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ is obtained containing 95 per cent. of bismuthic acid. If dil. nitric acid is employed, a large quantity of $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ is formed, and by the prolonged action of nitric acid of sp. gr. 1.3, the tetroxide dihydrate, $\text{Bi}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$, is obtained as an orange-yellow powder. The same compound is also obtained by the action of warm acetic acid on bismuthic acid.

The properties of bismuth pentoxide and bismuthic acid.—The wet methods for preparing the pentoxide furnish a scarlet-red powder which, according to the analyses of A. E. Arppe, and M. M. P. Muir, has the composition $\text{Bi}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or HBO_3 , and the sp. gr. 5.75 at 20°; and it forms the anhydride at 120°. The analyses of the pentoxide by A. E. Arppe, W. Heintz, M. M. P. Muir, and A. Hilger and P. A. von Scherpenberg agree with the formula Bi_2O_5 . The dark red powder was found by M. M. P. Muir to have a sp. gr. 5.10 at 20°. C. del Fresno studied the mol vol. E. Friederich gave 1.2×10^8 ohms per sq. mm. for the resistance of the pentoxide. A. Stromeyer said that the pentoxide gives off oxygen at the temp. of boiling mercury, forming the yellow trioxide; the pentoxide is reduced to the trioxide by **hydrogen** at a lower temp. than that at which the pentoxide is reduced when heated alone. At a red-heat, hydrogen reduces the oxide to metal. According to M. M. P. Muir, when the pentoxide is heated in hydrogen it is reduced to the tetroxide at 215°; and to the trioxide at 255°. W. Fränkel and co-workers studied the reduction of bismuth pentoxide by **carbon monoxide**, at 400°, 500°, and 600°. With carbon monoxide, the reduction begins at 75°. When heated in **air** or **oxygen**, at 250°, the pentoxide passes into the tetroxide, but even when heated alone, the evolution of oxygen begins at 150°; at 300°, in air or oxygen, yellow bismuth trioxide is formed. When kept in moist air, or under water, the pentoxide passes into a lower oxide. R. R. L. Worsley and P. W. Robertson said that the anhydrous pentoxide is incapable of existence because when the hydrate is left in vacuo (one mm. press.), over phosphorus pentoxide, it darkens in colour, and slowly loses oxygen and water. The decomposition is rapid at 100°. When heated in a current of **chlorine**, bismuth trichloride and oxychloride, $\text{Bi}_2\text{O}_2\text{Cl}_3$, are formed; and with the vapour of **bromine**,

bismuth tribromide and an oxybromide, $\text{Bi}_{11}\text{O}_{13}\text{Br}_7$, are produced. R. F. Weinland and O. Lauenstein found that when bismuthic acid is treated with 40 per cent. **hydrofluoric acid** at ordinary temp., a violent reaction occurs with the formation of bismuth trifluoride, and the evolution of ozonized oxygen; at a low temp., a pentafluoride seems to be formed. A. Stromeyer said that **hydrochloric acid** dissolves the pentoxide with the formation of chlorine; and with **hydriodic acid**, iodine and bismuth triiodide are formed. The pentoxide is converted into the trisulphide (*q.v.*) when treated with **hydrogen sulphide**, or with alkali sulphide; and A. Hilger and P. A. von Scherpenberg observed that the reaction with **hydrogen selenide** occurs with incandescence, and an oxyselenide is formed. A. Stromeyer found that **sulphurous acid**—not gaseous **sulphur dioxide**—slowly transforms the pentoxide into the ordinary sulphate; and a similar product is obtained by the action of **sulphuric acid**, but with the evolution of oxygen. C. Hoffmann found that dil. sulphuric acid converts the pentoxide into tetroxide. M. M. P. Muir said that the pentoxide is scarcely affected by dil. **nitric acid**, but conc. nitric acid transforms it into the hydrated tetroxide and subsequently into a soln. of bismuth nitrate as observed by A. Stromeyer. With phosphoric acid, oxygen is given off. When a mixture of the pentoxide with **carbon**, sugar, or other organic substance, is set on fire by a red-hot coal, it smoulders away like tinder without deflagration. A soln. of **oxalic, tartaric, citric, or acetic acid** does not act on the pentoxide even when boiling; but if sulphuric acid be present, dissolution occurs with violent effervescence. C. Hoffmann said that oxalic acid transforms the pentoxide at ordinary temp., forming bismuth oxalate and oxygen. H. Schiff said that an alcoholic soln. of oxalic acid or **sugar** does not reduce the pentoxide; but an alkaline soln. of sugar, when warmed, reduces it to the yellow trioxide and then to the metal. Tincture of **guaiacum** is coloured blue by the pentoxide; a soln. of **stannous chloride** reduces the pentoxide to the yellow trioxide which then reacts as previously indicated. G. Rauter represented the reaction with **silicon tetrachloride** in a sealed tube at $370^\circ\text{--}380^\circ$: $\text{Bi}_2\text{O}_5 + \text{SiCl}_4 = \text{Bi}_2\text{O}_3 + \text{SiO}_2 + 2\text{Cl}_2$; and $2\text{Bi}_2\text{O}_3 + 3\text{SiCl}_4 = 4\text{BiCl}_3 + 3\text{SiO}_2$. B. Diethelm and F. Förster, and E. Zinth and A. Rauch, studied the electrometric titration of bismuth salts with **titanous chloride**.

According to R. R. L. Worsley and P. W. Robertson, **bismuth hexoxide**, Bi_2O_6 , or BiO_3 , is produced in small quantities by the action of ammonium persulphate or potassium ferricyanide on bismuth trioxide suspended in a boiling conc. soln. of alkali hydroxide, together with bismuth tetroxide (Bi_2O_4 , or $\text{Bi}_2\text{O}_4 \cdot \text{H}_2\text{O}$), from which it can be separated by continuous extraction with warm nitric acid of sp. gr. 1.2. It may also be prepared by the oxidation of the tetroxide and subsequent treatment of the product with nitric acid. Bismuth hexoxide is pale brown and contains no water. At the ordinary temp. it loses oxygen slowly, darkening in colour.

The alkali bismuthates.—A. Stromeyer said that aq. soln. of **alkali hydroxides** have no action on the pentoxide. M. M. P. Muir said that a hot, conc. soln. of potassium hydroxide, which solidifies on cooling, dissolves 0.01 grm. of bismuthic acid per gram of hydroxide, and when diluted, the tetroxide is deposited as a reddish or yellowish powder. The existence of no definite bismuthate could be demonstrated, although **potassium bismuthate** probably exists in the presence of an excess of potassium hydroxide; these compounds are decomposed when the excess of potassium hydroxide is removed by washing. C. F. Bucholz and R. Brandes, V. A. Jacquelin, and A. Stromeyer assumed that an alkali bismuthate is formed when a mixture of bismuth trioxide and potassium hydroxide is fused while exposed to air. C. Hoffmann reported that potassium metabismuthate, associated with bismuth pentoxide or tetroxide, is deposited when chlorine is passed into boiling potash-lye with bismuth hydroxide in suspension. He said that with alkali-lye of sp. gr. 1.08, the product is $2\text{KBiO}_3 \cdot 4\text{Bi}_2\text{O}_5 \cdot \text{Bi}_2\text{O}_3$, and when chlorinated three times, $2\text{KBiO}_3 \cdot 5\text{Bi}_2\text{O}_5$; with lye of sp. gr. 1.128, $2\text{KBiO}_3 \cdot 5\text{Bi}_2\text{O}_5$; and with lye of sp. gr. 1.539, $\text{KBiO}_3 \cdot \text{Bi}_2\text{O}_5$, if bismuth hydroxide is used, and

$4\text{Bi}_2\text{O}_3 \cdot 6\text{Bi}_2\text{O}_5$, if the trioxide is used; if the latter product be washed with cold water, the product is $\text{KBiO}_3 \cdot \text{Bi}_2\text{O}_3$. M. M. P. Muir said that the products of successive experiments have a different composition, although the experimental conditions are as nearly the same as is practicable. G. André reported the bismuthate, $\text{KBiO}_3 \cdot \text{HBiO}_3$, but J. Lorch could not confirm this; nor could M. M. P. Muir or J. Lorch confirm C. Hoffmann's results. As indicated above, C. Deichler reported potassium bismuthate to be formed electrolytically, but A. Gutbier and R. Bünz could not obtain a homogeneous process by this means. J. Lorch also reported **sodium bismuthate** to be formed by the alkali-chlorine process; and C. Deichler, by the electrolytic process, but A. Gutbier and R. Bünz were unable to make definite bismuthates by this means. It therefore follows that alkali bismuthates probably exist in conc. soln. of alkali-lye, but are too readily hydrolyzed to enable them to be isolated in the ordinary way. According to J. Aloy and P. Frébault, potassium and sodium metabismuthates in an impure state can be prepared by slowly adding a soln. of bismuth nitrate in nitric acid to a conc. soln. of the alkali hydroxide, through which a current of chlorine was passed. The precipitate formed, when washed with water, gradually decomposed. When chlorine was replaced by hydrogen dioxide, anhydrous crystalline products were obtained, varying in colour, with the conc. of the alkali, from deep yellow to chocolate-brown. It is probable that these products consisted of the acid, H_3BiO_4 , in which one or more atoms of hydrogen were replaced by bismuthyl, BiO , and the remainder by the alkali metal, thus: $\text{BiO}_4(\text{BiO})_3$, $\text{BiO}_4\text{K}(\text{BiO})_2$, or $\text{BiO}_4\text{K}_2(\text{BiO})$. O. Ruff obtained sodium bismuthate by treating bismuth oxytrifluoride with soda-lye; and by adding, drop by drop, a soln. of bismuth pentoxide—60 per cent. hydrochloric acid at 0° into $N\text{-NaOH}$, also at 0° . The yellow precipitate, rapidly washed and partially dried on a porous plate, contained 95–98 per cent. of its bismuth in the quinquevalent form, and 1 mol. of sodium hydroxide. On further washing, sodium bismuthate loses alkali and darkens in colour; it does not lose much oxygen, even on heating to boiling, when excess of alkali is present. From this bismuthate by treating with ice-cold 15 per cent. nitric acid to neutral reaction and washing rapidly by decantation, a reddish-brown precipitate containing up to 93 per cent. of bismuth pentoxide is obtained. On treating the fresh pentoxide with 15 per cent. sodium hydroxide, it slowly changes to yellow bismuthate. Hence, in opposition to the belief of A. Gutbier and R. Bünz, the higher oxide of bismuth has acidic properties. According to A. Gutbier and H. Micheler, two different bismuthic oxides are here in question. W. D. Collins and co-workers discussed the testing of the purity of the commercial salt.

§ 10. The Bismuth Fluorides

H. Moissan¹ found that bismuth is attacked only superficially by fluorine. J. J. Berzelius obtained a white powder, which has been assumed to be **bismuth trifluoride**, BiF_3 , by evaporating a soln. of the trioxide in hydrofluoric acid. It is probably an oxyfluoride. M. M. P. Muir and co-workers heated bismuth trioxide with aq. hydrofluoric acid, replacing the acid as it evaporated; when action had ceased, the clear liquor when evaporated on a water-bath, furnished a deliquescent, greyish-white crystalline mass with a composition $\text{BiF}_3 \cdot 3\text{HF}$, or bismuth trihydrotrifluoride. If the product be heated until fumes of hydrofluoric acid are no longer evolved, a grey, crystalline powder, bismuth trifluoride, BiF_3 , is formed. The crystalline residue remaining after the reaction with hydrofluoric acid and bismuth trioxide had the composition $\text{BiOF} \cdot 2\text{HF}$, and when strongly heated in a covered platinum crucible for an hour, it furnished bismuth trifluoride. M. M. P. Muir and B. S. Gott also made the trifluoride by adding a conc. soln. of potassium fluoride to a soln. of bismuth nitrate containing as little nitric acid as possible, washing the product first with cold and then with hot water, and drying at 100° . H. B. Fullerton, and G. Gore also prepared the trifluoride as a grey crystalline powder of sp. gr. 5.32. It can be fused without decomposition. According to M. M. P. Muir, bismuth trifluoride is more stable towards water, and heat than any of the other bismuth halides. W. Herz and A. Bulla said that bismuth trifluoride is not hydrolyzed by cold or boiling water. A. C. Vournasos prepared complexes with pyridine, and quinoline. It is quite insoluble in, and is unacted on by water, is decomposed and dissolved by hot hydrochloric, sulphuric, or nitric acid, and is scarcely altered or volatilized by heating in an open platinum basin at a full red-heat. The trihydrotrifluoride is slowly decomposed by cold, more quickly by hot water, with formation of $\text{BiOF} \cdot 2\text{HF}$. If a little free hydrofluoric acid be present in the wash-water a considerable amount of bismuth goes into soln. It does not form *bismuth fluosulphide* when melted with sulphur.

H. von Helmholt prepared **ammonium tetrafluobismuthite**, NH_4BiF_4 , or $\text{NH}_4\text{F} \cdot \text{BiF}_3$, by cooling a sat. soln. of freshly precipitated bismuth hydroxide in a hot conc. soln. of ammonium fluoride. The white powder consists of tabular monoclinic or rhombic crystals. It is decomposed by water with the precipitation of bismuthyl fluoride, and the dissolution of a little bismuth. It is soluble in hot dil. acids. The corresponding *potassium fluobismuthite* could not be prepared by H. von Helmholt either by evaporation or by adding alcohol to a mixed soln. of the two fluorides.

According to R. F. Weinland and O. Lauenstein, when bismuth pentoxide is treated with 40 per cent. hydrofluoric acid at -10° , a very unstable **bismuth pentafluoride**, BiF_5 , is formed, which cannot be isolated; the soln. has strong oxidizing properties, liberates iodine from potassium iodide, or chlorine from

hydrochloric acid; converts alcohol into aldehyde, and rapidly destroys organic substances. With traces of manganese salts, the soln. gives a violet-red coloration; when concentrated in vacuo, it yields bismuth trifluoride, and when it is extracted with ether or poured into a large quantity of cold water, the theoretical quantity of bismuthic acid is precipitated. Potassium bismuthate behaves in a similar manner when treated with hydrofluoric acid. O. Ruff said that there is evidence of the formation of traces of the pentafluoride by the action of fluorine on bismuth trichloride at -80° . Evidence of the formation of an unstable *potassium fluobismuthate* was obtained by R. F. Weinland and O. Lauenstein.

§ 11. The Bismuth Chlorides

In addition to the ordinary *bismuth trichloride*, BiCl_3 , *bismuth dichloride*, BiCl_2 , or Bi_2Cl_4 , has been reported by a number of workers. The *bismuth pentachloride*, BiCl_5 , has not been prepared. The well-defined quinquevalency shown by arsenic and antimony in their oxides and halides has stimulated the quest for similar relations with bismuth. Although univalent bismuth forms an oxide, this element does not exhibit a higher valency than three in its fluorides. M. M. P. Muir¹ tried to prepare it by the action of chlorine on molten bismuth trichloride, and by heating bismuthyl chloride with charcoal in a stream of chlorine, but without success; nor did he succeed in making a mixed pentahalide. E. B. Hutchins and V. Lenher's attempts were also nugatory. They tried the action of chlorine on bismuth trichloride at the temp. of liquid air; the action of chlorine on a hydrochloric acid soln. of the trichloride at -10° ; the action of bismuth trichloride on the caesium pentahalides; and the saturation of a hydrochloric acid soln. of bismuth pentoxide at -10° , in the presence of ammonium chloride furnishes only the trichloride, $2\text{NH}_4\text{Cl} \cdot \text{BiCl}_3$. G. Rauter also failed to obtain the pentachloride by the action of carbon tetrachloride on bismuth pentoxide.

According to R. Weber,² and P. P. Dehérain, chlorine acts slowly on bismuth at ordinary temp., forming a brown, oily liquid—bismuth dichloride, BiCl_2 . W. Heintz obtained a violet trichloride by passing chlorine over molten bismuth. This was probably a mixture of the tri- and di-chlorides. W. Heintz tried to make it by heating bismuth and bismuth trichloride, but at no temp. did he find evidence of the formation of the dichloride; on the other hand, R. Weber said that in a sealed tube, a reaction begins at the m.p. of the trichloride, and by maintaining this temp. for a long time, obtained some brown dichloride. W. Herz and A. Guttmann examined the f.p. curve of mixtures of bismuth and bismuth trichloride, and found a maximum at 163° corresponding with the formation of the dichloride. B. G. Eggink observed no sign of the dichloride on his fusion curve of bismuth and chlorine, but he said that *bismuth monochloride*, BiCl , is formed. It melts at 320° , forming two liquid phases; there is also an endothermal compound, *bismuth tetrachloride*, BiCl_4 , partially dissociated on fusion. He observed no sign of the dichloride on the f.p. curve. L. Marino and R. Becarelli found that when mixtures of bismuth with 5–85 per cent. of bismuth trichloride are fused in sealed tubes, two layers are obtained above 320° —the upper one being black, the lower one white with a metallic lustre. Lowering the temp. from 320° results in the formation of (i) a crystalline product melting over the range 270° – 320° , and at about 240° two

other products are formed, one melting about 270° , and the other between 270° and 320° ; and (ii) the other stratum furnishes a eutectic Bi-BiCl₃, melting at about 180° . Thus, there is no evidence of the formation of a subchloride, the fused mixtures of bismuth and its trichloride yielding, over a certain interval of concentration, a series of solid soln., α -crystals—which undergo transformation, accompanied by marked development of heat, into β -crystals with m.p. points higher in all cases than those of bismuth and its trichloride. After complete fusion the β -crystals yield, on cooling, α -crystals of the different composition in presence of two liquid layers which reproduce the same phenomena. B. G. Eggink's curve is given in Fig. 18; it shows the probable formation of **bismuth tetrachloride**, BiCl₄, melting

FIG. 17.—Equilibrium Diagram of the System: Bi-BiCl₃.

FIG. 18.—Equilibrium Diagram of the System: Bi-Cl₂.

at 225° . W. Heintz, and R. Schneider sublimed bismuth trichloride in hydrogen without the occurrence of any appreciable change, but M. M. P. Muir said that if the trichloride be heated in a current of dry hydrogen it melts, and quickly changes colour, producing black bismuth dichloride, which, on raising the temp., is quickly decomposed, yielding a white crystalline sublimate of the trichloride, and a black residue of metallic bismuth. R. Schneider added that if a complex salt of bismuth trichloride, say ammonium chlorobismuthite, be heated to about 300° in a current of hydrogen, ammonia and hydrogen chloride are evolved, and a purple-red mass is produced which is a mixture of ammonium chloride, and of bismuth di- and tri-chlorides. By regulating the temp., the proportion of trichloride can be made very small, but the ammonium salt cannot be removed. R. Weber said that bismuth trichloride can be reduced to the dichloride by warming it with mercurous chloride, or with phosphorus, silver, zinc, mercury, or tin, but not with gold or platinum. The dichloride is also formed by heating an intimate mixture of bismuth and mercuric or mercurous chlorides in stoichiometrical proportions. A. Michaelis also obtained the dichloride mixed with bismuth phosphate and oxychloride by the action of heat on a mixture of phosphorus trichloride and bismuth trioxide.

Analyses of the dark brown crystalline mass by P. P. Dehérain, R. Weber, and R. Schneider agree with the formula BiCl₂. The product obtained by slowly cooling the molten dichloride may show acicular crystals when broken. W. Herz and A. Guttman gave 4.85-4.88 for the sp. gr. of the black, needle-like crystals—this is lower than the value for a corresponding mixture of bismuth and its trichloride. The dichloride is readily fused; W. Herz and A. Guttman gave 163° for the m.p.; and R. Schneider, V. Thomas, R. Weber, and M. M. P. Muir said that it decomposes at about 300° into the trichloride and bismuth. The dichloride is very hygroscopic, and is decomposed by water into bismuth oxychloride. P. P. Dehérain said that dry chlorine converts the di- into the tri-chloride; and that there is simultaneously formed *bismuth tritaoctochloride*, Bi₃Cl₈—but this statement has not been confirmed;

Solution	{	Bi_2O_3	0.60	2.60	11.44	23.75	50.74	58.72	58.59
		HCl	2.50	4.22	10.68	17.56	30.23	33.67	35.14

Solid phases

BiOCl

 BiCl_3

A. Mutscheller concluded that in acid soln., the basic salts are ionized to form a univalent $\text{Bi}(\text{OH})_2$ -ion; and in alkaline soln., a trivalent Bi^{+++} -ion.

R. Weber⁵ said that the trichloride can be obtained as a snow-white mass, which M. M. P. Muir obtained by sublimation in fine crystals. If some dichloride is present, the compound is coloured brown or grey. Analyses reported by J. Davy, W. Heintz, and J. B. A. Dumas agree with the formula BiCl_3 . V. A. Jacquelin found that the vapour density is 11.35 in agreement with 10.98 calculated for BiCl_3 . L. Rügheimer found the **vapour density** at 490° to be normal. C. H. D. Bödeker gave 4.56 for the **specific gravity** at 11° . R. Lorenz and W. Herz gave 4.75 at ordinary temp. and 3.910 at the m.p. A. Voigt and W. Biltz found the sp. gr. of molten bismuth trichloride varies from 3.87 at 250° to 3.64 at 350° , or $D=3.87-0.0023(\theta-250)$. W. Biltz studied the **molecular volume**; R. Lorenz and W. Herz gave 315.4 for the mol. vol. I. I. Saslowsky calculated a 0.99 per cent. contraction in the formation of this compound from its elements. F. M. Jäger found the sp. gr. at different temp. referred to water at 4° ; the **surface tension** θ dynes per cm.; the **specific cohesion**, a^2 in sq. mm.; and the molar **surface energy**, E ergs per sq. cm., to be:

	271°	304°	331°	353°	382°
θ	61.2	61.8	58.1	55.3	52.0
E	1254.4	1187.0	1126.6	1084.3	1032.4
a^2	3.54	3.58	3.22	3.11	2.98
Sp. gr.	3.811	3.735	3.632	3.621	3.554

He represented the sp. gr. of the liquid at θ° by $D=3.860-0.00232(\theta-250)$. S. Motylewsky found the drop-weight of bismuth trichloride to be 85 when that of water is 100. R. Lorenz and W. Herz studied some relations of the surface tensions of the family of halides. M. M. P. Muir gave 225° - 230° for the **melting point**; G. Scarpa, 224° ; and R. Lorenz and W. Herz, 232.5° . The last-named also gave 0.000545 for the coeff. of **thermal expansion**. T. Carnelley and W. C. Williams gave 427° - 439° for the **boiling point**; V. Meyer and A. Krause, 435° - 441° ; C. G. Maier, 442.2° ; V. Meyer and F. Freyer, and L. Rügheimer, 447° ; R. Anschütz and H. Weyer, 264° at 11 mm. C. G. Maier gave for the **vapour pressure**, p mm.:

p	94.1°	139.3°	212.3°	287.3°	371.4°	403.2°	434.0°	439.0°	445.1°	468.8°
	19.8	24.5	36.7	56.0	238.0	408.4	701.7	755.5	831.5	1235.6

V. A. Jacquelin observed that the trichloride can be sublimed in a current of carbon dioxide without decomposition. C. G. Maier also gave 18.3 Cals. for the **heat of vaporization** per mol. E. Liesegang found that the trichloride is sensitive to light, and paper soaked in the soln. becomes brown when exposed to light, but it becomes colourless again when kept in darkness. C. R. Crymble, and A. K. Macbeth and N. I. Maxwell measured the absorption spectrum of bismuth trichloride. K. Schäfer and F. Hein compared the absorption spectra of bismuth trichloride dissolved in aq. hydrochloric acid, ether, and ethyl acetate; and assumed that absorption complexes, $[\text{BiCl}_3(\text{Cl})(\text{OH})]\text{H}$, or $[\text{BiCl}_3(\text{H}_2\text{O})\text{Cl}_2]\text{H}_2$, are formed. A. K. Macbeth and N. I. Maxwell studied this subject. N. P. Peskoff found bismuth hydroxide sensitized organic substances affected by X-rays. A. A. Noyes and co-workers explained the conductivity of hydrochloric acid soln. of bismuth oxide on the assumption that with conc. acid, the complex *hydro-pentachlorobismuthous acid*, H_2BiCl_5 , and with a less conc. acid *hydrotetrachlorobismuthous acid*, HBiCl_4 , are formed—*vide infra*. G. Hänsel found that the electrolysis of bismuth chloride in soln. of hydrochloric acid or of sodium chloride is not satisfactory. M. Escher observed the absorption of polonium by bismuth hydroxide. L. Rügheimer and E. Rudolf measured the effect of some salts—sodium, barium, strontium, manganese, cobalt, and copper chlorides—on the b.p. of bismuth

trichloride, and inferred that their mol. wts. are nearly normal. A. Ditte and R. Metzner represented the heat of formation by $2\text{Bi} + 6\text{HCl} + 3\text{O} = 2\text{BiCl}_3 \cdot 3\text{H}_2\text{O} + 242.2$ Cals.; and J. Thomsen, $(\text{Bi}_2\text{Cl}_6) = 24.6$ Cals. A. Voigt and W. Biltz gave 0.0442 mho for the sp. electrical conductivity of the molten chloride at 260° ; 0.481 at 295° ; 0.506 at 315° ; 0.533 at 335° ; and 0.255 at 350° ; while W. Biltz and W. Klemm gave for the eq. conductivity $\lambda = 10.2 + 0.047(\theta - 250)$.

The effect of **hydrogen** on bismuth trichloride has been discussed in connection with the dichloride. V. A. Jacquelin observed that when heated to the vaporization temp., in **air**, bismuth oxychloride is formed. The salt deliquesces in air. **Water** or steam was found by R. W. E. MacIvor, V. Merz and W. Weith, W. Heintz, and V. A. Jacquelin to decompose the trichloride with the formation of the oxychloride, and W. Oswald found the result is in accord with the mass law—*confer* Fig. 19. W. Herz and A. Bulla showed that the equilibrium conditions agree with the relation $[\text{BiCl}_3]/[\text{HCl}]^2$, a constant, over a wide range of dilution; and R. Dubrisay obtained an analogous result at 18° , 80° , and 85° . The curves are continuous, and indicate a decrease in the hydrolysis as the temp. rises in harmony with the rule for exothermal reactions. Only one oxychloride, BiOCl , is formed. W. Heintz, A. E. Arppe, and W. Jacobs prepared the *dihydrate*, $\text{BiCl}_3 \cdot 2\text{H}_2\text{O}$ —*vide* Fig. 19. T. Karantassis studied the interchange of halogens—chlorine, bromine, and iodine. As indicated in connection with the higher chlorides of bismuth—*vide supra*—M. M. P. Muir showed that **chlorine** has no action on the trichloride; and **bromine** does not form an addition product. R. Engel observed that if a soln. of bismuth trichloride be sat. with **hydrogen chloride** at 20° , acicular crystals of **bismuth hydroheptachloride**, $2\text{BiCl}_3 \cdot \text{HCl} \cdot 3\text{H}_2\text{O}$, are formed. They are stable at ordinary temp. W. Jacobs obtained the anhydrous bismuth hydrotetrachloride, $\text{BiCl}_3 \cdot \text{HCl}$ —Fig. 18—not R. Engel's salt. A. Ditte also reported that he prepared **bismuth trihydrohexachloride**, $\text{BiCl}_3 \cdot 3\text{HCl}$, in prismatic crystals, by evaporating a hydrochloric acid soln. of bismuth trichloride; but W. Jacobs did not confirm this. A. E. Arppe examined these compounds. W. Eidmann, and H. E. Causse added that the presence of conc. **hydrochloric acid** or of **alkali chlorides** hinders the precipitation of the bismuthyl chloride. W. Herz and A. Bulla found that alkali chlorides increase the solubility of bismuth trichloride; bromides have a greater and acids a less influence than chlorides in reducing the hydrolysis. Sodium sulphate has no appreciable effect. According to G. Vortmann and C. Padberg, an acidic soln. of bismuth trichloride is not altered when boiled with **sulphur**. According to M. M. P. Muir and E. M. Eagles, and J. Durocher, when the trichloride is heated with sulphur, or in a current of **hydrogen sulphide**, it forms bismuth sulphochloride; at a red-heat, however, bismuth trisulphide is formed. U. Antony and G. Magri found that 100 c.c. of liquid hydrogen sulphide dissolves 0.08 gm. of the trichloride, forming a colourless soln.; and G. N. Quam showed that bismuth chlorosulphide, BiSCl , is formed. G. N. Quam and J. A. Wilkinson also observed that liquid hydrogen sulphide forms an insoluble compound with bismuth trichloride. M. M. P. Muir found that if the trichloride is heated to the volatilization temp., in a current of **sulphur dioxide**, a great part of the salt sublimes unchanged, and a small proportion of the oxychloride, $\text{Bi}_2\text{O}_2\text{Cl}_3$, is formed; no reaction occurs when the trichloride is heated with **sulphur monochloride**. A. Vogel found that conc. **sulphuric acid** converts the trichloride into sulphate.

According to G. Gore, liquid **ammonia** dissolves the trichloride, and J. Persoz found that when exposed to ammonia the absorption of the gas is accompanied by a small rise of temp.; and, added P. P. Dehérain, three amines are formed: (i) **bismuth aminobistrichloride**, $2\text{BiCl}_3 \cdot \text{NH}_3$, is a red stable compound which melts when heated, and crystallizes on cooling; it is sensitive towards moisture, and is decomposed by hydrochloric acid, forming $\text{NH}_4\text{Cl} \cdot 2\text{BiCl}_3$; (ii) **bismuth diamminotrichloride**, $\text{BiCl}_3 \cdot 2\text{NH}_3$, is a dirty-green substance which forms $2\text{NH}_4\text{Cl} \cdot \text{BiCl}_3$ when treated with hydrochloric acid; and (iii) **bismuth triaminotrichloride**, $\text{BiCl}_3 \cdot 3\text{NH}_3$, a colourless substance which can be volatilized unchanged in ammonia

gas, and which forms $3\text{NH}_4\text{Cl} \cdot \text{BiCl}_3$, when treated with hydrochloric acid. J. Hanus and A. Jilek showed that when a soln. of a bismuth salt is boiled with **hydrazine hydrate**, bismuth is quantitatively precipitated. A. Besson, and V. Thomas obtained **bismuth nitrosyltrichloride**, $\text{BiCl}_3 \cdot \text{NO}$, by the action of **nitric oxide**; the complex salt is very **hygroscopic** and can be melted without decomposition. J. J. Sudborough found that **nitrosyl chloride** reacts vigorously with bismuth trichloride; and from the resulting liquid, **bismuth nitrosyltetrachloride**, $\text{BiCl}_3 \cdot \text{NOCl}$, is separated as a deliquescent orange-yellow powder which is decomposed by water. H. Rheinboldt and R. Wasserfuhr found that it melts at 115° – 120° . A. Besson, and V. Thomas obtained **bismuth nitroxyltrichloride**, $\text{BiCl}_3 \cdot \text{NO}_2$, by exposing bismuth trichloride to **nitrogen peroxide** for 10 hrs. at ordinary temp. The yellow product loses no nitrogen peroxide in vacuo; it is stable in dry air, but is decomposed in moist air, and water transforms it into bismuthyl chloride. S. Schlesinger observed that **nitric acid** converts the trichloride into nitrate. As indicated in connection with the dichloride, R. Weber, and L. Rosenstein found that bismuth trichloride is reduced by **phosphorus**. A. Cavazzi, G. Vortmann and C. Padberg, and P. Kulisch studied the action of **phosphine**, and obtained a bismuth phosphide associated with some oxygen and chlorine. T. Karantassis found that **phosphorus triiodide** reacts by double decomposition with bismuth trichloride, but the reverse reaction does not occur. E. Glatzel found that **phosphorus pentasulphide** converts the trichloride into sulphophosphate; F. E. Brown and J. E. Snyder observed no reaction with **vanadium oxytrichloride**. As indicated above, **carbon dioxide** has no action on the heated trichloride. The trichloride is soluble in **alcohol**, and in **ether**. W. Eidmann found that the trichloride is soluble in **methylal**, and in **acetone**; A. Naumann and P. Schulz, that 100 grms. of acetone dissolve 17.89 grms. of the trichloride, forming a soln. of sp. gr. 0.9194 at $18^\circ/4^\circ$; the pale yellow liquid gradually turns brown, and behaves towards ammonia, potassium iodide, silver nitrate, and hydrogen sulphide like an aq. soln. of the salt. Bismuth trichloride dissolves in many **hydrocarbons** at appropriate temp., and can be recovered by crystallization as the soln. cools; at higher temp. the trichloride is reduced to dichloride, and bismuth trichloride thus serves as a feeble chlorinating agent. V. Thomas also observed that it can also serve as a condensation agent. L. Vanino and co-workers, C. Montemartini, H. Schiff, etc., studied its reactions with **organic compounds**. F. Challenger and co-workers, F. Hartl, L. Vanino and O. Hauser, A. Gutbier and M. Müller, and H. Schiff studied the organic derivatives of bismuth; and L. Vanino and F. Hartl, the compounds with organic bases. G. Bruni and A. Manuelli studied the hydrolysis of bismuth trichloride in a soln. of **formamide**. A. C. Vournasos prepared complexes with organic amines, pyridine, and quinoline. A. Naumann observed that the trichloride is soluble in **benzonitrile**, **methyl acetate**, and at 18° , 100 parts of **ethyl acetate** dissolve 1.36 parts of bismuth trichloride and the soln. has a sp. gr. 0.9106 at $18^\circ/4^\circ$. H. Cousin found that when the soln. is boiled with **dextrose** in excess, bismuth is quantitatively precipitated. J. P. Wibaut and co-workers studied bismuth trichloride as a catalyst in the addition of hydrogen chloride or bromide to ethylene and propylene.

A. C. Vournasos observed the reduction of a toluene soln. of bismuth halide by **potassium**. R. Weber observed the reducing action of **silver**, **zinc**, **mercury**, and **tin** on the trichloride—*vide supra*—**gold** and **platinum** are without action, although F. M. Jäger noted that platinum is attacked by the liquid towards 400° . F. Winkler studied the action of **bismuth** on the trichloride. K. Seubert and A. Schmidt observed that the vapour of the trichloride is reduced by **magnesium** to bismuth and its dichloride. R. Weber found that the trichloride is reduced when heated with **mercuric chloride**; and J. Volhard that when heated with **mercuric oxide** bismuth trioxide is formed. M. M. P. Muir found that bismuth trichloride is not attacked when heated with **chromyl chloride**; and E. Zintl and G. Rienäcker studied the electrometric titration of bismuth salts with **chromous chloride**.

Bismuth trichloride forms complex salts with the alkali and ammonium chlorides. A. A. Noyes and co-workers examined the electrical conductivity of soln. of bismuth trichloride and the solubility of bismuth oxychloride in hydrochloric acid, and explained the results on the assumption that **hydrotetrachlorobismuthous acid**, HBiCl_4 —*cf.* $\text{BiCl}_3 \cdot \text{HCl}$, Fig. 19—and **hydropentachlorobismuthous acid**, H_2BiCl_4 , are formed in soln. K. Schäfer and F. Hein obtained $\text{HBiCl}_4 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$ as a viscid oil by passing dry hydrogen chloride into an ethereal soln. of bismuth trichloride. A. Gutbier and M. Müller prepared a number of chloro-derivatives of organic bases. P. P. Dehérain obtained colourless, deliquescent needles of **ammonium heptachlorodibismuthite**, $\text{NH}_4\text{Cl} \cdot 2\text{BiO}_3$, by the action of hydrochloric acid on bismuth hemiamminohexachloride; and from bismuth diamminotrichloride he similarly obtained six-sided plates of **ammonium pentachlorobismuthite**, $2\text{NH}_4\text{BiCl}_5$; C. F. Rammelsberg obtained it as a *hemipentahydrate* by evaporating, at ordinary temp., a soln. containing equimolar parts of bismuth trichloride, and ammonium chloride; and V. A. Jacquelin from a soln. of a mol of bismuth trichloride and 2 mols of the ammonium salt. C. F. Rammelsberg said that the hydrated salt forms colourless rhombic prisms isomorphous with the corresponding bromide, and with the corresponding potassium salt. V. A. Jacquelin said that the anhydrous salt forms six-sided prisms. C. F. Rammelsberg obtained from the mother-liquor in the preparation of the preceding salt, tabular trigonal crystals of *ammonium henachlorodibismuthite*, $5\text{NH}_4\text{Cl} \cdot 2\text{BiCl}_3$, with the axial ratios $a:c=1:1.9728$. P. Groth regards the salt as the pentachlorobismuthite. P. P. Dehérain obtained tabular, rhombic crystals of **ammonium hexachlorobismuthite**, $3\text{NH}_4\text{Cl} \cdot \text{BiCl}_3$, by the action of hydrochloric acid on bismuth triamminotrichloride; and A. E. Arppe, by crystallization from a soln. of a mol of bismuth trichloride and six mols of ammonium chloride. A. Ferratini found that when an alcoholic soln. of the trichloride is boiled with an excess of hydrazine hydrochloride, it forms **hydrazine hexachlorobismuthite**, $\text{BiCl}_3 \cdot 3\text{N}_2\text{H}_5\text{Cl}$.

V. A. Jacquelin⁶ obtained deliquescent plates of trihydrated **sodium pentachlorobismuthite**, $\text{Na}_2\text{BiCl}_5 \cdot 3\text{H}_2\text{O}$, by crystallization from an aq. soln. of a mol of bismuth trichloride with 3 mols of water; A. E. Arppe prepared six-sided prisms of the *monohydrate* from a hydrochloric acid soln. of 2 mols of bismuth trioxide and 3 mols of sodium chloride. J. Aloy and A. Frébault prepared **potassium pentachlorobismuthite**, K_2BiCl_5 , by passing a current of chlorine and bismuth trichloride vapour over potassium chloride at a red-heat. The amber-yellow, crystalline mass is deliquescent, but is more stable than bismuth trichloride. It is hydrolyzed by water, forming bismuthyl chloride. The evaporation of the hydrochloric acid soln. furnishes the *hemipentahydrate*, $\text{K}_2\text{BiCl}_5 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. C. F. Rammelsberg obtained the hydrate by crystallization from an aq. soln. of the component salts in the molar ratio $\text{BiCl}_3:\text{KCl}=1:1$; V. A. Jacquelin from a soln. with this ratio 1:2; C. P. Brigham, 1:3; and A. E. Arppe, 4:3. According to C. F. Rammelsberg, the colourless plates are rhombic bipyramids with the axial ratios $a:b:c=0.6873:1:7.7979$. The salt is stable in air; it loses no water in the desiccator, but gives off all its water of crystallization at 100° . As indicated above, it is hydrolyzed by water; and crystallizes unchanged from conc. hydrochloric acid. C. P. Brigham showed that **potassium tetrachlorobismuthite**, $\text{KBiCl}_4 \cdot \text{H}_2\text{O}$, is formed when a hot, hydrochloric acid soln. of 5 mols of bismuth oxide and 4 mols of potassium chloride is evaporated until on cooling radiating masses of fibrous crystals separate out on cooling. The salt loses half its water of crystallization over calcium chloride, and the remainder at 105° . The salt begins to decompose at 140° . It can be recrystallized from a conc. soln. of bismuth trichloride; when crystallized from hydrochloric acid, it forms $\text{K}_2\text{BiCl}_5 \cdot 2\frac{1}{2}\text{H}_2\text{O}$; when treated with conc. sulphuric acid, it forms $\text{KBi}(\text{SO}_4)_2$. By a similar process, C. P. Brigham prepared **rubidium tetrachlorobismuthite**, $\text{RbBiCl}_4 \cdot \text{H}_2\text{O}$, in colourless needles. P. P. Dehérain obtained six-sided plates of **sodium hexachlorobismuthite**, Na_3BiCl_6 , by crystallization from a soln. with stoichiometrical proportions of the component salts. A. E. Arppe

reported that rhombic plates of **potassium hexachlorobismuthite**, K_3BiCl_6 , crystallize from a hydrochloric acid soln. of a mol of bismuth trichloride and 2 mols of potassium chloride, but C. F. Rammelsberg, and C. P. Brigham obtained the pentachlorobismuthite under these conditions. P. P. Dehérain said that rhombic plates of **ammonium potassium hexachlorobismuthite**, $(NH_4)_2KBiCl_5$, are produced from a soln. of the component salts. C. P. Brigham prepared **rubidium hexachlorobismuthite**, Rb_3BiCl_6 , as a crystalline precipitate by slowly adding a hydrochloric acid soln. of bismuth chloride to a conc. soln. of rubidium chloride in dil. hydrochloric acid. T. H. Behrens also prepared the salt. R. Godeffroy reported $6RbCl \cdot BiCl_3$ to be formed by this process, but C. P. Brigham showed that this product was probably a mixture; similar remarks apply to R. Godeffroy's $6CsCl \cdot BiCl_3$. C. P. Brigham prepared transparent plates of **cæsium hexachlorobismuthite**, $3CsCl \cdot BiCl_3$, and T. H. Behrens obtained a similar salt. C. P. Brigham obtained **rubidium hexadecachlorotribismuthite**, $7RbCl \cdot 3BiCl_3$ —possibly $23RbCl \cdot 10BiCl_3$ —analogous to the antimony compound, by crystallization from a dil. hydrochloric acid soln. of a mol of bismuth trioxide and 2 mols of rubidium chloride. It can be recrystallized from a soln. of bismuth trichloride; but by crystallization from a soln. in hydrochloric acid, rubidium hexachlorobismuthite is formed. If a hydrochloric acid soln. of bismuth trichloride be added to a soln. of cæsium chloride in dil. hydrochloric acid, a crystalline precipitate which is a mixture of the colourless plates of the hexachlorobismuthite, and yellow pyramids of **cæsium enneachlorodibismuthite**, $3CsCl \cdot 2BiCl_3$, are formed. The latter salt is decomposed by water, but can be crystallized unchanged from its soln. in hydrochloric acid. E. H. Duclaux examined the cæsium salt as an aid to the micro-detection of bismuth.

G. Hermann's measurements of the f.p. of mixtures of cuprous and bismuth chlorides give a simple V-curve, Fig. 20, with no evidence of the formation of a

FIG. 20.—Freezing-point Curve of Mixtures: $CuCl-BiCl_3$.

FIG. 21.—Freezing-point Curve of Mixtures: $ZnCl_2-BiCl_3$.

cuprous chlorobismuthite. R. F. Weinland and co-workers described a series of salts of an imaginary *pentachlorobismuthous acid*, $H_2[BiCl_5]$, represented by **calcium pentachlorobismuthite**, $CaBiCl_5 \cdot 7H_2O$, in tabular crystals; **strontium pentachlorobismuthite**, $SrBiCl_5 \cdot H_2O$, in rectangular, four-sided plates, and **barium pentachlorobismuthite**, $BaBiCl_5 \cdot 4H_2O$, in rhombic plates. Another series referred to *tetrachlorobismuthous acid*, $HBiCl_4$, was represented by colourless needles of **calcium tetrachlorobismuthite**, $Ca(BiCl_4)_2 \cdot 7H_2O$; stout needles of **strontium tetrachlorobismuthite**, $Sr(BiCl_4)_2 \cdot 7H_2O$; and slender needles of **barium tetrachlorobismuthite**, $Ba(BiCl_4)_2 \cdot 5H_2O$. Yet a third series corresponding with *heptachlorodibismuthous acid*, HBi_2Cl_7 , is represented by **strontium heptachlorodibismuthite**, $Sr(Bi_2Cl_7)_2 \cdot 12H_2O$. Other representatives of these acids have been made: **magnesium pentachlorobismuthite**, $MgBiCl_5 \cdot 8H_2O$, in stout, rectangular plates; and **magnesium heptachlorodibismuthite**, $Mg(Bi_2Cl_7)_2 \cdot 16H_2O$, in six-sided leaflets. G. Hermann's observations on the f.p. of mixtures of zinc and bismuth chlorides are summarized in Fig. 21. The two salts are only partially miscible in the liquid state, but solid soln. are formed to a limited extent, but no *zinc chlorobismuthite* is formed.

J. Nicklès obtained a complex salt with thallium by adding a soln. of potassium

thallium chloride to one of a bismuth salt. G. Scarpa studied the f.p. curve of the system $\text{TlCl}-\text{BiCl}_3$. The results are summarized in Fig. 22. There is a eutectic at 360° and 12.5 molar per cent. of bismuth trichloride, and a maximum at 413° corresponding with **thallium hexachlorobismuthite**, $3\text{TlCl}\cdot\text{BiCl}_3$. F. Ephraim and

FIG. 22.—Freezing-point Curves of the Binary System: $\text{TlCl}-\text{BiCl}_3$.

P. Barteczko prepared thin, colourless plates of this compound in a hydrochloric acid soln. of its components if an excess of bismuth trichloride be used, thallium enneachlorobismuthite, $6\text{TlCl}\cdot\text{BiCl}_3$, is formed. G. Scarpa observed a break in the f.p. curve at 330° and about 40 molar per cent. of the trichloride corresponding with the formation of **thallium pentachlorobismuthite**, $2\text{TlCl}\cdot\text{BiCl}_3$; and another break at 225° and about 52 molar per cent. of bismuth trichloride corresponding with **thallium enneachlorodibismuthite**, $3\text{TlCl}\cdot 2\text{BiCl}_3$. There is a eutectic at 150° and 67 molar per cent. of the trichloride; with more trichloride, mixed crystals are formed. G. Hermann's observations on the f.p. of mixtures of lead and bismuth chlorides are summarized in Fig. 23. There is a break at 323.5°

corresponding with the formation of lead chlorobismuthite of unknown composition. Resuming the observations of R. F. Weinland and co-workers, A. C. Vournasos studied the complex chloro- and chlorofluoroamines. Flesh-coloured, six-sided plates of **manganese heptachlorodibismuthite**, $\text{Mn}(\text{Bi}_2\text{Cl}_7)_2\cdot 12\text{H}_2\text{O}$; faintly yellowish-red plates of **ferrous heptachlorodibismuthite**, $\text{Fe}(\text{Bi}_2\text{Cl}_7)_2\cdot 12\text{H}_2\text{O}$, were obtained by the same process. G. Hermann's observations on the f.p. curve of ferric and bismuth chlorides are summarized in Fig. 24. There is a simple V-curve with no indication

FIG. 23.—Freezing-point Curve of Mixtures: $\text{PbCl}_2-\text{BiCl}_3$.

FIG. 24.—Freezing-point Curve of Mixtures: $\text{FeCl}_3-\text{BiCl}_3$.

of a *ferric chlorobismuthite*. R. F. Weinland and co-workers prepared prisms of **cobalt pentachlorobismuthite**, $\text{CoBiCl}_5\cdot 6\text{H}_2\text{O}$; green needles of **nickel pentachlorobismuthite**, $\text{NiBiCl}_5\cdot 6\text{H}_2\text{O}$; **cobalt heptachlorodibismuthite**, $\text{Co}(\text{Bi}_2\text{Cl}_7)_2\cdot 12\text{H}_2\text{O}$, in red, six-sided plates; and **nickel heptachlorodibismuthite**, $\text{Ni}(\text{Bi}_2\text{Cl}_7)_2\cdot 12\text{H}_2\text{O}$, in pale green, six-sided plates. These salts were obtained by dissolving bismuth chloride in the smallest possible quantity of conc. hydrochloric acid, and treating the soln. with the carbonate, hydroxide, or chloride of the bivalent metal. The heptachlorobismuthites are produced from the sat. soln. of the metal hydroxide or carbonate in the soln. of bismuth trichloride; the tetrachlorobismuthites from soln. with the molar ratio of bismuth trichloride to that of the bivalent metal chloride is as 5 : 2 or 5 : 1; and the heptachlorodibismuthites when this ratio is 10 : 1.

§ 12. The Bismuth Bromides

According to R. Weber,¹ when 2 mols of bismuth trichloride are melted together with a gram-atom of bismuth, and cooled, a brown mass of needle-like crystals is obtained which is probably **bismuth dibromide**, BiBr_2 . G. S. Sérullas' description of bismuth dibromide as a steel-grey mass makes it probable that his product was contaminated with the tribromide. M. M. P. Muir also observed that in the preparation of the tribromide by the action of bromine on bismuth, the dibromide may be formed in dark grey crystals which are very difficult to separate from the tribromide. W. Herz and A. Gutmann gave 5.9 for the sp. gr. of the black leaflets, and 198° for the m.p. R. Weber said that the dibromide is decomposed by water, and by hydrochloric acid with the separation of bismuth. B. G. Eggink observed no sign of the dichloride on the f.p. curve of bismuth and bromine; but he observed the formation of *bismuth monobromide*, BiBr , melting at 287° , forming two liquid phases. L. Marino and R. Becarelli found that when the mixtures of bismuth with 5 to 85

FIG. 25.—Portion of Equilibrium Diagram of the System: $\text{Bi}-\text{BiBr}_3$.

per cent. of bismuth tribromide are fused in sealed tubes, two layers are obtained above 320° —the upper one being black, the lower one white. Lowering the temp. from 320° results in the formation of (i) a crystalline product melting over the range 270° – 305° , and at about 240° this is transformed into a product melting at about 260° and one at 270° – 305° ; and (ii), the other stratum furnishes the eutectic $\text{Bi}-\text{BiBr}_3$, melting at about 202° . Hence, the solidification of the fused mixtures lying within definite limits of concentration yields two layers, the upper one consisting of black, acicular crystals and the lower one of a mass of crystals with metallic lustre, m.p. 230° – 270° , and covered with a black skin; the lower crystals are sensitive to light, and soon lose their brilliancy and become iridescent and then greyish-blue. The black upper layer does not consist of a single compound, but is separable into a highly hygroscopic black mass and a crystalline network melting over a range of temp. above 270° . From all the upper layers formed in the different mixtures of bismuth and its tribromide at 200° , there drops in greater or less quantity, according to the composition of the mixture, a black hygroscopic substance. For each of these strata there remains a crystalline network which melts between about 270° and 300° —

305°, and is regarded as a series of mixed crystals, which undergo transformation into a β -form and then into a γ -form with pronounced development of heat. The m.p. of the γ -crystals is always above those of bismuth and bismuth tribromide, and on fusion and cooling they yield α -crystals of different composition, together with two liquid strata which reproduce this series of changes. At 153°, bismuth tribromide undergoes transformation into the solid form. There is no evidence of the formation of a sub-bromide. B. G. Eggink studied the system and interpreted his results on the assumption that a sub-bromide is formed.

Bromine does not unite so vigorously with bismuth as it does with antimony, and G. S. Sérullas² said that **bismuth tribromide**, BiBr_3 , is formed. If the bismuth be in excess, R. Weber, and M. M. P. Muir showed that some dibromide is formed. R. Weber obtained the tribromide by heating bismuth in the vapour of bromine; V. Meyer and A. Krause, by introducing finely powdered bismuth into bromine, distilling off the tribromide after it has stood for a few days; and purifying the product by repeated distillation; J. Nicklès, by adding powdered bismuth to a mixture of equal parts of bromine and ether, filtering the liquid after it had stood for some time, and evaporating in vacuo; M. M. P. Muir, by heating the oxide in a current of bromine vapour—the oxybromide, $\text{Br}_{11}\text{O}_{13}\text{Br}_7$, is formed as a by-product; P. Jannasch, by strongly heating the trisulphide in a current of bromine vapour; G. Oddo and U. Giachery, by heating a mixture of stoichiometrical proportions of bismuth oxide and sulphur in a current of bromine; and A. C. Vournasos, by heating to 100° a mixture of bismuth trioxide and potassium bromide with acetic acid.

Bismuth tribromide furnishes an orange-yellow, crystalline mass, or, when slowly sublimed, golden-yellow crystals. M. M. P. Muir's analysis corresponds with BiBr_3 . C. H. D. Bödeker gave 5.604 for the **specific gravity** of the crystals; and M. M. P. Muir, 5.4 at 20°. R. Lorenz and W. Herz gave 5.604 for the sp. gr. at ordinary temp., and 4.682 at the b.p. W. Biltz studied the **molecular volume**; R. Lorenz and W. Biltz gave 448.8 for the mol. vol. I. I. Saslawsky calculated a 0.01 per cent. contraction in the formation of this compound from its elements. F. M. Jäger gave the following values for the sp. gr. of the liquid, referred to water at 4°; the **surface tension**, σ dynes per cm.; the **specific cohesion**, a^2 sq. mm.; and the molar **surface energy**, E ergs per sq. cm.:

	250°	281°	299°	320°	346°	370°	389°	417°	442°
Sp. gr.	4.598	4.525	4.471	4.416	4.348	4.286	4.237	4.164	4.099
σ	66.5	63.6	61.6	59.5	56.7	53.8	52.0	48.9	46.2
E	1407.6	1360.6	328.4	293.8	1245.7	1191.3	1162.3	1105.8	1055.8
a^2	2.95	2.88	2.81	2.74	2.66	2.58	2.50	2.40	2.30

The sp. gr., D , at θ° was represented by 4.598—0.0026(θ —250). S. Motylewsky gave 78 for the drop-weight of the tribromide when that of water is 100. R. Lorenz and W. Herz studied some relations of the surface tensions of the family of halides. R. Lorenz and W. Herz gave 0.000375 for the coeff. of thermal expansion. R. Weber said that the tribromide melts to a red liquid; and F. M. Jäger, to a yellow liquid. G. S. Sérullas gave 200° for the **melting point**; R. W. E. MacIvor, 198°—202°; J. Kendall and co-workers, 220.4°; M. M. P. Muir, 210°—215°; R. Lorenz and W. Herz, 217.5°; F. M. Jäger, 215°; T. Carnelley and W. C. Williams found the **boiling point** to be 454°—498°; V. Meyer and A. Krause, 453°; and R. Anschütz and H. Weyer, 278° at 11 mm. press. V. Meyer and A. Krause said that the vapour is deep red, very like that of sulphur; and it can be heated in a glass vessel for an hour without decomposition. K. Schäfer and F. Hein measured the **absorption spectrum** of soln. of bismuth tribromide in hydrobromic acid and in ether, and inferred that the absorbing complex in the aq. soln. is a simple bromobismuthous acid. W. A. Isbekoff measured the **decomposition voltage** of bismuth tribromide dissolved in aluminium bromide; and W. Finkelstein found that in nitrobenzene soln., the decomposition voltage is 0.60 volt.

M. M. P. Muir said that the tribromide can be distilled in **hydrogen** without change; and when heated in **air**, the oxybromide, $\text{Bi}_3\text{O}_{15}\text{Br}_6$, is formed, while

V. Thomas said that very little oxidation occurs, for only a little BiOBr is formed. G. S. Sérullas, and M. M. P. Muir found that the tribromide attracts moisture from air, and is decomposed by **water** with the separation of bismuthyl bromide. A. K. Sanyal and N. R. Dhar found that bismuth bromide is decomposed by exposure to tropical sunlight. W. Herz and A. Bulla observed that the tribromide behaves like the trichloride (*q.v.*) towards water, and only one oxybromide, BiOBr , is formed; the hydrolysis is very little affected by a rise of temp. from 25° to 50° . J. Aloy and A. Frébault found that when the tribromide is dissolved to saturation by conc. **hydrobromic acid**, and cooled to -10° , **hydropentabromobismuthous acid**, $\text{H}_2\text{BiBr}_5 \cdot 4\text{H}_2\text{O}$, or $\text{BiBr}_3 \cdot 2\text{HBr} \cdot 4\text{H}_2\text{O}$, is formed. The yellow, deliquescent needles lose hydrogen bromide when exposed to air. According to M. M. P. Muir, only a little sulphobromide is formed when bismuth tribromide is heated with **sulphur**, and, according to M. M. P. Muir and E. M. Eagles, the same compound is produced by the action of **hydrogen sulphide** at a suitable temp.—but at a higher temp., bismuth trisulphide is formed. The tribromide is not changed by heating it in a current of **sulphur dioxide**. According to M. M. P. Muir, when the tribromide is warmed in a current of dry **ammonia**, it melts, and a yellow vapour is given off which condenses in the cold part of the tube as **bismuth triamminotribromide**, $\text{BiBr}_3 \cdot 3\text{NH}_3$, as a straw-yellow, amorphous powder which attracts moisture from the air, is decomposed by water, forming an oxybromide; and with hydrochloric acid it forms $3\text{NH}_4\text{Cl} \cdot \text{BiBr}_3 \cdot \text{H}_2\text{O}$. If bismuth tribromide be melted in ammonia gas, the olive-green residue is **bismuth diamminotribromide**, $\text{BiBr}_3 \cdot 2\text{NH}_3$. It deliquesces in air; is decomposed by water; and forms $3\text{NH}_4\text{Cl} \cdot \text{BiBr}_3 \cdot 3\text{H}_2\text{O}$ when treated with hydrochloric acid. If molten bismuth tribromide be heated in ammonia until no more vapour is given off at a red-heat, the product is **bismuth hemipentamminotribromide**, $2\text{BiBr}_3 \cdot 5\text{NH}_3$. It is also formed by heating one of the oxybromides in a current of ammonia. The greyish-green sublimate decomposes when heated in air giving off the tribromide, and leaving an oxybromide as residue. It is not decomposed by water, and is freely soluble in dil. acids, with hydrochloric acid, it forms $5\text{NH}_4\text{Cl} \cdot 2\text{BiBr}_3 \cdot \text{H}_2\text{O}$. R. Weber said that the tribromide dissolves with decomposition in **nitric acid**, and V. Thomas, that at ordinary temp. **nitrogen peroxide** transforms it into bismuthyl oxide. A. Cavazzi and D. Tivoli observed that **phosphine** in an ethereal soln. of bismuth tribromide, yields $\text{P}(\text{BiBr}_2)_3\text{HBr}$, **phosphorus tribismuthodibromide hydrobromide**. J. W. Retgers said that bismuth tribromide readily dissolves in **arsenic tribromide**; and S. Tolloczko, that when bismuth tribromide is added to antimony tribromide, the f.p. is raised. J. Nicklès said that the tribromide is freely soluble in **ether**, and forms a crystalline complex. R. Brix studied the action of bismuth tribromide on ethyl iodide, and on ethyl monochloracetate. A. C. Vournasos prepared complexes with organic amines, pyridine, and quinoline. W. A. Isbekoff said that bismuth tribromide is soluble in **aluminium tribromide**.

K. Schäfer and F. Hein showed that a bromobismuthous acid is probably formed in soln. of hydrobromic acid; and they isolated ethereal compounds of **hydropentabromobismuthous acid**, $\text{H}_2\text{BiBr}_5 \cdot 4(\text{C}_2\text{H}_5)_2\text{O}$ and $\text{H}_2\text{BiBr}_5 \cdot 10(\text{C}_2\text{H}_5)_2\text{O}$. J. Aloy and P. Frébault prepared this acid—*vide supra*. Complex salts of bismuth tribromide with ammonium and alkali bromides have been prepared in yellow crystals which are decomposed by water. Thus, J. Nicklès obtained yellow, rhombic needles of **ammonium tetrabromobismuthite**, $\text{NH}_4\text{BiBr}_4 \cdot \text{H}_2\text{O}$, by the action of bromine and alcohol on bismuth in the presence of ammonium bromide. The salt is soluble in alcohol. He also obtained **ammonium pentabromobismuthite**, $(\text{NH}_4)_2\text{BiBr}_5 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, by heating in a sealed tube a mixture of bismuth tribromide, ammonium bromide, alcohol, and a little ammonium acetate. The greenish-yellow, rhombic crystals were found by C. F. Rammelsberg to be isomorphous with those of the corresponding chloride, and the potassium salt. J. Nicklès reported $2\text{NH}_4\text{BrBi}(\text{Br}, \text{Cl})_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, in mixed isomorphous crystals. The water of crystallization is all expelled at 100° ; the salt is decomposed by heat, and by water.

J. Aloy and A. Frébault prepared **potassium pentabromobismuthite**, K_2BiBr_5 , by the method employed for the corresponding chloride, namely, by passing bromine vapour with the aid of carbon dioxide over molten bismuth and the tribromide passed over potassium bromide at a red-heat. The product is cooled in a current of carbon dioxide. The amber-yellow, crystalline mass becomes dark-yellow and then brownish-red when heated; it melts at about 600° without giving off vapours. It is decomposed by water.

Some mixed salts have been reported. Thus, M. M. P. Muir obtained yellow crystals of **ammonium dichlorotribromobismuthite**, $2NH_4Cl \cdot BiBr_3 \cdot 3H_2O$, by the action of hydrochloric acid on bismuth diamminotribromide; by similarly treating the hemipentamminotribromide he obtained ammonium pentachlorohexabromobismuthite, $5NH_4Cl \cdot 2BiBr_3 \cdot H_2O$; while the triamminotribromide yields **ammonium trichlorotribromobismuthite**, $3NH_4Cl \cdot BiBr_3 \cdot H_2O$, in pale yellow, deliquescent plates. E. Field obtained the same salt from a soln. of equimolar parts of bismuth trichloride and ammonium bromide, or of ammonium chloride and bismuth tribromide. E. Field obtained what was regarded as **potassium pentachlorobromobismuthite**, $K_2BiBrCl_4$, by crystallization from a soln. of equimolar parts of bismuth trichloride and potassium bromide; a soln. of equimolar parts of bismuth tribromide and potassium chloride furnishes **potassium chlorotetrahromide**, $K_2BiClBr_4$. R. W. Atkinson said that **potassium trichlorodibromide**, $K_2BiCl_3Br_2 \cdot 1\frac{1}{2}H_2O$, separates in yellow prisms from a soln. of bismuth tribromide in a sat. soln. of potassium chloride. J. Kendall and co-workers found that the f.p. curve of mixtures with aluminium bromide, Fig. 27, showed the existence of **aluminium hexabromobismuthite**, $AlBr_3 \cdot BiBr_3$. C. Canneri and G. Perina prepared **thallous pentabromobismuthite**, Tl_2BiBr_5 , by adding potassium bromide to a soln. of bismuth carbonate in nitric acid. It forms lustrous, lemon-yellow, hexagonal lamellæ, and is rapidly hydrolyzed in neutral aq. soln. to thallous

FIG. 26.—Freezing-point Curve of Lead and Bismuth Bromides.

FIG. 27.—Freezing-point Curve of Mixtures: $AlBr_3$ - $BiBr_3$.

bromide, bismuth oxybromide, and bromine. G. Hermann measured the f.p. of mixtures of lead and bismuth bromides; the results are summarized in Fig. 26. There is a break at 238.5° , corresponding with the formation of **lead bromobismuthite** of unknown composition. A. C. Vournasos studied the complex mixed halogenoamines.

§ 13. The Bismuth Iodides

According to R. Weber,¹ bismuth triiodide readily dissolves bismuth, and when the cold mass is treated with hydrochloric acid, bismuth remains as a fine black powder; if the iodide is fused with an excess of bismuth, a part of the dissolved metal separates out on cooling, and the regulus contains 55.8 per cent. of bismuth—bismuth triiodide has 35.4 per cent., and the diiodide, 45.1 per cent. It is uncertain whether an intermediate **bismuth diiodide**, BiI_2 , is formed. A change of colour analogous to that obtained with bismuth trichloride or tribromide does not occur. L. Marino and R. Becarelli examined the f.p. of mixtures of bismuth

FIG. 28.—Freezing-point Curves of the Binary System: Bi-I.

and iodine, and their results are summarized in Fig. 28. There is here no evidence of the formation of any iodide other than the triiodide. The eutectic of bismuth and bismuth triiodide lies at 284°. When mixtures containing 5–43 per cent. of iodine are cooled, two layers are formed, of which the upper contains excess of bismuth triiodide, and the lower excess of bismuth. At 340°, the upper layer begins to deposit solid bismuth triiodide, and as an invariant system is thus formed, this crystallization continues until all the upper has solidified; during this process the upper layer contains 66.5 per cent. of bismuth triiodide, and the lower 7.73 per cent. Mixtures with 43–64.63 per cent. of iodine deposit bismuth triiodide, until the temp. 340° is reached; two layers are then formed as before. After the upper layer has crystallized, the temp. falls until the eutectic 284° is reached, but there is a thermal effect at 294°, possibly due to a transformation product of bismuth. Mixtures containing more than 64.63 per cent. of iodine deposit bismuth triiodide, and show a eutectic at 117°, but mixtures with more than 90 per cent. of iodine could not be investigated, owing to the breakage of the tubes by the press. of the iodine vapour. H. S. van Klooster also examined the f.p. curve, and said that there is a reaction between the triiodide and the matrix, indicating the formation of bismuth monoiodide, BiI ; there was no evidence of the formation of a diiodide. On the other hand, W. Herz and A. Guttmann said that they obtained crystals of bismuth diiodide by heating the triiodide with the calculated amount of bismuth; and H. G. Denham obtained the diiodide by distilling methyl iodide over lead suboxide below 262°. The reaction vessel contained a non-volatile, brick-red powder—bismuthyl iodide—and a bright-red sublimate of bismuth diiodide.

H. G. Denham said that bismuth diiodide is a volatile substance which crystallizes in red, rhombic needles, which, according to W. Herz and A. Guttmann, have a sp. gr. of 6.5, and decompose below their m.p. H. G. Denham found that in aq. soln., the diiodide gives stronger reactions for bismuth and iodine than the oxyiodide; it dissolves freely in potassium iodide soln., giving soln. of the colour of dichromate

soln. It speedily reduces aq. soln. of iodine and acid permanganate, and is decomposed at 400° into bismuth triiodide and bismuth. The distillate of excess methyl iodide from the preparation of the above compounds was yellow in colour, but on exposure to air it became colourless, and a white solid which turned yellow on keeping separated. This white compound is probably *bismuth dimethide*, and is insoluble in alcohol; it is a strong reducing agent, and on oxidation is converted into *bismuth dimethoxide*, $\text{Bi}(\text{OCH}_3)_2$.

J. B. Berthelot prepared what was probably impure **bismuth triiodide**, BiI_3 , by heating bismuth in iodine vapour. J. Nicklès employed a similar process; R. Weber, by adding strongly heated bismuth to iodine vapour; and W. Heintz, R. Schneider, and M. M. P. Muir and co-workers, by heating an intimate mixture of iodine and bismuth in an atm. of hydrogen or carbon dioxide. C. F. Rammelsberg added potassium iodide to an acetic acid soln. of a bismuth salt—with nitric acid soln., A. E. Arppe said that the precipitate is contaminated with nitrate; and M. M. P. Muir and B. S. Gott, with iodine. Both obtained it pure by precipitating its soln. in conc. hydriodic acid with cold water. The reaction was studied by F. B. Stone, and J. C. Thresh; A. C. Vournasos, by heating to 100° a mixture of bismuth trioxide and potassium iodide with acetic acid; M. M. P. Muir, and C. F. Rammelsberg obtained bismuth triiodide by the action of conc. hydriodic acid on bismuth trioxide or oxyiodide at ordinary temp.; and of hydrochloric acid on bismuth oxyiodide; R. Schneider, and M. M. P. Muir and E. M. Eagles, by sublimation from a mixture of iodine and bismuth trisulphide—bismuth sulphoiodide remains in the residue; G. Oddo and U. Giachery, by heating a mixture of the trioxide and sulphur in the vapour of iodine; V. Auger, by the action of ethyl iodide on bismuth trichloride when ethyl chloride is formed as a by-product; and L. Birckenbach, by saturating a soln. of stannous chloride, sat. with hydrogen chloride with iodine, then adding a hydrochloric acid soln. of bismuth trioxide or oxychloride, then drying the crystals first on porous tiles and afterwards in vacuo over calcium chloride; and subliming the crystals in a current of hydrogen or carbon dioxide.

J. Nicklès described the sublimed triiodide as consisting of six-sided, probably hexagonal crystals isomorphous with antimony triiodide; and R. Schneider, as crystalline plates with a metallic lustre. G. E. Linck said that the crystals belong to the hexagonal system. W. Heintz said the colour is dark green; J. Nicklès, black; and R. Schneider, greyish-black; J. W. Retgers said that when crystallized from methylene iodide, the hexagonal plates have a dark brownish-violet colour. C. H. D. Bodeker gave 5.65 for the **specific gravity** of the sublimed triiodide at 10° ; F. W. Clarke, 5.9225 at 16° , and 5.88 at 17.5° ; and M. M. P. Muir, 5.64 at 20° for the precipitated iodide. W. Biltz studied the mol. vol. T. Carnelley and W. C. Williams found the **melting point** to be 439° ; H. S. van Klooster, 408° ; and L. Marino and R. Becarelli, 412° . R. Schneider, and W. Heintz said that at a higher temp., the triiodide sublimes, and yields a reddish-brown vapour.

Analyses, reported by C. F. Rammelsberg, W. Heintz, R. Schneider, M. M. P. Muir, A. E. Arppe, and L. Birckenbach agree with the formula BiI_3 . E. Rimini and F. Olivari found the effect of the triiodide on the b.p. of fenchone agrees with the same formula. R. Hanslian measured its effect on the b.p. of iodine and found it dissociated into atoms. According to W. Heintz, R. Schneider, R. Weber, and M. M. P. Muir, bismuth triiodide can be sublimed in **hydrogen** or carbon dioxide without decomposition; and R. Schneider, M. Berthelot, and J. Nicklès said that when heated in **air**, most of it sublimes unchanged, but a small part is oxidized to the oxyiodide—V. Thomas said that the non-volatilized residue is bismuth trioxide. R. Schneider said that the sublimed iodide is scarcely attacked by cold **water**, and M. M. P. Muir found that the precipitated iodide is rather more quickly attacked; hot water was found by W. Heintz, R. Schneider, and R. Weber to transform it into the oxyiodide. W. Herz and A. Bulla found that the triiodide is hydrolyzed by water so slowly at 25° and 50° that measurements of the speed of the reaction could not be made. According to R. Dubrisay, the addition of water

to soln. of bismuth triiodide gives a black precipitate which turns brick-red when the conc. of the bismuth in the liquid phase falls below 0.002 gram-atoms per litre. This shows that probably two oxyiodides are formed. According to R. Schneider, **hydrochloric acid** dissolves the triiodide, forming a brown soln., without perceptible decomposition; while A. E. Arppe found that by evaporating, over sulphuric acid, a soln. of the triiodide in conc. **hydriodic acid**, rhombic pyramids of **bismuth hydro-tetraiodide**, $\text{BiI}_3 \cdot \text{HI} \cdot 3\text{H}_2\text{O}$, are formed: the product fumes in dry air; is decomposed by water, forming bismuthyl iodide; and it dissolves in a soln. of potassium iodide. According to M. M. P. Muir and E. M. Eagles, when the triiodide is heated with **sulphur** it does not behave like the trichloride and tribromide and form sulpho-iodide—both elements sublime separately; nor is the triiodide altered when it is strongly heated in **hydrogen sulphide**. E. C. Franklin and C. A. Kraus found the triiodide to be slightly soluble in liquid **ammonia**. When the triiodide is warmed in a current of dry ammonia, it forms a brick-red mass of **bismuth triamminotri-iodide**, $\text{BiI}_3 \cdot 3\text{NH}_3$, from which water extracts ammonium iodide. W. Heintz said that **nitric acid** decomposes the triiodide with the separation of iodine; V. Thomas, that **nitrogen peroxide** transforms it at ordinary temp. into the trioxide, not the oxyiodide; while M. M. P. Muir reported that the nitrous vapours obtained from a mixture of nitric acid and starch form a little oxyiodide. H. Moissan said that the triiodide is readily reduced by heated **boron**. M. M. P. Muir and B. S. Gott found that 100 parts of **alcohol** at 20° dissolve about 3.5 parts of the triiodide; J. Nicklès reported it to be insoluble in ethyl alcohol, **amyl alcohol**, **ether**, and **carbon disulphide**; J. W. Retgers, that it is soluble in **benzene**, **toluene**, and **xylene**; that 100 parts of **methylene iodide** at 12° dissolve 0.15 part of the triiodide, forming a wine-red soln.—the solubility increases only a little as the temp. is raised; and that it dissolves readily in warm arsenic triiodide. A. Naumann found bismuth triiodide to be soluble in **methyl acetate**, and in **acetone**. P. Planés said that the presence of **glycerol** hinders the decomposition of the triiodide by water. S. Delépine, K. Kraut, H. Ley, and A. B. Prescott studied the reactions with various **organic compounds**. G. Dragendorff, and E. Léger used a soln. of bismuth triiodide in potassium iodide as a reagent for **alkaloids**. A. C. Vournasos prepared complex salts with organic amines, pyridine, and quinoline. According to R. Schneider, bismuth triiodide is decomposed at ordinary temp. by the **alkali hydroxides** with the separation of bismuth trioxide, and iodate; **alkali carbonates** act similarly but more slowly; **alkali sulphides** quickly form bismuth trisulphide; and when heated with an excess of **mercuric oxide** it forms bismuth trioxide, and with **mercuric sulphide**, bismuth trisulphide. F. Winkler studied the action of **bismuth** on the triiodide.

Bismuth triiodide forms a series of complex compounds with the ammonium and the metal iodides. The products usually form red or brownish-red crystals which are decomposed by water, forming bismuthyl iodide; and are soluble in ethyl acetate. Thus, J. Nicklès obtained **ammonium tetraiodobismuthite**, $\text{NH}_4\text{BiI}_4 \cdot \text{H}_2\text{O}$, by the action of iodine on bismuth in a conc. soln. of ammonium chloride—the complex chloride simultaneously formed remains in soln. He also obtained it by the action of iodine on bismuth in alcohol in the presence of ammonium iodide. The black, needle-like crystals belong to the rhombic system. Isomorphous mixed crystals with the antimony salt were also obtained, $\text{NH}_4(\text{Bi},\text{Sb})\text{I}_4 \cdot 2\text{H}_2\text{O}$. E. M. Bartholomew and G. J. Burrows obtained a *phenyl-dimethylarsine tetraiodobismuthite*, $[\text{As}(\text{C}_6\text{H}_5)(\text{CH}_3)_2\text{H}]\text{BiI}_4$; W. Linau prepared **ammonium heptaoidobismuthite**, $(\text{NH}_4)_4\text{BiI}_7 \cdot 3\text{H}_2\text{O}$, by slowly evaporating a sat. soln. of bismuth triiodide in a conc. soln. of ammonium iodide. The dark reddish-brown, hygroscopic crystals are isomorphous with the corresponding iodoantimonite. E. M. Bartholomew and G. J. Burrows isolated the *hexaiodobismuthites* of aniline, dimethylaniline, phenyldimethylarsine, etc. These are all crystalline compounds which can be recrystallized from conc. hydrochloric acid without change. They may all be regarded as derivatives of bismuthous iodide.

The anilinium, pyridinium, dimethylanilinium, and *p*-toluidinium salts are all derivatives of hexa-iodo bismuthic acid, $H_3(BiI_6)$, whilst phenyl dimethyl arsonium tetra-iodobismuthite is a derivative of the acid $H(BiI_4)$.

C. Astre obtained black, acicular, rhombic crystals of **potassium hepta-iodobismuthite**, KI_2BiI_3 , from a soln. of iodine and bismuth in one of potassium chloride. J. Nicklès had previously reported the product to be **potassium tetra-iodobismuthite**, $KI.BiI_3.H_2O$; and he also reported **sodium tetra-iodobismuthite**, $NaI.BiI_3.H_2O$, to be formed by the action of iodine on bismuth and a sat. soln. of sodium chloride. The dark brown, prismatic crystals were found by C. F. Rammelsberg to belong to the monoclinic system and to have the axial ratios $a:b:c = 0.864:1:0.717$, and $\beta = 102^\circ 21'$. The crystals effloresce in dry air. They form isomorphous mixed crystals with the corresponding iodoantimonite, $Na(Bi,Sb)I_4.H_2O$. W. Linau prepared **sodium enne-iodobismuthite**, $3NaI.2BiI_3.12H_2O$, in small, garnet-red, rectangular prisms from a sat. soln. of bismuth triiodide in a conc. soln. of sodium iodide. The crystals are probably isomorphous with the corresponding iodoantimonite. A. C. Vournasos prepared **potassium hexa-iodobismuthite**, $K_3[BiI_6]$, and **sodium hexa-iodobismuthite**, $Na_3[BiI_6]$. C. Astre obtained quadratic prisms of **potassium enne-iodobismuthite**, $3KI.2BiI_3.2H_2O$, by allowing a mixture of iodine (1.5 mols), potassium iodide (2 mols), an excess of bismuth, and 50 c.c. of water to stand for 2 months with frequent shaking, and crystallizing the product from ethyl acetate. A. E. Arppe obtained rhombic plates of a similar salt by evaporating a soln. of potassium iodide and bismuth triiodide. H. L. Wells made **caesium enne-iodobismuthite**, $3CsI.2BiI_3$, in crystals sparingly soluble in water. C. Astre reported **potassium penta-iodobismuthite**, $2KI.BiI_3$, to be formed from a soln. of a mol of bismuth triiodide and 3 mols of potassium iodide in ethyl acetate. P. P. Dehérain obtained six-sided plates of **sodium hexachlorobismuthite**, $3NaCl.BiCl_3$, from a soln. of the component salts, and C. Astre, **potassium hexachlorobismuthite**, $3KCl.BiCl_3$, by rubbing up a mol of bismuth nitrate with 4 mols of potassium iodide and 50 c.c. of water, evaporating to dryness; and extracting the complex salt with ethyl acetate. A. E. Arppe prepared small black crystals of **potassium hepta-bismuthite hemi-hydriodide**, $4KI.BiI_3.\frac{1}{2}HI$, by concentrating a mixed soln. of potassium iodide and bismuth triiodide in hydriodic acid. When warmed, **potassium hepta-iodobismuthite**, $4KI.BiI_3$, is formed.

W. Linau prepared **calcium penta-iodobismuthite**, $CaI_2.BiI_3.9H_2O$, was prepared by evaporating a warm soln. of calcium iodide with bismuth triiodide. The red, rhombic prisms are probably isomorphous with the corresponding antimonite. The salt loses its water of crystallization at 150° . He also made **barium penta-iodobismuthite**, $BiI_2.BiI_3.9H_2O$, in a similar way, and found that it had similar properties. A. Welkoff made **beryllium iodobismuthite** by a process analogous to that used for the corresponding antimonite. W. Linau prepared **magnesium octo-iodobismuthite**, $MgI_2.2BiI_3.12H_2O$, by the method used for the barium salt; it forms garnet-red, rectangular prisms which lose their water of crystallization at 175° . Similarly with **zinc octo-iodobismuthite**, $ZnBi_2I_8.12H_2O$, which forms garnet-red, hygroscopic, rectangular prisms which lose their water at 100° . He also obtained crystals of **zinc bromo-iodobismuthite** from a soln. of bismuth triiodide, and zinc bromide. W. Linau could not make **cadmium iodobismuthite** analogous to the zinc salt. A. Welkoff made **aluminium iodobismuthite**, analogous to the corresponding antimonite. G. Canneri and G. Perina obtained **thallous penta-iodobismuthite**, Tl_2BiI_5 , in red, hexagonal plates, by adding potassium iodide to an acidic soln. containing thallium and bismuth. The salt resembles the corresponding bromide; and, in consequence of its low solubility in water, *viz.* 1 in 20,000, its formation can be used for the detection and estimation of bismuth. A. Mosnier showed that when a boiling sat. soln. of bismuth triiodide in fuming hydriodic acid is mixed with lead iodide and cooled, small red, needle-like crystals of **lead enne-iodobismuthite**, $Pb_3BiI_9.12H_2O$, are formed. They are decomposed

by water and alcohol. The heat of soln. in 40 parts of water at 15° is -17.2 Cals.; when heated to 45° the salt becomes anhydrous. The heat of soln. is then +16.6 Cals.; and the heat of formation ($\text{BiI}_3, 3\text{PbI}_2$) = 13.8 Cals. F. Ephraim and P. Mosimann prepared **cobaltibismuth hexamminoiodide**, $[\text{Co}(\text{NH}_3)_6\text{I}_3]\cdot\text{BiI}_3$, in dark red pointed crystals; **cobaltibismuth chloropentamminoiodide**, $[\text{Co}(\text{NH}_3)_5\text{Cl}]\text{I}_3\cdot 2\text{BiI}_3$, as a red microcrystalline powder; **cobaltibismuth dinitroxyl-tetramminoiodide**, $[\text{Co}(\text{NH}_3)_4(\text{NO}_3)_2]\text{I}_3\cdot\text{BiI}_3$, hexagonal rods—flavo salt—or as a microcrystalline powder of the croceo-salt; and **cobaltibismuth carbonatotetramminoiodide**, $[\text{Co}(\text{NH}_3)_4\text{CO}_3]\text{I}\cdot\text{BiI}_3$, in reddish-yellow grains by adding the bismuth iodide dissolved in an excess of potassium iodide to a soln. of the necessary amine. A. C. Vournasos studied the complex mixed amines.

§ 14. The Oxylalides of Bismuth

M. M. P. Muir ¹ and co-workers found that by repeated treatment of bismuth trihydrotrifluoride or of a soln. of bismuth hydroxide in hydrofluoric acid with boiling water, there is formed **bismuthyl fluoride**, or **bismuth oxyfluoride**, BiOF . It is also produced by adding freshly precipitated bismuth hydroxide to hot hydrofluoric acid, until the acid reaction disappears, washing the precipitate with hot water, drying at 100°, and feebly calcining the product. The heavy, white, non-hygroscopic powder has a sp. gr. 7.5 at 20°; it is stable at a dull red-heat but decomposed at a higher temp. When bismuth hydroxide is digested with hydrofluoric acid, part dissolves and part remains as insoluble **bismuthyl dihydrotrifluoride**, or **bismuth oxydihydrotrifluoride**, $\text{BiOF}\cdot 2\text{HF}$. This is washed with cold water and dried at 100°—if washed with hot water, bismuthyl fluoride is formed. The

oxydihydrotrifluoride is also obtained by the action of cold water on bismuth trihydrotrifluoride. When the white powder is strongly calcined, it forms bismuth trifluoride.

According to R. F. Weinland and O. Lauenstein, the product obtained by the action of conc. hydrofluoric acid on metabismuthic acid at -10° gives a reddish-brown soln. and powder, which decomposes at ordinary temp. with a brisk evolution of ozonized oxygen; the mixture acquires a pale yellow colour and furnishes no quinquivalent bismuth. It is supposed that an unstable quinquivalent compound of bismuth with oxygen in fluorine is formed analogous with, say, potassium fluoroarsenate, KAsOF_4 , or with arsenic oxyfluoride, AsOF_3 . O. Ruff also found that when bismuthic acid is added to conc. hydrofluoric acid, the colourless unstable soln. which is formed consists mainly of **bismuth oxytrifluoride**, BiOF_3 . When the soln. is evaporated in vacuo, the oxytrifluoride is partially decomposed; and on adding a molar proportion of potassium fluoride before evaporation, a compound or mixture with the composition $\text{Bi}_3\text{OF}_7 \cdot 3\text{KF}$ is obtained in small, yellow crystals; and with three molar proportions, **potassium oxyhexafluoride**, $\text{BiOF}_3 \cdot 3\text{KF}$, is formed in colourless, prismatic crystals, which become yellow, and decompose rapidly in moist air. A. C. Vournasos prepared **potassium tribromotriiodobismuthite**, $\text{K}_3[\text{BiBr}_3\text{I}_3]$, and **potassium tricyanidotriiodobismuthite**, $\text{K}_3[\text{BiI}_3\text{Cy}_3]$.

According to A. E. Arppe,² C. F. Bucholz, W. Heintz, R. Phillips, H. Rose, and E. Ruge, when bismuth trichloride is decomposed by cold or hot water—say by treatment of a hydrochloric acid soln. of the trichloride with water—or when a soln. of bismuth nitrate is treated with an alkali chloride, **bismuthyl chloride**, or **bismuth oxychloride**, BiOCl , is formed. H. Rose said that if sulphur or phosphoric acid be present the precipitate will be contaminated with bismuth sulphate or phosphate respectively. A. de Schulten obtained crystals of the oxychloride by dissolving 3 grms. of bismuth trioxide in 300 c.c. of hydrochloric acid of sp. gr. 1.05; adding 2.5 litres of boiling water; and the filtered soln., on cooling, deposits colourless, quadratic crystals. V. A. Jacquelin obtained it by heating the trichloride in steam, and removing the unchanged trichloride by heating it to a higher temp. According to V. A. Jacquelin, and V. Thomas, it is also produced in small quantities when the trichloride is sublimed in air; or, according to W. Heintz, in hydrogen containing some air. According to W. Herz and A. Bulla, the oxychloride is also obtained by treating a soln. of bismuth hydroxide with an alkali chloride, $\text{BiO} \cdot \text{OH} + \text{KCl} \rightleftharpoons \text{BiOCl} + \text{KOH}$, the equilibrium constant is 0.082. M. M. P. Muir made it by treating bismuth trioxide with dil. hydrochloric acid. E. Lebaigue obtained micaceous plates by heating bismuth sulphate with sodium chloride, and leaching out the soluble salts with water.

Analyses by A. E. Arppe, W. Heintz, V. A. Jacquelin, H. Rose, E. Ruge, and V. Thomas agree with the formula BiOCl . C. Haushofer described the oxychloride as a snow-white, amorphous powder; A. de Schulten, as forming colourless, transparent, quadratic crystals. E. Ruge said that when dried in air at 100° – 125° , it retains what is eq. to one-sixth of a mol of water which is lost only at 300° ; and W. Heintz, that it is anhydrous when dried at 100° ; A. E. Arppe, when dried at 125° ; and W. Herz, when dried in vacuo. A. de Schulten said the sp. gr. is 7.717 at 15° . and the mol. vol. 33.7; M. M. P. Muir gave 7.2 at 20° for the sp. gr. of the precipitated oxychloride. P. Grouvelle, and V. A. Jacquelin found that the oxychloride melts at a red-heat without decomposition; and E. Ruge added that there is but an insignificant volatilization of bismuth trichloride when the oxychloride is strongly heated, but A. E. Arppe observed that the proportion of chlorine is reduced when the oxychloride is strongly calcined. A. de Schulten, and V. Thomas confirmed this. J. Thomsen gave for the heat of formation $(\text{Bi}, \text{O}, \text{Cl}, \text{H}_2\text{O}) = 88.41$ Cals.; $(\text{BiCl}_3, \text{H}_2\text{O}, \text{Aq.}) = 7.83$ Cals.; and $\{\text{Bi}(\text{OH})_3, \text{HCl aq.}\} = 14.18$ Cals. A. K. Sanyal and N. R. Dhar found that bismuth oxychloride is decomposed by exposure to tropical sunlight for a few hours. R. Robl observed no fluorescence when the salt is exposed to ultra-violet light. A. A. Noyes and

co-workers found that the electrical conductivity of hydrochloric acid is diminished by the addition of bismuth chloride. The observed diminution can be most satisfactorily interpreted on the assumption that hypobromobismuthic acid is formed. Measurements of the solubility of bismuth oxychloride in hydrochloric acid soln. of varying conc. at 25° afford support for this hypothesis in the case of the more conc. soln., whilst for the less conc. acid soln. the solubility data suggest that the predominant complex acid has the formula HBiCl_4 .

H. Rose found that when the oxychloride is reduced in **hydrogen** a little bismuth trichloride is volatilized; and that it is sparingly soluble in **water**. E. Ruge said that when treated with boiling water, no more basic chloride is produced. V. A. Jacquelin found that at a dull red-heat, **chlorine** transforms the oxychloride into the trichloride, with the liberation of some oxygen. It dissolves in **hydrochloric acid**, and this subject was studied by A. A. Noyes and co-workers—*vide supra*, Fig. 19. M. M. P. Muir observed that **hydriodic acid** transforms its oxychloride into the trichloride and triiodide, while it is not changed by a soln. of **potassium iodide**. C. F. Bucholz said that when freshly precipitated it dissolved in a soln. of **potassium chloride**, but when dried, it is insoluble in that menstruum; L. Moser and E. Neusser said that the oxychloride is completely converted into sulphide when heated in **hydrogen sulphide**. V. A. Jacquelin found that when heated with **sulphuric acid** it is transformed into bismuth sulphate; and that on evaporation of the soln. in **nitric acid**, the oxychloride remains unchanged. H. Rose found that molten **potassium cyanide** reduces the oxychloride to metal. A. Stromeyer, and V. A. Jacquelin said that the trioxide is not attacked by a boiling dil. soln. of **potassium hydroxide**; R. Warrington found that a little decomposition occurs; and with the hot, conc. lye, the oxychloride is completely decomposed to grey bismuth trioxide which, according to R. Phillips, becomes yellow when fused. According to W. Herz and G. Muhs, at 30°, when equilibrium: $\text{BiOCl} + \text{KOH} \rightleftharpoons \text{BiO.OH} + \text{KCl}$, is attained, there must be some secondary reactions because the results do not agree with $[\text{KOH}] = K[\text{KCl}]$. The oxychloride becomes greyish-yellow when treated with alkali-lye, and it is inferred that there are several distinct hydroxides. As indicated above, W. Herz and A. Bulla obtained 0.082 for the constant. E. F. Smith and P. Heyl found that when calcined with **mercuric oxide**, the oxychloride is completely transformed into the oxide.

Several other oxychlorides have been reported. V. Merz and W. Weith obtained one by heating bismuth trichloride with ten times its weight of water in a sealed tube. A yellowish or greyish-white, amorphous, compact earth, or fibrous mineral found by I. Domeyko in Cerro de Tazna, Bolivia, was named **daubréite**—after A. Daubrée. Its composition corresponds with hydrated bismuth, $\text{Bi}_2\text{O}_6\text{Cl}_3 \cdot 3\text{H}_2\text{O}$. The sp. gr. is 6.4–6.5, and the hardness 2.0–2.5. P. P. Dehérain heated bismuth dichloride in air and obtained a crystalline mass approximating **bismuth trioxydichloride**, $\text{Bi}_2\text{O}_3\text{Cl}_2$. M. M. P. Muir reported **bismuth dioxytrichloride**, $\text{Bi}_3\text{O}_2\text{Cl}_3$, to be formed as an orange-yellow, crystalline powder, by slowly subliming bismuth trichloride in air, or in sulphur dioxide; by heating bismuth trioxide or pentoxide in chlorine; or by passing nitric acid vapours over molten bismuth trichloride. V. Thomas made this oxychloride by the action of nitrogen peroxide on bismuth trichloride. The dioxytrichloride may be impure BiOCl .

M. M. P. Muir obtained **bismuthyl bromide**, or **bismuth oxybromide**, BiOBr , by treating with water solid bismuth tribromide, or a soln. of that salt in hydrobromic acid; and probably by heating the trioxide with the tribromide. R. Dubrişay found that the variation of the proportions of bismuth and bromine in the liquid, when the tribromide is diluted with water, follows a regular curve showing that only one oxybromide is formed. The effect of temp. between 15° and 95° on the degree of hydrolysis is not appreciable. A. de Schulten obtained bismuthyl bromide by dissolving 3 grms. of bismuth trioxide in 50 c.c. of hydrobromic acid of sp. gr. 1.38, and adding 1500–1600 c.c. of hot water to the boiling liquid. When the clear filtrate cools, it deposits the oxybromide in crystals which are washed with water to remove the adherent acid. The salt occurs as a snow-white amorphous powder, or in colourless, transparent crystals. A. de Schulten gave 8.082 for the

sp. gr. of the crystals at 15°, and M. M. P. Muir, 6·7 for the amorphous powder at 20°. M. M. P. Muir said that the oxybromide can be heated to redness without decomposition; while A. de Schulten found that it melts at a bright red-heat, and some tribromide is volatilized. W. Herz said that when exposed to light it is darkened, and this more readily in a closed than in an open vessel. M. M. P. Muir said that the oxybromide is insoluble in water, and soluble in dil. hydrobromic acid; and when heated in a current of ammonia, a part is reduced to bismuth, and a little sublimes as the hemipentamminotribromide. W. Herz and G. Muhs observed the equilibrium conditions of the reaction with a soln. of potassium hydroxide: $\text{BiOBr} + \text{KOH} \rightleftharpoons \text{BiO.OH} + \text{KBr}$, and W. Herz and A. Bulla gave 0·57 for the equilibrium constant.

M. M. P. Muir reported *bismuth tridecaoxyheptabromide*, $\text{Bi}_{11}\text{O}_{13}\text{Br}_7$, to be formed by heating bismuth tri- or penta-oxide in a current of bromine. Some bismuth tribromide is formed at the same time. The white, amorphous powder is not changed in air; it becomes darker in colour when heated; and it is insoluble in hot or cold water, but soluble in nitric or hydrochloric acid. M. M. P. Muir obtained *bismuth pentadecaoxyhexabromide*, $\text{Bi}_3\text{O}_{15}\text{Br}_6$, by the action of nitric acid fumes on the molten tribromide; and by subliming the tribromide in the presence of air. V. Thomas said that bismuthyl bromide is the product of these reactions. M. M. P. Muir described the pentadecaoxyhexabromide as a greyish-yellow, crystalline powder which when heated in hydrogen is reduced to the metal; and with carbon forms bismuth tribromide. It is soluble in water; and in mineral acids; and it behaves towards ammonia like bismuthyl bromide.

H. G. Denham³ reported bismuth suboxyiodide, $\text{BiI}_2\cdot 3\text{BiO}$, to be formed as a by-product in the preparation of bismuth diiodide (*q.v.*). It appears as a non-volatile, brick-red substance which is stable in dry air. It commences to decompose at 350°. A sat. soln. gives a faint darkening with hydrogen sulphide; and a faint turbidity with silver nitrate. It is decomposed into the metal and a soluble trivalent bismuth salt by sulphuric, hydrochloric, and acetic acids. It is insoluble in alcohol, and in aq. soln. of potassium iodide; and it reduces acidic soln. of potassium permanganate.

J. B. Berthelot⁴ prepared *bismuthyl iodide*, or *bismuth oxyiodide*, BiOI , by boiling bismuth triiodide with water; M. M. P. Muir, by pouring a hydriodic acid soln. of the triiodide in hot water; and A. de Schulten, by dissolving 0·250 grm. of bismuth trioxide in 40 c.c. of hydriodic acid, of sp. gr. 1·2, and mixing the liquid with 6 litres of cold water. The liquid is warmed on the water-bath and crystals of the oxyiodide are formed. These are washed with water. The great excess of hydriodic acid is necessary to prevent the evaporation of bismuth triiodide. E. R. Schneider observed that the oxyiodide is formed when the triiodide is heated in air. This product is the *bismutum oxyiodatum* of pharmaceutical chemistry. Its preparation for this purpose was described by C. Astre, B. Fischer, F. W. Fletcher and H. P. Cooper, C. Greene, G. Greuel, J. Jaillet, O. Kaspar, and C. Mayr and co-workers. The pharmaceutical product can be obtained by treating a cold or hot, dil. nitric acid soln. with potassium iodide—with or without acetic acid—and also by the action of potassium iodide on bismuth oxynitrate. R. Dubrisay obtained indications of the formation of a brick-red oxyiodide, BiOI , and of a black *bismuthyl trihydropentaiodide*, $2\text{BiOI}\cdot 3\text{HI}\cdot \text{H}_2\text{O}$, or $\text{Bi}_2\text{O}_3\cdot 5\text{HI}$, in the hydrolysis of bismuth triiodide (*q.v.*).

W. Heintz, and A. E. Arppe described the oxyiodide as a brick-red powder, which, according to B. Fischer, consists of cubic crystals. A. de Schulten obtained copper-red, quadratic crystals, and E. R. Schneider, rhombic plates. A. de Schulten gave 7·922 for the sp. gr. at 15°, and 44·4 for the mol. vol. He also said that the salt melts at a red-heat with decomposition. The oxyiodide is stable in air, and in the absence of air, it can be sublimed without decomposition, but when strongly heated in air, E. R. Schneider observed that it is converted into the trioxide—but, added A. E. Arppe, all the iodine cannot be expelled by roasting. Boiling water was found by A. E. Arppe, and E. R. Schneider to have only a slight action on the salt; M. M. P. Muir, and B. Fischer found that dil. mineral acids convert it into the

triiodide; E. R. Schneider, and B. Fischer observed that conc. hydrochloric acid dissolves it, forming a yellow soln.; while conc. sulphuric or nitric acid decomposes it with the separation of iodine, and acetic acid is without action. J. B. Berthelot found that the oxyiodide is decomposed when boiled with water and zinc or iron; and that hot dil. soln. of alkali hydroxides or carbonates, or lime-water, or baryta-water have only a slight action; but conc. alkali-lye forms bismuth trioxide. According to W. Heintz, the decomposition is incomplete. C. F. Rammelsberg reported the oxyiodide $\text{Bi}_{11}\text{O}_{13}\text{I}_3$; and T. R. Blyth, $\text{Bi}_{14}\text{O}_{15}\text{I}_{12}$, and $\text{Bi}_7\text{O}_7\text{I}_3$ to be formed by the action of alkali-lye on the oxyiodide. M. M. P. Muir found that a soln. of potassium chloride has no action on the oxyiodide; while E. R. Schneider showed that a mixture of alkali-lye and ammonium sulphide transforms the oxyiodide into trisulphide. M. M. P. Muir and E. M. Eagles found hydrogen sulphide to be without action.

A. C. Vournasos⁵ prepared **ammonium chloriodobismuthite**, $\text{NH}_4[\text{BiCl}_3\text{I}]$, in transparent needles, by the action of bismuth halide on ammonium iodide in an organic solvent; **hydrazine chloroacetatobismuthite**, $\text{N}_2\text{H}_4[\text{BiI}_3\text{CH}_3\text{COOH}]$, was obtained in colourless prisms in an analogous way.

§ 15. The Bismuth Sulphides

The affinity of bismuth for sulphur was discussed by K. Jellinek and J. Zakowsky.¹ E. R. Schneider reported **bismuth disulphide**, Bi_2S_2 , or *bismuth*

subsulphide, to be formed by the action of hydrogen sulphide on bismuth dioxide. This was confirmed by W. Herz and A. Guttmann, but they both gave up the idea that bismuth disulphide is so formed. E. R. Schneider also made the disulphide by dissolving 8 parts of bismuth tartrate in the necessary amount of potash-lye, diluting the soln. with air-free water to 1500 c.c., adding an alkaline soln. of 2 parts of stannous chloride and passing hydrogen sulphide through the liquid. The bismuth disulphide is precipitated, the tin remains in soln. as a sulpho-salt. The product is washed with hot dil. potash-lye, finally with water, and then dried in a steam-oven. L. Vanino and F. Treubert said that the product is really a mixture of bismuth and bismuth trisulphide, though E. R. Schneider contested this. C. Hoffmann made the disulphide by heating bismuth trioxide with an aq. soln. of potassium cyanide and thiocyanate.

According to D. Lagerhjelm, and G. Werther, bismuth trisulphide and bismuth are mutually soluble in all proportions; and, on cooling the fused mass, the disulphide crystallizes out first, carrying with it all the nickel and copper contained as impurities in the bismuth. If a 10 : 3-mixture of bismuth and sulphur be fused in a crucible, and the operation on the product repeated three times with fresh sulphur, and the product quickly cooled, there is formed a radiating mass with a nest of crystals of the disulphide in the interior. This was confirmed by W. Heintz, and E. R. Schneider. Nevertheless, E. R. Schneider said that the crystals are to be regarded as bismuth trisulphide mixed mechanically with bismuth, because when treated with hydrochloric acid, bismuth remains undissolved—but this *probus* is not a good one. E. R. Schneider said that if all the bismuth is to be transformed into sulphide, the mixture must be re-fused a number of times at as low a temp. as possible. This agrees with G. Rose's observation that these crystals are the same as those of the trisulphide. H. Pélabon made some observations on the fusibility of mixtures of bismuth and sulphur; and the subject was investigated by A. H. W. Aten. The results show that

Sulphur	0	0.9	4.2	17.2	28.8	40.7	46.9	52.4 at. per cent.
F.p. { Start	277°	318°	452°	535°	602°	656°	702°	760°
End	277°	271°	272°	233°	267°	270°	—	—

There is nothing here to show the existence of bismuth disulphide, although H. Pélabon believed that such a compound is formed. A. H. W. Aten represented what he believed to be the general form of the equilibrium diagram by Fig. 29. Here, *A* and *B* represent respectively the b.p. and m.p. of bismuth; and *C* and *D*, those of sulphur. *AH*, *KC*, *AI*, and *LC* are boiling curves, the first two belonging to the liquid, and the last two, to the vapour; *HE* and *KF* are solubility curves of the trisulphide; *BE*, that for bismuth, and *DF*, that for sulphur. *IL* represents the vapour curve of the solid trioxide. The region *AJLC* represents homogeneous vapour; *AHEB* and *KCDF*, homogeneous liquids; *AHI*, and *KIC*, liquids in contact with vapour; *HMOE*, and *KFPN*, soln. in contact with the solid trisulphide; *BEQ*, soln. in contact with solid bismuth, and *DRF*, soln. in contact with solid sulphur; below *QEO*, the solid trisulphide is in contact with solid bismuth, and below *PFR*, in contact with solid sulphur.

According to E. R. Schneider, bismuth disulphide appears as a dark grey powder. W. Herz and A. Guttmann gave 7.6–7.8 for the sp. gr.; G. Werther, 7.29; and L. Playfair and J. P. Joule, 7.466. E. R. Schneider said that bismuth disulphide decomposes into bismuth and the trisulphide when heated to redness in an atm.

FIG. 29.—Equilibrium Conditions of the Binary System: Bi-S (Diagrammatic).

of carbon dioxide; and if heated very strongly most of the sulphur can be driven off. When fused in hydrogen, the disulphide is reduced to metal; H. Pélabon studied the reaction with hydrogen. The disulphide is fairly stable in air, but, according to W. Herz and A. Guttman, when heated in air it forms sulphur dioxide; and when heated in steam, H. V. Regnault observed that some bismuth is formed. E. R. Schneider said that acids decompose the disulphide with the separation of bismuth: $3\text{Bi}_2\text{S}_2 + 12\text{HCl} = 2\text{Bi} + 4\text{BiCl}_3 + 6\text{H}_2\text{S}$; and if the liquid is boiled in air, the excess of hydrochloric slowly dissolves the bismuth. H. Pélabon studied the fusibility of silver and antimonious sulphides with the alleged disulphide. He said that there is a maximum with the $\text{Ag}_2\text{S}-\text{BiS}$ curve at 750° corresponding with *silver sulphohypobismuthite*, $\text{Ag}_2\text{S}\cdot 4\text{BiS}$; and with the $\text{Sb}_2\text{S}_3-\text{BiS}$ curve there are singularities at 632° corresponding with *bismuthous orthosulphoantimonite*, $3\text{BiS}\cdot\text{Sb}_2\text{S}_3$, or $\text{Bi}_3(\text{SbS}_3)_2$; and at 591° corresponding with *bismuthous metasulpho-antimonite*, $\text{BiS}\cdot 4\text{Sb}_2\text{S}_3$, or $\text{BiSb}_8\text{S}_{13}$.

Attempts to make *bismuth pentasulphide*, Bi_2S_5 , have not been successful. M. M. P. Muir,² A. Hilger and P. A. von Scherpenberg tried passing hydrogen sulphide into water or a dil. soln. of potassium hydroxide or boiling benzene holding bismuth pentoxide in suspension; and by heating potassium polysulphide with the pentoxide—sulphobismuthites or oxysulphides are formed. The trisulphide is not changed by melting with sulphur, potassium carbonate, and carbon.

J. G. Wallerius³ described a *galena wismuthi* which he supposed contained bismuth, cobalt, and arsenic; and it was considered by J. B. L. Romé de l'Isle to be *mine de bismuth sulphureuse*. A. Cronstedt also made an analogous term. It was called *bismuth glance*, or rather *Wismuthglanz*, by A. G. Werner, and L. A. Emerling; *sulphurated bismuth* by R. Kirwan; *sulphuret of bismuth* by W. Phillips; *bismutolamprite* by E. F. Glocker; *bismuthin* by F. S. Beudant; and **bismuthinite** by J. D. Dana. The form *bismuthite* also occurs in literature—e.g. by P. Groth—but this term has also been applied to the carbonate. An early analysis by B. G. Sage,⁴ in 1782, was rather a bad one; later analyses reported by H. Rose, A. Bianchi, A. Carnot, A. Wehrle, A. von Hubert, V. R. von Zepharovich, R. Warrington, C. F. Rammelsberg, T. Scheerer, F. A. Genth, D. Forbes, I. Domeyko, W. H. Melville, and G. C. Hoffmann agree with the formula for **bismuth trisulphide**, Bi_2S_3 . Confirmatory analyses of the artificial product were made by F. Rössler,⁵ D. Lagerhjelm, J. Davy, and H. Rose. K. Jellinek and J. Zakowsky studied the affinity of bismuth for sulphur in forming the trisulphide.

Bismuth trisulphide is prepared by fusing a mixture of the elements as indicated in connection with the disulphide. As shown by E. R. Schneider, the fusion should be repeated many times to ensure the complete dissolution of the bismuth. It was made in this way by E. R. Schneider, F. Rössler, H. Pélabon, A. H. W. Aten, C. M. Marx, etc. W. Spring reported that he had made it by compressing an intimate mixture of powders of the constituent elements. It is not easy to make the trisulphide of a high degree of purity from its elements, but it is easily obtained by precipitation by the action of hydrogen sulphide, or of an alkali sulphide on a soln. of a bismuth salt. H. Rose observed that if soln. of bismuth nitrate are used, the precipitate will probably contain some free sulphur; with hydrochloric acid soln., no sulphochloride has been observed. S. Ramachandran showed that bismuth trisulphide is not precipitated from soln. when the conc. of the hydrochloric acid exceeds one part of the conc. acid to 3 parts of water; nor is the precipitation complete when the conc. of the acid exceeds 1:5. Conversely, the trisulphide is almost completely soluble in acid of conc. 1:3 at 30° . The first sign of the evolution of hydrogen sulphide with an acid diluted 1:1 is at about 30° ; 1:3, at 38° ; 1:4, at 50° ; 1:5, at 65° ; 1:7, at 75° ; 1:10, at 80° ; and with the 1:16 acid, at 85° . H. Müller and L. Kürthy found the retarding action of urine on the precipitation gradually diminishes with time owing to the formation of complexes. J. Durocher, H. de Sénarmont, and W. W. Mather obtained a crystalline trisulphide by the action of the vapour of bismuth trichloride on hydrogen sulphide.

M. M. P. Muir and E. M. Eagles strongly heated bismuth trichloride or tribromide, and A. Carnot, bismuthyl chloride, in hydrogen sulphide. Bismuth trisulphide was made by F. Faktor by the action of sodium thiosulphate on a neutral soln. of a bismuth salt—J. T. Norton worked with the mixture in sealed tubes at 140°–200°; by N. Tarugi, by the action of thioacetic acid on a nitric acid soln. of bismuth nitrate; by E. R. Schneider, by heating bismuth triiodide with mercuric sulphide in a current of dioxide; and by J. Milbauer, by melting bismuth trioxide with potassium thiocyanate—if the temp. be too high, potassium sulphobismuthite is formed.

O. Schumann said that if bismuth trioxide is heated in a current of hydrogen sulphide, **bismuth tritetrasulphide**, Bi_4S_3 , is formed—but this statement lacks confirmation. M. Mayençon observed needles of bismuth trisulphide along with lead sulphide as a sublimate or incrustation from gob-fires in the coal pits of St. Étienne. C. Winssinger obtained a **colloidal solution** of bismuth trisulphide by passing hydrogen sulphide into a very dil. soln. of bismuth nitrate acidified with acetic acid, and removing the extraneous acids and salts by dialysis. The reddish-brown liquid can be heated to the b.p. without decomposition. P. B. Gangully and N. R. Dhar found that the sol is coagulated by exposure to tropical sunlight. According to A. Kuhn and H. Pirsch, bismuth sulphide sols are stable only in the presence of protective colloids. With 1 per cent. of gum arabic a sol containing 10 mgrms. per c.c. may be obtained. By mixing bismuth sulphide, sulphiodide, or hydroxide with wool fat, subsequent intensive pulverization of the mixture at the temp. of liquid air, and dissolution of the product in sesamé oil, fairly stable sols result containing 12–16 mgrms. of bismuth per c.c. for 15–20 per cent. of protective colloid. By G. Bredig's method—**3. 23, 10**—stable sols of the metal may be prepared containing 8 mgrms. per c.c. with 5 per cent. of wool fat and 0.6 mgrm. per c.c. with 1 per cent. of caoutchouc-ether sol. By T. Svedberg's protected arc method—**3. 23, 10**—metal sols cannot be obtained in water even with a protective colloid, but in sesamé oil with at least 5 per cent. of wool fat stable sols containing 6 mgrms. per c.c. are formed.

The mineral bismuthinite usually occurs in grey or tin-white masses with a foliated or fibrous structure; it also occurs in acicular **crystals**. The artificial compound is greyish or brownish-black; and H. de Sénarmont obtained the trisulphide in crystals by heating it with soln. of potassium sulphide in a sealed tube at 200°. H. Rose, and W. Phillips showed that the natural and artificial crystals belong to the rhombic system; and P. Groth found the axial ratios to be $a : b : c = 0.96794 : 1 : 0.98498$; E. Quercigh gave $0.985 : 1 : 1.004$. The **cleavage** on the (010)-face is perfect, and that on the (100)- and (110)-faces, imperfect. Measurements were also made by A. Bianchi, and G. Lugaro. A. Russell studied the **twinning** of the crystals; and O. Mügge, the **gliding planes**. H. de Sénarmont, F. Rinne, and P. Groth regarded the crystals as isomorphous with those of antimony trisulphide. P. F. Kerr studied the **X-radiogram**. C. J. B. Karsten gave 7.0001 for the **specific gravity** of bismuth trisulphide which had been obtained by precipitation and fusion; F. W. Clarke gave 7.00–7.81; C. J. B. Karsten, 7.0001; A. Wehrle, 7.807; W. Herapath, 7.591 at 14.5°; and for the native sulphide, D. Forbes gave 7.16; A. Bianchi gave 6.55; A. Weisbach, 6.643; V. R. von Zepharovich, 5.73; W. H. Melville, 6.624; F. A. Genth, 6.306; and G. C. Hoffmann, 6.781. The **hardness** is 2. E. Madelung and R. Fuchs found the **compressibility** to be 0.42×10^{12} dynes per sq. cm. C. M. Marx said that the trisulphide melts at a higher temp. than bismuth, and the liquid expands in a marked degree on solidification. H. Pélabon gave 685° for the **melting point**; and L. H. Borgström, 718°. Y. Takahashi gave 680°, and found that at the m.p. about 1.5 per cent. is dissociated into bismuth and sulphur. J. Joly found that a sublimation occurs at 400°–600°; E. R. Schneider, that it very slowly sublimes undecomposed at a high temp. in a current of carbon dioxide; and L. Merz observed that sublimation begins at about 300° in the vacuum of the cathode light.

C. M. Marx said that after the trisulphide has been heated and re-heated a number of times, globules of bismuth separate from the molten mass; and E. R. Schneider observed that if heated to whiteness in a current of carbon dioxide for a long time, the sulphur is completely or almost completely volatilized; while A. Mourlot found that the trisulphide is completely desulphurized when heated a short time in the electric arc-furnaces. K. Jellinek and J. Zakowsky calculated the mol. **heat of formation** to be 39.8 Cals. W. W. Coblenz and H. Kohler found that bismuth trisulphide exhibits a **photoelectric effect** when exposed to radiations from 0.6μ in the visible spectrum to 3μ in the ultra-red. The sensitiveness is increased at low temp. At -166° there are maxima at 0.64μ and 1.08μ . B. Aulenkamp also studied this subject. E. T. Wherry found that the crystals are poor **radio-detectors**. A. de Gramont examined the **spark spectrum** of the mineral; and O. Stelling, the **X-ray absorption spectrum**—K-series. A. Karl said that the sulphide is triboluminescent. F. Beijerinck said that its **electrical conductivity** is good, and is about 4 times greater when vertical to the chief axis than when parallel thereto. T. W. Case found the electrical resistance to be greater than a megohm, and to be lessened by exposure to light. O. Weigel found the conductivity of the sat. aq. soln. to be 0.527×10^{-6} mho at 18° . A. Schrauf and E. S. Dana found that the **thermoelectric effect** in contact with copper is negative.

According to H. Rose,⁶ bismuth trisulphide is slowly reduced when heated in a current of **hydrogen**. H. Pélabon studied the balanced reaction: $\text{Bi}_2\text{S}_3 + 3\text{H}_2 \rightleftharpoons 3\text{H}_2\text{S} + 2\text{Bi}$. L. Moser and E. Neusser said that the decomposition of bismuth sulphide in a neutral atm. begins at 300° , forming bismuth and sulphur. K. Jellinek and J. Zakowsky found for the ratio $v_{\text{H}_2\text{S}}/v_{\text{H}_2}$, 2.59 at 515° ; 3.85 at 630° . They calculated for the vap. press. of the sulphur at 440° , $\log p = -6.27$; and at 515° , -5.10 . H. Rose found that the trisulphide is stable in **air**, and can be heated to 100° without changing in weight. C. R. Fresenius observed a slow oxidation. H. Rose said that it loses 0.13 per cent. in weight at 200° , and more as the temp. rises, reaching 0.54 per cent. at dull redness; it can then be kept at this temp. without any further loss. This result may be due to the presence of free sulphur or to moisture. The effect of still higher temp. is indicated above. A. Mailfert observed that **ozone** converts bismuth trisulphide into sulphate. O. Weigel said that the solubility of the trisulphide in **water** is 0.35×10^{-6} mol. per litre at 18° . H. V. Regnault said that at a red-heat, steam forms bismuth trioxide and hydrogen sulphide together with a little bismuth. The **halogens** form chloro-, bromo-, and iodo-sulphides (*q.v.*). Thus, M. M. P. Muir and E. M. Eagles represented the reaction with chlorine at dull redness: $\text{Bi}_2\text{S}_3 + 3\text{Cl}_2 = \text{Bi}_2\text{S}_3 + 3\text{BiCl}_3 + \text{S}_2\text{Cl}_2$; at a higher temp., bismuth trichloride is formed. Dil. **hydrochloric acid** has no action on the trisulphide, but the hot conc. acid forms the soluble trichloride and hydrogen sulphide—*vide supra*, the preparation of the trisulphide. F. von Kobell showed that when the trisulphide is fused with **potassium iodide**, it forms a bright red deposit of bismuth iodide. H. Picton and S. E. Linder observed that bismuth trisulphide forms no compound with **hydrogen sulphide**, and in this respect differs from the corresponding sulphide of arsenic, and antimony. H. Feigel found that bismuth trisulphide and a benzene soln. of **sulphur monochloride** form a thiophenol complex, and also some bismuth trichloride. A. Guerout found that the trisulphide is slightly soluble in **sulphurous acid**, but C. R. Fresenius observed that it is insoluble in an aq. soln. of **sodium sulphite**; and it is insoluble in a soln. of **sodium thiosulphate**. J. Milbauer and J. Tucek found that when **sulphur dioxide** is passed over heated bismuth trisulphide the sulphate and sulphur are formed. When the trisulphide is heated with conc. **sulphuric acid**, it furnishes sulphur dioxide; and it is attacked by dil. **nitric acid** with the separation of sulphur. N. R. Dhar found that the action of nitric acid on bismuth gives only nitrous acid and hyponitrous acid and not hydroxylamine, hydrazine, or ammonia, which are formed by the hydrogenation of nitric acid. Bismuth can take only oxygen away from nitric acid and cannot add hydrogen to it. The corrosion of this metal,

therefore, takes place by direct formation of an oxide. Nitrogen is formed by decomposition of hyponitrous acid and nitric oxide from the decomposition of nitrous acid. G. Gore found that the trisulphide is insoluble in liquid **ammonia**. P. de Clermont found that a boiling soln. of **ammonium chloride** is without action on the trisulphide. H. Rose observed that when heated in a current of **phosphine**, the trisulphide is reduced to bismuth with the formation of phosphorus and hydrogen sulphide. J. J. Berzelius noted that when heated with **carbon**, the trisulphide is reduced to metal; H. Rose that it is slowly reduced by molten **potassium cyanide**. According to N. D. Costeanu, bismuth trisulphide is not affected chemically when heated to 1000° in an atm. of **carbon dioxide** although the sulphide is dissociated. T. Rosenblatt said that the trisulphide is insoluble in a soln. of **potassium thiocarbonate**. C. Hoffmann found that an aq. soln. of potassium cyanide is without action; and F. W. Schmidt, that when evaporated to dryness with an ammoniacal soln. of **mercuric cyanide**; and the residue heated, a mixture of bismuth and its trioxide is formed. F. Paneth and W. Thimann examined the adsorption of aniline dyes by bismuth trisulphide.

L. Kahlenberg and W. J. Trautmann observed no reaction with **silicon** at relatively low temp., but at very high temp. there is a rapid reaction. N. Parravano and P. Agostini studied the action of aluminium. Dil. soln. of **alkali hydroxides** are without action. W. R. Schoeller found that **bismuth trioxide** and trisulphide react at a comparatively low temp. in a current of carbon dioxide. A little basic sulphate is produced. Dil. aq. soln. of **alkali sulphides** are without action; but T. Stillmann, and G. C. Stone found that the sulphide is slightly soluble in soln. of alkali sulphides. When the trisulphide is treated with a conc. soln. of the alkali sulphides, or fused with the solid, sulphobismuthites are formed; and J. Knox found that, at 25°, soln. with 0.5, 1.0, and 1.5 mols of sodium sulphide per litre dissolve respectively 0.0040, 0.0238, and 0.1023 grm. of bismuth trisulphide per 100 c.c.; soln. with 0.5, 1.0, and 1.25 mols of potassium sulphide per litre dissolve respectively 0.0042, 0.0337, and 0.0639 grm. of bismuth trisulphide per 100 c.c.; soln. with a mol of sodium hydroxide and 0.5 and 1.0 mol of sodium trisulphide per litre dissolve respectively 0.0185 and 0.0838 grm. of the trisulphide per litre; while soln. with 0.5 mol K_2S and 1.0 mol KOH , 1.0 mol K_2S and 1.0 mol KOH , and 1.25 mol K_2S and 1.25 mol KOH per litre dissolve respectively 0.0240, 0.1230, and 0.2354 grm. of bismuth trisulphide per litre. The trisulphide is insoluble in **2N-ammonium sulphide**. A. Hilger and P. A. von Scherpenberg found that the trisulphide is insoluble in a soln. of the **alkali polysulphides**. J. Knox said that 0.090 grm. of bismuth trisulphide dissolves in 100 c.c. of $N-Na_2S$. H. de Sénarmont observed that a little is dissolved by a soln. of **sodium hydrocarbonate** in a sealed tube at 200°. F. Raschig found that when bismuth trisulphide is boiled with an aq. soln. of **cupric chloride**, cupric sulphide, and bismuth trichloride or oxychloride are formed; with **cuprous chloride**, cuprous sulphide is formed. E. Schürmann found that with a soln. of **copper sulphate**, bismuth sulphate and cupric sulphide are formed, while **cadmium, lead, and antimony salts** are without action. J. B. Cammerer represented the reaction with **ferric chloride**: $Bi_2S_3 + 6FeCl_3 = 2BiCl_3 + 3S + 6FeCl_2$; and J. Hanus, with **ferric sulphate**: $Bi_2S_3 + 3Fe_2(SO_4)_3 = Bi_2(SO_4)_3 + 6FeSO_4 + 3S$, and by titrating the resulting ferrous sulphate, it is possible to determine the bismuth concerned in the reaction.

§ 16. Complex Bismuth Sulphides; Sulphobismuthites

Metal sulphides unite with bismuth sulphide, forming **sulphobismuthites**; those of copper, silver, and lead occur in minerals. As in the case of the sulpharsenates and sulphantimonites, the sulphobismuthites have been referred to complex sulphobismuthous acids. Thus, there are representatives of

Orthosulphobismuthous acid	H_2BiS_3
Metasulphobismuthous acid	$HBiS_2$
Orthosulphotetrabismuthous acid	$H_2Bi_4S_9$
Metasulphotetrabismuthous acid	$H_2Bi_4S_7$

The preparation of these salts is indicated below.

E. R. Schneider¹ prepared **potassium metasulphobismuthite**, $KBiS_2$, by fusing a mixture of one part of bismuth with six parts each of sulphur, and potassium carbonate, and washing the matters soluble in water from the cold product. A. Hilger and P. A. von Scherpenberg used a similar process, and they also melted together a mixture of bismuth trioxide and potassium polysulphide and washed away the soluble matters as before. J. Milbauer made the salt by fusing at a high temp. of mixture of potassium thiocyanate and bismuth trioxide; if the heating is not sufficient, bismuth trisulphide is formed. According to E. R. Schneider, the salt forms needle-like crystals which are stable in air; and they can be heated out of contact with air without decomposition, but if heated in air, potassium and bismuth sulphates are formed. When heated in hydrogen, a mixture of potassium sulphide and bismuth is formed, while hydrogen sulphide is given off. The salt is insoluble in water. The salt is soluble in hydrochloric acid with the evolution of hydrogen sulphide. E. R. Schneider made **sodium metasulphobismuthite**, $NaBiS_2$, by a method similar to that employed for the potassium salt. The sodium salt is more easily decomposed by hydrogen than the potassium salt.

A. Ditte found that amorphous, precipitated bismuth trisulphide dissolves readily in a cold soln. of potassium sulphide, in a proportion increasing with the quantity of alkali sulphide present, and forms a red soln. If an excess of bismuth trisulphide is added and the liquid is heated, a further quantity dissolves, and, when the soln. is sufficiently conc. and is allowed to cool, it deposits very brilliant, transparent, highly refractive, reddish-yellow rhombohedra, of **basic potassium sulphobismuthite**, $Bi_2S_3 \cdot 4K_2S + 4H_2O$. The crystals effloresce in dry air, and in moist air become covered with a black film of bismuth trisulphide. They are immediately decomposed by water with separation of bismuth trisulphide, and a similar decomposition takes place on adding a small quantity of water to their mother-liquor. If the amorphous trisulphide is placed in a soln. of potassium sulphide just sufficiently conc. to form a small quantity of the double salt, and if the liquid is heated in such a way that the temp. is not uniform, the double sulphide will form

in the cooler parts and be decomposed in the hotter parts, and the bismuth trisulphide will separate in a crystalline form, not readily attacked by the alkali sulphide. In this way, the whole of the bismuth trisulphide may become crystalline. According to A. Ditte, bismuth trisulphide is only slightly soluble in cold sat. soln. of sodium sulphide, and, although on heating the soln., and allowing it to concentrate at the same time, the solubility increases sufficiently to produce a small quantity of double salt, and thus convert the bismuth trisulphide into the crystalline form, the liquid does not deposit the double sulphide.

W. Guertler,² and W. Meissner made a study of the ternary system: Cu-Bi-S. C. J. Selb described a mineral from Wittichen, Baden, which he called *Kupferwismuthherz*; C. C. von Leonhard called it *Wismuthkupfererz*; F. von Kobell, *wittichite*; and G. A. Kenngott, **wittichenite**. Analyses reported by M. H. Klaproth, J. Stauffacher, C. Weltzien, E. Tobler, E. R. Schneider, A. Hilger, T. Petersen, and F. Sandberger indicate that the mineral is **cuprous orthosulphobismuthite**, Cu_3BiS_3 . This same salt was prepared by E. R. Schneider by boiling a soln. of cupric oxide in conc. hydrochloric acid with bismuth in an atm. of carbon dioxide until the green colour became yellow, and potash-lye gave a voluminous yellow precipitate; the yellow soln. was mixed with tartaric acid, and treated with hydrogen sulphide. The precipitate was filtered, washed, and dried, and melted at a red-heat. Wittichenite occurs in steel-grey or tin-white, coarse or granular masses; it may also be disseminated in small masses, or occur as an aggregate of imperfect prisms. According to A. Breithaupt, the rhombic crystals are isomorphous with those of bournonite—but P. Groth considers this doubtful. The sp. gr. ranges from 4.3 to 4.5—A. Hilger gave 4.3. E. R. Schneider gave 5.9 for the sp. gr. of the artificial salt which had been fused. J. J. Saslawsky estimated the contraction which occurs when the mineral is formed from its component sulphides. The hardness is 2-3. Wittichenite is decomposed by nitric acid with the separation of sulphur; and dissolves in hydrochloric acid with the evolution of hydrogen sulphide.

C. J. Selb³ described a copper bismuth sulphide ore from Tannenbaum, Saxony, and it was called *Kupferwismuthglanz* by E. R. Schneider; **empletite**—from *ἐμπλεκτος*, entwined or interwoven—in allusion to its intimate association with quartz—by G. A. Kenngott; *tannenite*, by J. D. Dana; and *hemichalcite*—from *ἡμί*, half; *χαλκός*, copper, in allusion to its containing half the proportion of copper in wittichenite—by F. von Kobell. Analyses reported by E. R. Schneider, T. Petersen, W. F. Hillebrand, F. R. Daw, J. A. Krenner, I. Domeyko, and C. Guillemain are in agreement with the formula $\text{Cu}_2\text{S.Bi}_2\text{S}_3$, or **copper metasulphobismuthite**, CuBiS_2 . E. H. Kraus and J. P. Goldsberry represent empletite as a member of a series represented by the general formula $M'_nR_2S_{\frac{1}{2}n+3}$, where *R* denotes trivalent bismuth, antimony, or arsenic. The salt was prepared by E. R. Schneider by melting together the correct proportions of chalcocite, Cu_2S , and artificial bismuth trisulphide; by triturating potassium metasulphobismuthite, in the absence of air, with an ammoniacal soln. of cuprous oxide in hydrochloric acid, and shaking the mixture in a closed vessel frequently for 8-10 days. The soln. is decolorized, and is then mixed with a freshly prepared soln. of hydrogen sulphide in dil. hydrochloric acid (1:10), and melted at a red-heat out of contact with air. Sodium metasulphobismuthite gives a very poor yield; the reaction is slower with more conc. acid, and with more dil. acid, basic chlorides are formed. F. Rössler obtained this salt as a regulus by fusing together the component elements. Before fusion, the salt appears as a black powder; and after fusion, as a greyish-white or tin-white mass with a radiating, crystalline structure. J. L. C. Schröder van der Kolk made some observations on the colour of the mineral. Empletite occurs in grey or tin-white thin striated prisms which belong to the rhombic system, and, according to A. Weisbach, have the axial ratios $a:b:c=0.5430:1:0.6256$. The cleavage on the (100)-face is perfect—that on the (010)-face is less clear, and that on the (506)-face is distinct. The crystals were also examined by H. Dauber, V. Goldschmidt, and P. Groth. L. J. Spencer discussed the isomorphism of

empletite with zinckenite, etc. E. R. Schneider gave 6·10 at 15° for the artificial product; and for the mineral, A. Weisbach gave 5·18. The sp. gr. of empletite ranges between 6·23 and 6·52; and J. J. Saslawsky estimated the contraction which occurs when the mineral is formed from its constituents. The hardness is 2. J. Joly gave 400°–600° as the temp. at which a sublimation occurs. T. W. Case found that the high resistance of empletite is not affected appreciably by light. E. R. Schneider said that his product loses three-fourths of its sulphur when heated in hydrogen, and a mixture of cuprous sulphides and bismuth remains. The mineral is decomposed by nitric acid with the separation of sulphur.

T. Petersen and F. Sandberger⁴ found a mineral which they named **klaprothite**—after M. H. Klapproth; but since lazulite was named klapprothite by F. S. Beudant in 1824, G. J. Brush suggested that the term be altered to *klapprotholite*. Klapprothite occurs with other bismuth minerals near Wittichen, Baden; and in a few other localities. Analyses by E. R. Schneider, and T. Petersen agree with the formula $3\text{Cu}_2\text{S}\cdot 2\text{Bi}_2\text{S}_3$, or **cuprous orthosulphotetrabismuthite**, $\text{Cu}_6\text{Bi}_4\text{S}_9$. E. H. Kraus and J. P. Goldsberry regarded this mineral as a member of a series including rathite, warrenite, and schirmerite, represented by the general formula $M'_nR_4S_{4n+6}$, where R denotes arsenic, antimony, or bismuth. The colour is steel-grey tarnishing to brass-yellow; the furrowed, prismatic crystals belong to the rhombic system with $a : b : c = 0\cdot 74 : 1 : -$. The cleavage on the (100)-face is distinct; and twinning occurs about the (110)-plane. The sp. gr. given by T. Petersen is 4·6, and the hardness 2·5. J. J. Saslawsky estimated the contraction which occurs when the mineral is formed from its constituents. It dissolves in nitric and hydrochloric acids. F. Sandberger discussed the products obtained by the weathering of klapprothite. A mineral from Dognacska, Hungary, was called by J. A. Krenner, **dognacskaite**. Analyses reported by J. A. Krenner,⁵ and F. Neugebauer agree with $\text{Cu}_2\text{S}\cdot 2\text{Bi}_2\text{S}_3$, or **cuprous metasulphotetrabismuthite**, $\text{Cu}_2\text{Bi}_4\text{S}_7$. A. Otto thought that it is the same as wittichenite, but F. Neugebauer regards it as a distinct mineral species. Its sp. gr. is 6·79.

O. Grosspietsch⁶ described an Alpine mineral from the magnesite of Eichberg, and he called it **eichbergite**. It is iron-grey with an irregular fracture. The analysis agrees with $(\text{Cu}, \text{Fe})_2\text{S}\cdot 3(\text{Bi}, \text{Sb})_2\text{S}_2$, or **cuprous metasulphotrisantimonitobismuthite**, $\text{Cu}, \text{Sb}_3\text{Bi}_3\text{S}_5$. Its sp. gr. is 5·36; and its hardness, 6. A mineral occurring in the quartz gangue of the Missouri mine, Colorado, was regarded by W. H. Hillebrand⁷ as a sulphobismuthite of copper and silver. J. D. Dana called it **cuprobismuthite**. Analyses by W. F. Hillebrand agree with the formula $3(\text{Cu}, \text{Ag}, \text{Pb})\text{S}\cdot 4\text{Bi}_2\text{S}_3$, and it is usually represented as $3\text{Cu}_2\text{S}\cdot 4\text{Bi}_2\text{S}_3$, or **cuprous mesosulphoctobismuthite**, $\text{Cu}_6\text{Bi}_8\text{S}_{15}$. It occurs in dark-bluish compact masses, or in groups of slender, prismatic crystals striated longitudinally. The sp. gr. is 6·31–6·38. It is soluble in acids.

C. F. Rammelsberg⁸ described a *Silberwismuthglanz* from the Matilde mine near Morococha, Peru. P. y Rico named it *peruvite*; A. d'Achiardi, **matildite**; M. F. Heddle, *morocochite*; and F. A. Genth, *argentobismuthinite*. Analyses reported by C. F. Rammelsberg, F. A. Genth, T. Wada, T. L. Walker, E. R. Schneider, and F. Rössler agree with the formula $\text{Ag}_2\text{S}\cdot \text{Bi}_2\text{S}_3$, or **silver metasulphobismuthite**, AgBiS_2 . In some cases, a little silver is replaced by lead. F. Sandberger described a non-black mineral from Schapbach, Baden, which he called plenargyrite. The analysis approximated to that of *matildite*. E. R. Schneider found that when finely powdered bismuth trisulphide is shaken with a feebly ammoniacal, one per cent. soln. of silver nitrate, practically no change occurs, a mere trace only of silver being thrown down as sulphide; but if the silver nitrate soln. be neutral, the silver will be precipitated as sulphide and the bismuth converted into basic nitrate. One gm. of finely powdered potassium metasulphobismuthite is put into a flask (60 c.c.) together with 25–30 c.c. of air-free water and a soln. of 0·550 gm. of silver nitrate to which ammonia has been added until the brown precipitate just redissolves; the flask is then filled up with air-free water and continually shaken. After 12–24 hrs., the supernatant liquid is found to be free from silver; it is then decanted,

and the residue shaken with air-free water for two days, then filtered, washed with water and absolute alcohol, pressed between filter-paper, and dried at 100°. Artificial silver-bismuth-glance was also prepared by fusing silver sulphide and bismuth trisulphide together in mol. proportion. F. Rössler prepared steel-grey octahedra by melting a mixture of 20 grms. of bismuth and 2 grms. of silver sulphide, and washing the cold product with cold nitric acid of sp. gr. 1.1. Matildite occurs in slender, prismatic, grey crystals, and also in compact masses. E. R. Schneider described silver metasulphobismuthite as a dark-grey powder; if crystals of bismuth sulphide are employed instead of powder in the above prescription, the resulting glance is crystalline and of the same form as the bismuth sulphide. It fuses without decomposition; the fused mass is light-grey and of metallic lustre; its fracture shows a homogeneous, leafy, crystalline structure; it is brittle, but not easily powdered. The powder is grey; its hardness is about 3.5; its sp. gr. at 15° is 6.96, that of the mineral being 6.92 (C. F. Rammelsberg). J. J. Saslawsky calculated the contraction which occurs when matildite is formed from its constituents. Cold nitric acid and hydrochloric acid do not attack it, but both acids decompose it when hot.

The mineral **aramayoite**—named after F. A. Aramayo—was discovered by M. Roberts in a silver-tin mine at Chocaya, Potosi, Bolivia, and described by L. J. Spencer. The analysis corresponds with **silver sulphoantimoniobismuthite**, $\text{Ag}(\text{Sb}, \text{Bi})\text{S}_2$; E. Kittl gave $\text{Ag}(\text{Sb}, \text{As}, \text{Bi})\text{S}_2$. The colour is iron-black with a brilliant metallic lustre on the perfect cleavage. It shows an irregular and confused aggregate of bright cleavage surfaces with striated areas at the edges, like "books" of mica. These cleavage flakes are pliable but not elastic. The crystals appear as if they were tetragonal with perfect basal (001)-cleavage, and good cleavages in the (001-100)-, (001-110)-zones. K. Yardley gave for the axial ratios of the triclinic crystals $a : b : c = 0.9972 : 1 : 0.9886$, and $\alpha = 86^\circ 55'$, $\beta = 90^\circ 53'$, and $\gamma = 93^\circ 18'$. The X-radiogram corresponds with a triclinic cell with the dimensions $a = 5.672$ A., $b = 5.688$ A., and $c = 5.623$ A. According to L. J. Spencer, when the mineral is powdered in a mortar it breaks up into short fibres which have a tendency to clog together. The sp. gr. is 5.602; the hardness, 2.5. The cleavage flakes are quite opaque. G. A. König⁹ described what he called *aurobismuthinite* as a mineral with the composition $(\text{Ag}_2\text{Au}, \text{Bi})_5\text{S}_6$.

The **lead sulphobismuthite**, $\text{PbS} \cdot \text{Bi}_2\text{S}_3$, or $\text{Pb}(\text{BiS}_2)_2$, found on Vulcano, Lipari Islands, in the deeper parts of the fumaroles, at a temp. of 560°–615°, occurs in lead-grey, flattened crystals which F. Zambonini and co-workers¹⁰ say are probably rhombic. They called the mineral **cannizzarite**—after S. Cannizzaro. This may be the same mineral as chiviatite—*vide infra*. A mineral from the Baltic Lode in Colorado was described by G. A. König, and called **beegerite**—after H. Beeger. Analyses reported by G. A. König, and F. A. Genth correspond with $6\text{PbS} \cdot \text{Bi}_2\text{S}_3$, or $6(\text{Pb}, \text{Ag}_2)\text{S} \cdot \text{Bi}_2\text{S}_3$, or **lead trisulphorthosulphobismuthite**, $3\text{PbS} \cdot \text{Pb}_3(\text{BiS}_3)_2$. R. F. Weinland regarded it as containing mixed tetra- and penta-sulphobismuthous acid anions, $[(\text{BiS}_3)(\text{BiS}_4)]\text{Pb}_6$. E. H. Kraus and J. P. Goldsberry regarded it as a member of the series:

Bismuthinite, Bi_2S_3	Galenabismuthinite, $\text{Pb}(\text{BiS}_2)_2$	Cosalite, $\text{Pb}_2\text{Bi}_2\text{S}_5$	Lillante, $\text{Pb}_3(\text{BiS}_3)_2$	Beegerite, $\text{Pb}_6\text{Bi}_2\text{S}_9$	Galena, PbS
6.5	6.88–7.14	6.39–6.75	6.7	7.273	7.45

E. T. Wherry and W. F. Foshag questioned whether beegerite is homogeneous and a mineralogical individual. The colour of the mineral is light or dark grey; it occurs indistinctly crystalline—probably cubic. The cleavage is cubic. The sp. gr. given by G. A. König is 7.273, and when silver is present the sp. gr. may fall to 6.565. J. J. Saslawsky calculated the contraction which occurs when the mineral is formed from its constituents. A. de Gramont examined the spark spectrum. E. T. Wherry found the crystals to be fair radio-detectors. Beegerite is soluble in conc. hydrochloric acid. According to F. Ducatte,¹¹ the methods of

synthesis employed by H. Sommerlad for the sulpharsenites and sulphantimonites are inapplicable because the chlorine cannot be removed from the products.

H. F. and H. A. Keller¹² obtained crystals of a mineral from the mines of the Lilian Mining Co., Leadville, Colorado, and they called it **lilianite**. It has also been found at Hoena, Sweden. Analyses reported by H. F. and H. A. Keller, C. F. Rammelsberg, G. Lindström, T. L. Walker and E. Thomson, and G. Flink agree with the formula $3(\text{Pb}, \text{Ag}_2)\text{S} \cdot \text{Bi}_2\text{S}_3$, or $3\text{PbS}(\text{Bi}, \text{So})_2\text{S}_3$, or **lead orthosulphobismuthite**, $\text{Pb}_3(\text{BiS}_3)_2$. The steel-grey mineral occurs massive and crystalline. The mineral is probably rhombic with the axial ratios $a : b : c = 0.8002 : 1 : 0.5435$. The cleavage on the (100)-face is very distinct, that on the (010)-face less so. T. L. Walker and E. Thomson consider it to be a definite species. C. F. Rammelsberg gave 6.145 for the sp. gr.; T. L. Walker and E. Thomson, 7.090; and G. Flink, 7.40. The hardness is 2-3. J. Setterberg described a mineral from Hoena, Sweden, which he called **kobellite**—after F. von Kobell. Analyses were reported by J. Setterberg, C. F. Rammelsberg, H. F. Keller, and G. Flink. The analyses of J. Setterberg, and H. F. Keller agree with $2\text{PbS}(\text{Bi}, \text{Sb})_2\text{S}_3$, and the others with $3\text{PbS}(\text{Bi}, \text{Sb})_2\text{S}_3$. G. Rose gave $3(4\text{PbS} \cdot \text{FeS}) \cdot (4\text{Bi}_2\text{S}_3 \cdot \text{Sb}_2\text{S}_3)$. P. Groth and K. Mieleitner gave $\text{Pb}_3\{(\text{Sb}, \text{Bi})\text{S}_3\}_2$. There is therefore some confusion of this mineral with lilianite. The lead-grey or steel-grey mineral occurs massive—granular, and radiated and fibrous like stibnite. The hardness is 2.5-3.0; and the sp. gr. 6.29-6.32. J. J. Saslawsky estimated the contraction which occurs when the mineral is formed from its component sulphides. J. Joly found bismuth oxide sublimes when the mineral is heated to a high temp in air. T. W. Case said that the resistance is greater than a megohm, and is not affected appreciably by light. E. T. Wherry found the crystals to be poor radio-detectors.

F. Mohs¹³ described what he called *Nadelierz*—**needle ore**—from Berezoff, Urals. E. J. Chapman called it **aikinite**; W. Haidinger, *patrinite*—after E. L. M. Patrin; J. Nicol, *aciculite*; and E. F. Glocker, *belonite*—from *βελόνη*, a needle. Analyses reported by C. Guillemain, G. Lindström, J. F. John, H. Frick, E. J. Chapman, and R. Hermann agree with C. F. Rammelsberg's formula CuPbBiS_3 , or **cuprous lead orthosulphobismuthite**. Analogous formulæ were given by E. T. Wherry and W. F. Foshag, W. F. Foshag, C. Guillemain, and P. Groth and K. Mieleitner. E. H. Kraus and J. P. Goldsberry represented aikinite as a member of a series with the general formula $M'_n\text{RS}_{\frac{1}{2}n+3}$, where R denotes As, Sb, or Bi—e.g. bournonite, and seligmannite. M. Hörner observed the isomorphism of the crystals with those of bournonite. The dark, lead-grey mineral may occur massive, and also in embedded acicular crystals, longitudinally striated. According to H. A. Miers, the rhombic crystals have the axial ratios $a : b : c = 0.9719 : 1 : -$. The sp. gr. is 6.1-6.8, and the hardness 2. J. Joly gave 420°-670° for the temp. at which sublimation occurs. A. de Gramont examined the spark spectrum. E. T. Wherry found the crystals are good radio-detectors. The mineral is decomposed by nitric acid with the separation of lead sulphate. The weathering of the mineral was noted by F. A. Genth, J. R. Blum, G. Sillem, G. Rose, C. C. Leonhard, and E. L. M. Patrin.

H. Sjögren¹⁴ described a mineral from Nordmark, Sweden, which he called **galenobismuthite**. The analysis corresponded with $\text{PbS} \cdot \text{Bi}_2\text{S}_3$, or **lead meta-sulphobismuthite**, $\text{Pb}(\text{BiS}_2)_2$. The colour varies from dark lead-grey to tin-white. The mineral occurs in compact masses, in foliated or radiated masses, or in columnar crystals with indistinct faces. E. V. Shannon described prismatic crystals of the mineral. The sp. gr. is 6.88, and the hardness 3-4. J. Joly gave 470°-560° for the temp. at which sublimation occurs. T. W. Case found that the mineral has a resistance less than a megohm, and is not affected by light. E. T. Wherry found galenobismuthite a poor radio-detector. G. A. König described an argentiferous variety from the Alaska mine, Colorado, and he called it **alaskaite**. It contained 3.26-8.74 per cent. of silver, and 3.46-5.11 per cent. of copper, making the mineral $(\text{Pb}, \text{Ag}_2, \text{Cu}_2)(\text{Bi}_2\text{S}_2)_2$. This agrees with the views of E. T. Wherry

and W. F. Foshag, and E. H. Kraus and J. P. Goldsberry. P. Groth and K. Mieleitner gave $\text{Pb}(\text{Ag,Cu})(\text{BiS}_2)_3$. It was also described by F. Ahlfeld. T. Liweh's analysis makes alaskaite resemble fahlerz; H. W. Brown regarded it as a galena-bismuthinite. A. de Gramont studied the spark spectrum. The sp. gr. was 6.782–6.788. M. Weibull also described a seleniferous variety from Falun, Sweden, which contained 12.43–13.61 per cent. of selenium, replacing the sulphur. Its sp. gr. was 6.97–7.145. E. T. Wherry found the crystals are poor radio-detectors. T. L. Walker and E. Thomson have reported analyses of Fahln galenobismuthite which make it like cosalite. W. F. Foshag gave $\text{Ag}_2\text{PbBi}_4\text{S}_8$.

The mineral **cosalite** from a silver mine at Cosala, Mexico, was described by F. A. Genth.¹⁵ H. Sjögren, and A. E. Nordenskjöld obtained a similar mineral from the Bjelke mine, Nordmark, Sweden, and called it *bjelkite*; and an impure form of the mineral from Rezbanya, Hungary, was called by R. Hermann. *rezbanyite*. Analyses were reported by F. A. Genth, R. Hermann, J. Loczka, A. Frenzel, H. Sjögren, E. le Neve Foster, W. F. Hillebrand, G. A. König, A. H. Low, H. Bancroft, T. L. Walker and E. Thomson, and G. Lindström. The results agree with the formula $2(\text{Pb,Ag}_3)\text{S.BiS}_3$, or with **lead pyrosulphobismuthite**, $\text{Pb}_2\text{Bi}_2\text{S}_5$. The lead-grey mineral usually occurs massive with an indistinct crystalline structure—fibrous or radiated. The rhombic crystals were found by G. Flink to have the axial ratios $a : b : c = 0.91874 : 1 : 1.4601$; and he said that the mineral is isomorphous with dufrenoyite and jamesonite. A. Frenzel gave 6.22–6.33 for the sp. gr. of rezbanyite; H. Sjögren, 6.39–6.75 for bjelkite; and for cosalite, G. A. König gave 6.782; and T. L. Walker, 6.55. J. J. Saslawsky calculated the contraction which occurs during the formation of cosalite from its constituent sulphides. The hardness is 2.5–3.0. J. Joly gave 720° for the temp. at which a sublimation occurs. T. W. Case found the resistance is less than a megohm, and is not affected appreciably by light. A. de Gramont examined the spark spectrum. Cosalite is slowly attacked by hydrochloric acid, and is decomposed by nitric acid with the formation of lead sulphate.

The *wismuthisches Silber* from Schapbach, Baden, was described by C. J. Selb,¹⁶ and L. A. Emmerling, and called by C. C. von Leonhard, *Wismuthbleierz*, and by G. A. Kennigott, and F. Sandberger, **schapbachite**. Its analyses reported by M. H. Klaproth, and F. Sandberger agree with the formula $\text{PbS.Ag}_2\text{S.Bi}_2\text{S}_3$, or **lead silver pyrosulphobismuthite**, $\text{PbAg}_2\text{Bi}_2\text{S}_5$; this was confirmed by W. F. Foshag. It occurs in lead-grey masses and in minute, acicular crystals, probably rhombic. E. le Neve Foster described what he called lead silver *sulphobismuthite*, as a mineral occurring at Chihuahua, Mexico, with the composition $2(\text{Ag,Pb,Cu})\text{S.Bi}_2\text{S}_3$, or $\text{Ag}_4\text{PbBi}_5\text{S}_{13}$. It sp. gr. was 5.8, and its hardness 3–3.5.

The mineral **rezbanyite**, from Rezbanya, Hungary, has been regarded as an impure cosalite—*vide supra*. A. Frenzel's¹⁷ analysis agrees with the formula $4\text{PbS.5Bi}_2\text{S}_3$, or $\text{Pb}_4\text{Bi}_{10}\text{S}_{19}$, while E. T. Wherry and W. F. Foshag represent it by the formula $2\text{PbS.3Bi}_2\text{S}_3$; and K. Johansson, by $3\text{PbS.Cu}_2\text{S.5Bi}_2\text{S}_3$. The sp. gr. is 6.09–6.38; and the hardness, 2.5–3.0. K. Johansson described **lindströmite**—named after G. Lindström—from the Gladhammar mine; its composition corresponds with **cuprous lead metasulphohexabismuthite**, $2\text{PbS.Cu}_2\text{S.3Bi}_2\text{S}_3$. The crystals of the light blue mineral have a sp. gr. 7.01; and hardness 3.0–3.5; and **gladite** from the same locality, and having a composition corresponding with **cuprous lead tetrerosulphodecabismuthite**, $2\text{PbS.Cu}_2\text{S.5Bi}_2\text{S}_3$. The sp. gr. is 6.96, and the hardness 2–3.

F. Zambonini and co-workers¹⁸ observed a crystalline mineral in the fumaroles of Vulcano, Lipari Islands, where the temp. is 550° – 615° , and where the emission of acidic volcanic gases is greatest, and access of air is prevented. He called the mineral **cannizzarite**—after S. Cannizzaro. Its analysis corresponds with **lead deuteriosulphotetrabismuthite**, $\text{PbS.2Bi}_2\text{S}_3$. The sp. gr. is 6.54 at 10° . The mineral is rhombic, and isogonal with bismuthinite and antimonite in the (001)-

zone. It is supposed to have been formed by the action of hydrogen on the chlorides of bismuth and lead. C. F. Rammelsberg described a mineral from Chiviato, Peru, which he called **chiviatite**. It occurs in foliated masses resembling bismuthinite. The analyses reported by C. F. Rammelsberg, and A. Raimondi agree with the formula $2\text{PbS}\cdot 3\text{Bi}_2\text{S}_3$, or *lead mesosulphohexabismuthite*, $\text{Pb}_2\text{Bi}_6\text{S}_{11}$. This formula was also given by G. Cesaro. On the other hand, E. T. Wherry and W. F. Foshag gave $\text{PbS}\cdot 2\text{Bi}_2\text{S}_3$, or *lead metasulphotetrabismuthite*, PbBi_4S_7 . The sp. gr. given by C. F. Rammelsberg is 6.920, and J. J. Saslawsky calculated the contraction which occurs when it is formed from its component sulphides. E. T. Wherry found the crystals are fair radio-detectors. The composition of **benjaminite** described by E. V. Shannon, and obtained from the Round Mountain, Nevada, corresponds with *silver copper lead orthosulphotetrabismuthite*, $\text{Pb}_2(\text{Cu}, \text{Ag})_2\text{Bi}_4\text{S}_9$. The grey mineral has a hardness 3.5, and it is soluble in hot nitric or hydrochloric acid. F. A. Genth¹⁹ described a mineral from the Treasury lode, Colorado, and he named it **schirmerite**—after J. F. L. Schirmer. The analysis agrees with the formula $3(\text{Ag}_2, \text{Pb})\text{S}\cdot 2\text{Bi}_2\text{S}_3$, or *silver lead orthosulphobismuthite*, $(\text{Ag}_2, \text{Bi})_3\text{Bi}_4\text{S}_9$; W. F. Foshag gave $2\text{Ag}_2\text{S}\cdot \text{PbS}\cdot 2\text{Bi}_2\text{S}_3$. It occurs in finely granular masses; the colour is lead-grey; and the sp. gr. 6.737. The schirmerite described by F. M. Endlich is a mixture of petzite and pyrite—*vide infra*, hammarite. A. de Gramont examined the spark spectrum. T. W. Case said that the mineral is a poor conductor, and light has no appreciable effect.

E. S. Simpson²⁰ described a mineral, found near Lake Goongardie, Western Australia, which he called **goongardite**. The analysis corresponds with $4\text{PbS}\cdot \text{Bi}_2\text{S}_3$, and it is a **lead disulphopyrosulphobismuthite**, $\text{Pb}_4\text{Bi}_2\text{S}_7$,

and this belongs to the jordanite group. The crystals are probably isomorphous with jordanite, and meneghinite. The sp. gr. is 7.29; the hardness, 3; and its m.p., 950°. Dil. nitric acid has very little action, but it is decomposed by the conc. acid forming lead sulphate. J. Krenner and J. Loczka reported *warthaite* as a steel-grey mineral occurring as radially fibrous bundles in the Hungarian limestones. The analysis corresponds with $4(\text{Pb}, \text{Cu}, \text{Ag})\text{S}\cdot \text{Bi}_2\text{S}_3$, that is, with $(\text{Pb}, \text{Cu}, \text{Ag})_4\text{Bi}_2\text{S}_7$, so that it appears to be a variety of goongardite.

E. V. Shannon²¹ described a lead-grey fibrous mineral occurring at Wickes, Montana. It is completely soluble in hot, conc. hydrochloric acid. The analysis agrees with $5\text{PbS}\cdot 4\text{Bi}_2\text{S}_3$, and it therefore forms a family group with liveingite, $5\text{PbS}\cdot 4\text{As}_2\text{S}_3$, and pligionite, $5\text{PbS}\cdot 4\text{Sb}_2\text{S}_3$ —hence the name **bismutoplagonite**, or **lead heptadecasulphoctobismuthite**, $\text{Pb}_5\text{Bi}_8\text{S}_{17}$. K. Johansson reported a leaden grey **lead selenosulphohexabismuthite**, $5\text{PbS}\cdot 3\text{Bi}_2(\text{S}, \text{Se})_3$, occurring in the Falun Mine, Sweden. He called it **wittite**—after T. Witt. The mineral has either rhombic or monoclinic symmetry as shown by the X-radiograms. The sp. gr. is 7.12; the hardness 2.0–2.5; and the cleavage is good. E. T. Wherry found the crystals are poor radio-detectors. K. Johansson found a steel-grey, reddish mineral in the Gladhammar mine of Kalmar, Sweden, and he called it **hammarite**. It occurs in short needles or prisms—possibly monoclinic. Its composition was represented by $5\text{PbS}\cdot 3\text{Bi}_2\text{S}_3$, or **lead sulphohexabismuthite**; but since the mineral has 7.6 per cent. of copper, W. F. Foshag regarded it as $2\text{PbS}\cdot \text{Cu}_2\text{S}\cdot 2\text{Bi}_2\text{S}_3$, the copper analogue of schirmerite. The sp. gr. is high, the hardness 3–4. K. Johansson obtained from the same locality lead-grey prismatic crystals of a mineral which he called **lindströmite**—after G. Lindström—and represented as **cuprous lead deuteriosulphohexabismuthite**, $\text{Cu}_2\text{S}\cdot \text{PbS}\cdot 3\text{Bi}_2\text{S}_3$. Its sp. gr. is 7.01, and hardness 3–3.5. Yet a third mineral called gladite appeared in lead-grey prismatic crystals with the sp. gr. 6.96, and hardness 2–3. Its composition approximated **cuprous lead triterosulphodecabismuthite**, $2\text{PbS}\cdot \text{Cu}_2\text{S}\cdot 5\text{Bi}_2\text{S}_3$.

G. A. König²² described a mineral from Nacozari, Somora, Mexico, and he called it **stibiobismuthinite**. It occurs in long prismatic crystals with the cleavage and structure of bismuthinite. The analysis approximates $(\text{Sb}, \text{Bi})_4\text{S}_7$. E. Quercigh suggested that it belongs to the type of mixed sulphides $(\text{Bi}, \text{Sb})_2\text{S}_3$, prepared by C. Geitner.

G. Tschermak²³ described a mineral occurring at Orawitza, Hungary, and named it **allocalsite**, or rather *Allocalas*—from $\alpha\lambda\lambda\omicron\varsigma$, another; $\kappa\lambda\acute{\alpha}\epsilon\iota\nu$, to break, in allusion to its cleavage, which at that time was believed to differ from those of arsenopyrite and marcasite—*vide* maltite. Analyses reported by G. Tschermak, A. von Hubert and A. Patera, and A. Frenzel were represented by C. F. Rammelsberg by the formula $\text{Co}_6\text{As}_{10}\text{S}_9$; by P. Groth, by $\text{Co}(\text{As}, \text{V}, \text{S})$, or **cobalt ferrous sulphoarsenitobismuthite**, $(\text{Co}, \text{Fe})(\text{As}, \text{Bi})\text{S}$. A. Lacroix supposed the bismuthiferous arsenical pyrites of Meymac to be a variety of allocalsite. The mineral occurs in steel-grey aggregates or rarely in rhombic crystals with the axial ratios $a : b : c = 0.15 : 1 : 1.36$. The cleavage on the (110)-face is perfect, and that on the (001)-face is distinct. W. F. de Jong found the X-radiogram closely resembled that of glaucodolite. The sp. gr. is 6.6, and the hardness 4.5. J. Joly gave 440° as the temp. at which a sublimation occurs. It is soluble in nitric acid.

The *Nickelwismuthglanz* obtained by F. von Kobell²⁴ from Grüneau, was named *saynite*; A. Breithaupt called it *theophrastite*; and J. Nicol, **grünanite**. Analyses reported by F. von Kobell, and C. F. Rammelsberg correspond with $\text{Bi}_2\text{S}_3.12(\text{Ni}, \text{Co}, \text{Fe})_2\text{S}_3$, or $\text{Bi}_2\text{S}_3.10\text{R}_2\text{S}_3$; M. L. Frankenheim gave $\text{NiS}(\text{Ni}, \text{Bi})_2\text{S}_3$. H. Laspeyres considers it to be polydymite contaminated with bismuthinite. The steel-grey mineral furnishes cubic crystals with an octahedral cleavage. The sp. gr. is 5.13; and the hardness, 4.5. H. Laspeyres²⁵ described a mineral from Schönstein, Rhine provinces, and he called it **kallilite**—from a local name. The analysis corresponds with $\text{NiBi}_2.\text{NiS}_2$, or **nickel sulphobismuthite**, NiBiS . It is considered to be a variety of ullmanite. M. L. Huggins examined the electronic structure of kallilite. The sp. gr. is 7.011. R. Scheibe also described a nickel bismuth sulphide from Niederhöfels. G. Werther obtained a complex nickel sulphobismuthite, $\text{Ni}_5\text{Bi}_{24}\text{S}_{22}$, by melting nickel with 64 parts of bismuth, 8 parts of sodium carbonate, and one part of sulphur. The reddish crystals had a sp. gr. 9.15.

§ 17. Bismuth Sulphates, and Oxysulphides

According to A. Hilger and P. A. von Scherpenberg,¹ bismuth trioxysulphide, Bi₂O₃S, is formed with incandescence when bismuth pentoxide is treated with

dry hydrogen sulphide, or by passing the gas into boiling benzene in which the finely-divided oxide is suspended. If the benzene is cold, the product does not contain so much sulphur. The greyish-black powder is stable in air, and it can be heated to 120° without change, but at a higher temp., sulphur dioxide and bismuth trioxide are formed; it dissolves in hydrochloric acid, and is decomposed by water with the separation of sulphur.

R. Hermann² described a mineral from Altai, Russia, which he called **karelinite**—after M. Karelin. Its composition approximates Bi_4SO_3 . It occurs in lead-grey masses, with a crystalline structure. The mineral is not homogeneous, and when treated with hydrochloric acid to remove the carbonates, etc., a metallic powder remains which is supposed to be the mineral karelinite. R. Hermann, and C. F. Rammelsberg consider that it is free from bismuth metal, but P. Groth doubted this. The sp. gr. is 6.60; and the hardness 2. When heated in air, it gives off sulphur dioxide, and forms a grey slag. It is reduced to bismuth when heated in hydrogen. R. Hermann obtained a complex oxy-sulphide, $\text{Bi}_2(\text{S}_2\text{O}_3)_3$, or $\text{Bi}_{10}\text{S}_9\text{O}_8$, by heating a mixture of bismuth trioxide and sulphur so as to volatilize the excess of sulphur. The grey mass has a sp. gr. 6.31. It contains some bismuth. I. Domeyko described a *bismuth oxydisulphide*, approximating $\text{Bi}_4\text{S}_3\text{O}_3$, as a mineral from Chlorofque, Bolivia. It was called *bolivite*, and was said to be derived from the oxidation of bismuthinite. It is considered by P. Groth to be a mixture of bismuthinite and bismuth ochre.

The early workers prepared more or less impure bismuth sulphates, but the results are complicated by the tendency of the salt to hydrolyze in dil. soln., and to form acidic salts in conc. soln. D. Lagerhjelm³ obtained normal **bismuth sulphate**, $\text{Bi}_2(\text{SO}_4)_3$, by evaporating bismuth trioxide with an excess of conc. sulphuric acid, and gently heating the residue until its weight was constant. G. H. Bailey, A. Classen, C. Hensgen, and J. G. C. de Marignac used this process; A. Gutbier and R. L. Janssen evaporated the nitrate with conc. sulphuric acid, and heated the product to constant weight at 380°; and they also analyzed the salt and found it corresponded with the formula just indicated. The needle-like crystals obtained by C. Schultz-Sellack by evaporating a soln. of bismuth trioxide in conc. sulphuric acid was shown by A. Leist to have the composition $\text{Bi}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$. Instead of starting from the trioxide, the trisulphide can be used. The crystals of the salt were said by G. Bodman to be isomorphous with the sulphates of lanthanum, didymium, and yttrium. L. de Boisbaudran noted that as in the case of the trioxide (*q.v.*), it stimulates the phosphorescence of alkaline earth sulphides. C. Hensgen said that the salt is very hygroscopic, and at ordinary temp. forms with water the *hemiheptahydrate*, $\text{Bi}_2(\text{SO}_4)_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$; and when evaporated at 100°, the dihydrate, $\text{Bi}_2(\text{SO}_4)_3 \cdot 2\text{H}_2\text{O}$, is formed, and it loses no water when kept over conc. sulphuric acid. The sulphate is slowly hydrolyzed by cold water, rapidly by hot water, forming dibismuthyl sulphate, $(\text{BiO})_2\text{SO}_4$. According to G. H. Bailey, the normal sulphate can be heated to 405° without change; but between 405° and 418° decomposition sets in, producing, according to W. Heintz, dibismuthyl sulphate. At a high enough temp. G. H. Bailey, and F. W. Schmidt found that all the combined sulphuric acid can be expelled. K. Schäfer and F. Hein examined the absorption spectrum in the ultra-violet of a soln. of bismuth sulphate in sulphuric acid. J. A. Arfvedson said that hydrogen reduces the sulphate to metal at a red-heat. E. Hensgen observed that when exposed to hydrogen chloride it becomes warm, and absorbs over 3 mols of the gas per mol of sulphate; it dissolves in hydrochloric acid. A. B. Prescott found that 0.836 grm. remained undecomposed when a gram of the sulphate was evaporated on a water-bath to dryness with 3.5 c.c. of hydrochloric acid of sp. gr. 1.153. When heated in ammonia gas, W. R. E. Hodgkinson and C. C. Trench found that the sulphate is reduced to metal. The normal salt dissolves in nitric acid. G. Bodman found that bismuth sulphate forms complex salts with the ammonium and alkali sulphates; and solid soln. with some rare earth sulphates.

A number of basic sulphates have been reported. Their composition depends on the temp. and conc. of the acid. F. B. Allan found that at 50°, acid bismuth

sulphate, $\text{Bi}_2\text{O}_3 \cdot 4\text{SO}_3$, is in equilibrium with sulphuric acid of more than 51.4 per cent. concentration; $\text{Bi}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, with sulphuric acid between 51.4 and 5.4 per cent.; and $\text{Bi}_2\text{O}_3 \cdot \text{SO}_3$, with sulphuric acid soln. below 5.4 per cent. The latter compound is not acted on by water at 50° . The other basic sulphates were not found in aq. soln. at 50° . According to R. H. Adie, with sulphuric acid between $\text{H}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$ and $\text{H}_2\text{SO}_4 \cdot 12\text{H}_2\text{O}$, the product has the composition $5\text{Bi}_2\text{O}_3 \cdot \text{HSO}_3 \cdot 17\text{H}_2\text{O}$. This does not appear to be a chemical individual because F. B. Allan could not obtain the same result. R. H. Adie also reported that with an acid between $\text{H}_2\text{SO}_4 \cdot 3\text{H}_2\text{O}$ and $\text{H}_2\text{SO}_4 \cdot 5\text{H}_2\text{O}$, he obtained a product of **bismuth dihydrotetrasulphate**, $\text{Bi}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$, or $\text{Bi}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 7\text{H}_2\text{O}$; and with an acid between $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$ and $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, he obtained a lower hydrate, $\text{Bi}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{Bi}(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$. A. Leist found that when bismuth trioxide is treated with dil. sulphuric acid (1 : 2 or 3), much oxide dissolves, but most remains as a basic salt; if much hot sulphuric acid be used—100 grms. of acid to one gram of oxide—the basic sulphate dissolves, and when the filtered soln. is cooled, and evaporated until the fumes of the sulphuric acid appear, the same acid sulphate is formed. F. B. Allan said that the acid sulphate is in equilibrium with 51.4 per cent. sulphuric acid. The silky, needle-like crystals were found by R. H. Adie to form dibismuthyl sulphate at 170° ; and by A. Leist to form the basic salt $4\text{Bi}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 15\text{H}_2\text{O}$, as a white powder, when treated with water. D. L. Hammick found $4\text{Bi}_2\text{O}_3 \cdot 3\text{SO}_3$ to be the ultimate product of the action of sulphur dioxide on bismuth mono- or tri-oxide.

M. Websky obtained a basic sulphate by melting bismuth with potassium hydro-sulphate; and F. Rössler, by warming to 60° a soln. of bismuth in boiling conc. sulphuric acid. N. Athanasesco heated a feebly acidic soln. of bismuth nitrate with an excess of sodium sulphate in a sealed tube at 250° , and obtained white, microscopic needles of the basic sulphate $3\text{Bi}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 2\text{H}_2\text{O}$, **bismuth heptoxy-disulphate**, $\text{Bi}_6\text{O}_7(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$:

W. Heintz prepared **bismuthyl sulphate**, $\text{Bi}_2\text{O}_3 \cdot \text{SO}_4$, or $(\text{BiO})_2\text{SO}_4$, by evaporating to dryness a soln. of bismuth trioxide in sulphuric acid and heating the residue to redness; it was also obtained by W. Heintz, W. Lüddecke, C. Hensgen, and E. Ruge, by heating the more acid sulphates under similar conditions; by W. Lüddecke, by heating ammonium bismuth sulphate; and by C. P. Brigham, by heating potassium bismuth sulphate, and washing the product with water. The sulphate prepared at the high temp. is an anhydrous white powder; and that prepared at the lower temp. is dihydrated. F. B. Allan said that the white powder is not attacked by water; it is soluble in nitric and hydrochloric acids; and when calcined, J. L. Gay Lussac said that it loses oxygen and sulphur dioxide. F. E. Brown and J. E. Snyder observed no reaction with bismuth sulphate and vanadium oxytrichloride.

According to W. Heintz, when conc. sulphuric acid is added to a soln. of bismuth nitrate in nitric acid, **bismuth hydroxysulphate**, $\text{Bi}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{Bi}(\text{OH})\text{SO}_4 \cdot \text{H}_2\text{O}$, crystallizes out. The crystals are separated from the mother-liquor by draining on porous tiles. E. Ruge employed this method. W. Lüddecke found that when ammonium bismuth sulphate is digested for a long time with acetic or dil. sulphuric acid, part dissolves, and the hydroxysulphate remains as a residue; and A. Leist obtained it by evaporating a soln. of bismuth trioxide in hot, dil. sulphuric acid (1 : 2 or 3); according to F. B. Allan, the evaporation should proceed until a large

proportion of the sulphuric acid has volatilized. The prismatic or acicular crystals are transformed by water into bismuthyl sulphate; and W. Heintz found that the hydroxysulphate forms a complex salt—**potassium bismuth hydroxydisulphate**, $K_2SO_4 \cdot Bi(OH)SO_4$, or $K_2Bi(OH)(SO_4)_2$ —with potassium sulphate. This is obtained as a white precipitate by adding a soln. of potassium sulphate to a dil. soln. of bismuth nitrate.

W. Lüddecke obtained **ammonium sulphatobismuthite**, $(NH_4)Bi(SO_4)_2 \cdot 4H_2O$, in six-sided plates by mixing a soln. of a mol. of bismuth nitrate with 3 mols. or more of bismuth sulphate. The precipitate was drained on a porous tile. It is freely soluble in nitric and hydrochloric acids, and less soluble in conc. sulphuric acid and hot dil. acids. It is decomposed by water, forming bismuthyl sulphate; and cold acetic acid or dil. sulphuric acid converts it into bismuth hydroxysulphate. Microscopic, prismatic crystals of **sodium sulphatobismuthite**, $3Na_2SO_4 \cdot 2Bi_2(SO_4)_3$, or $Na_6Bi_4(SO_4)_9$, were obtained in a similar manner, and W. Heintz obtained **potassium trisulphatobismuthite**, $K_3Bi(SO_4)_3$, as a white precipitate by adding an excess of potassium sulphate or hydrosulphate to a conc. soln. of bismuth nitrate. If the bismuth nitrate soln. be not conc., and the alkali sulphate not in great excess, the precipitate has a variable composition. The precipitate is dried on a porous tile. T. H. Behrens described hexagonal crystals which he obtained in a similar way. C. P. Brigham obtained **potassium disulphatobismuthite**, $KBi(SO_4)_2$, by heating the corresponding chloride with conc. sulphuric acid. The acicular or tabular crystals are insoluble in cold water; and with boiling water, they yield bismuthyl sulphate. V. Caglioti and A. Stolfi observed the formation of only the one compound **potassium trisulphatobismuthite**, $3K_2SO_4 \cdot Bi_2(SO_4)_3$, or $K_3Bi(SO_4)_3$, in the ternary system $Bi_2(SO_4)_3 - K_2SO_4 - H_2O$ at 25° . It is stable in soln. containing 5.32 to 12.8 per cent. of K_2SO_4 . Some evidence was obtained of the formation of a basic sulphate. G. Bodman, and V. Cuttica showed that *bismuth sulphate and the sulphates of didymium, lanthanum, and yttrium*, are isomorphous and form a series of solid soln.—*vide* the rare earths. R. F. Weinland and H. Kühl evaporated a conc. sulphuric acid soln. of stannic acid and bismuth sulphate, and obtained rhombic leaflets of **stannic bismuth hydroxytrisulphate**, $Bi(OH)Sn(SO_4)_3$.

F. Ephraim found that bismuth sulphate absorbs rather more than 4 vols. of hydrogen chloride at atm. temp., forming **bismuth sulphatotetrahydrochloride**, $Bi_2(SO_4)_3 \cdot 4HCl$, stable up to 110° ; at 111° , **bismuth sulphatodihydrochloride**, $Bi_2(SO_4)_3 \cdot 2HCl$, is formed; and at 154° , **bismuth sulphatohydrochloride**, $Bi_2(SO_4)_3 \cdot HCl$.

§ 18. The Bismuth Halogenosulphides, or Sulphohalides

M. M. P. Muir¹ observed no tendency on the part of bismuth trifluoride to form a **bismuth fluosulphide** when it is melted with sulphur; but if bismuth trichloride be similarly treated, the dark red, crystalline product is **bismuth chlorosulphide**, BiSCl . M. M. P. Muir and E. M. Eagles exposed bismuth trichloride to the action of hydrogen sulphide at ordinary temp. or at a temp. not exceeding dull redness, and obtained the same chlorosulphide—at a higher temp., bismuth trisulphide is formed. They also obtained it by the action of chlorine on bismuth trisulphide at dull redness. G. N. Quam found that bismuth trichloride reacts with liquid hydrogen sulphide, forming this chlorosulphide. According to E. R. Schneider, when 8–10 grms. of ammonium pentachlorobismuthite are heated with one part of sulphur in a retort, and the fused mass when cold extracted with dil. hydrochloric acid, a small yield of the chlorosulphide is obtained; similarly when the same salt is heated to 250° – 300° in a stream of hydrogen sulphide and the product treated as before; and also when the same salt is fused with bismuth trisulphide and the product treated as before—this process gives the best yield.

Bismuth sulphochloride appears in dark grey needles which in thin layers appear brick-red or dark cherry-red in transmitted light. When heated in hydrogen, some bismuth trichloride is given off, then hydrogen chloride and sulphide, and bismuth contaminated with a little sulphide and chloride remains; and in air, some bismuth trichloride is volatilized, and at a higher temp., sulphur dioxide is formed—the residue is a mixture of bismuth oxychloride and basic sulphate. Boiling water does not decompose the sulphochloride; dil. acids have no action at ordinary temp.; and with conc. hydrochloric acid, hydrogen sulphide is evolved. When heated in hydrogen sulphide, at a red-heat, bismuth trisulphide is formed; and in carbon dioxide, bismuth trichloride and trisulphide are formed. Conc. nitric acid decomposes the sulphochloride with the separation of sulphur. All the chloride is removed by a soln. of an alkali-hydroxide, forming black oxysulphide; soln. of alkali carbonates act similarly, but more slowly.

M. M. P. Muir prepared **bismuth bromosulphide**, BiSBr , by the action of bromine vapour on bismuth trisulphide at a dull red-heat. The reaction begins at ordinary temp., and at too high a temp. it forms the trisulphide. Similar results were obtained by the action of hydrogen sulphide on bismuth tribromide. The greyish-red crystalline product is washed with hydrochloric acid. When heated in hydrogen sulphide, bismuth trisulphide is formed.

E. R. Schneider, and M. M. P. Muir and E. M. Eagles obtained **bismuth iodide-sulphide**, BiSI , by dissolving bismuth trisulphide in molten bismuth triiodide. The product contains the sulphoiodide mixed with an excess of iodine. It is purified by repeatedly washing it with dil. hydrochloric acid. E. R. Schneider obtained it by heating bismuth trisulphide with iodine, the bismuth triiodide formed as a by-product volatilizes; W. Linau, by heating a mixture of iodine, sulphur, and bismuth trisulphide in a clay crucible for a long time; and N. Tarugi, by the action of thioacetic acid on bismuth iodide, or potassium iodobismuthite: $\text{BiI}_3 + \text{CH}_3\text{COSH} + \text{H}_2\text{O} = \text{BiSI} + \text{CH}_3\text{COOH} + 2\text{HI}$. The small, steel-grey, acicular crystals resemble bismuth glance. When heated out of contact with air, bismuth triiodide is given off, but the residue of bismuth trisulphide retains some iodine even when heated for a long time. Boiling water or a dil. mineral acid has no action; it is decomposed by hot, conc. hydrochloric acid giving off hydrogen sulphide; with nitric acid, sulphur, and iodine are separated; aq. ammonia extracts the iodine, forming an oxysulphide; a soln. of alkali hydroxide acts similarly; and likewise also with a boiling mixture of zinc oxide and water. In the last case, the action is slow and

incomplete. A. Kuhn and H. Pirsch found that bismuth sulphoiodide sols cannot be prepared without protective colloids. Sols containing 0.3 mg. of bismuth per c.c. with 0.59 per cent. of gum arabic, 1.6 mg. with 0.5 per cent. of hæmoglobin, and 0.3 mg. with 0.25 per cent. of gelatin may be obtained. The gum arabic sol is reversible—*vide supra*, bismuth trisulphide.

F. L. Ducatte² melted stoichiometrical proportions of bismuth sulphide and cuprous chloride in an atm. of carbon dioxide and obtained **cuprous chlorosulphobismuthite**, $2\text{Cu}_2\text{S}\cdot\text{Bi}_2\text{S}_3\cdot 2\text{BiSCl}$, which may be a mixture of BiSCl with cuprous and bismuth sulphides. The product has a sp. gr. 6.78; it is stable at ordinary temp., but decomposes when heated in air; and is attacked by dil. acids with the liberation of hydrogen sulphide. It is insoluble in cold water, but is decomposed by boiling water, forming hydrochloric acid. F. L. Ducatte obtained in a similar manner **cuprous bromosulphobismuthite**, $2\text{Cu}_2\text{S}\cdot\text{Bi}_2\text{S}_3\cdot 2\text{BiSBr}$, of sp. gr. 6.41; and **cuprous iodosalphobismuthite**, $2\text{Cu}_2\text{S}\cdot\text{Bi}_2\text{S}_3\cdot 2\text{BiSI}$, of sp. gr. 6.50. The properties of these compounds are like those of the chloro-sulphobismuthite. He also prepared **lead chlorosulphobismuthite**, $\text{PbS}\cdot\text{Br}_2\text{S}_3\cdot 2\text{BiSCl}$, by heating a mixture of equal parts of lead chloride and bismuth sulphide to the fusion point in a current of carbon dioxide. It is obtained in long crystals of sp. gr. 6.42, which are quite stable in the air and insoluble in water. It oxidizes at a red-heat and is decomposed by boiling water. With acid, it gives hydrogen sulphide. The corresponding **lead bromosulphobismuthite**, $\text{PbS}\cdot\text{Bi}_2\text{S}_3\cdot 2\text{BiSBr}$, of sp. gr. 6.50; and **lead iodosalphobismuthite**, $\text{PbS}\cdot\text{Bi}_2\text{S}_3\cdot 2\text{BiSI}$, of sp. gr. 6.59, are prepared similarly, and have analogous properties.

§ 19. The Bismuth Carbonates

In 1817, A. G. Werner¹ referred to a mineral from Schneeberg, Saxony, which he called *Arsenikwismuth*; and A. Weisbach showed that the mineral is probably a basic carbonate, which he called **bismutosphaerite**. Analyses reported by A. Frenzel, C. Winkler, E. S. Sperry, and H. L. Wells correspond with $2\text{Bi}_2\text{O}_3\cdot\text{Bi}_2(\text{CO}_3)_3$, or **bismuthyl carbonate**, $(\text{BiO})_2\text{CO}_3$. The compound was made by W. Heintz, and K. Seubert and M. Elten by adding an excess of an alkali carbonate to an excess of a soln. of bismuth nitrate; and in order to free the precipitate from basic nitrate it should be heated for some time in contact with its mother-liquor. It is then washed with water and dried at 100° . It is difficult to remove the alkali nitrate, and carbonates adsorbed by the precipitate. L. Vanino recommended the following mode of preparation:

A little water is added to 18.2 grms. of mannitol and the whole triturated with 48.2 grms. of powdered bismuth nitrate, whereoy a soln. is obtained. To 100 c.c. of this soln. at 0° are added 20.7 grms. of potassium carbonate dissolved in the minimum quantity of water; when almost all the potassium carbonate has been added the bismuthyl carbonate separates as a fine, heavy powder. The precipitate is washed with water, alcohol, and ether, and dried in the air. Ammonium carbonate may be used instead of potassium carbonate. Bismuth metahydrate, dissolved in conc. hydrochloric acid, is not suitable for the preparation of bismuthyl carbonate.

J. Lefort said that if an alkali hydrocarbonate be used as precipitant, the *monohydrate*, $(\text{BiO})_2\text{CO}_3\cdot\text{H}_2\text{O}$, is formed. When the white powder is dried at 100° , or

over sulphuric acid in vacuo, it retains from 0.5 to 1.0 mol of water which W. Heintz attributes to the presence of some bismuth hydroxide as impurity. A. J. Jones discussed the effect of concentration, and temp. on the density of the carbonate. While the artificial preparation is white, bisautosphaerite is coloured bright yellow to dark grey or brown, and it occurs in a spherical form with concentric, fibrous, radiated structures; and in pseudomorphs after bismuthinite. A. Frenzel gave for the sp. gr. of the mineral 7.59; C. Winkler, 7.30-7.64; and H. L. Wells, 6.83-7.42. The hardness is 3.0-3.5. R. Robl observed that the carbonate gives no fluorescence in ultra-violet light. When heated, bismuthyl carbonate loses carbon dioxide. C. R. Fresenius, and H. Rose said that the carbonate is insoluble in water, in an aq. soln. of carbon dioxide, and in potash-lye; but it is slightly soluble in a soln. of an alkali carbonate, and when the soln. is warmed, or treated with alkali hydroxide, the basic carbonate is again precipitated. R. H. Brett said that the freshly precipitated carbonate is readily soluble in a soln. of ammonium chloride, but not in one of ammonium nitrate. F. E. Brown and J. E. Snyder observed a reaction with the hydrated carbonate and vanadium oxytrichloride.

A. Breithaupt² described a *kohlensaures Wismuthoxyd* from Schneeberg, and called it **bismutite**. Analyses were reported by A. Liversidge, C. F. Rammelsberg, F. A. Genth, H. Louis, C. Winkler, A. Carnot, F. G. Cairns, W. Bodenbender, and K. Thaddéeff. C. F. Rammelsberg represented it by $2\text{Bi}_2(\text{CO}_3)_3 \cdot 3\text{Bi}_2\text{O}_3 \cdot 3\text{H}_6\text{Bi}_2\text{O}_6$; A. Carnot, by $\text{Bi}_2\text{O}_3(\text{CO}_2, \text{H}_2\text{O}) \cdot n\text{Bi}_2\text{O}_3(\text{HO}, \text{CO}_2)$; A. Weisbach, by $\text{Bi}_6\text{CO}_{11} \cdot \text{H}_2\text{O}$; F. G. Cairns, $\text{Bi}_2\text{C}_3\text{O}_9 \cdot 2\text{Bi}_2\text{H}_2\text{O}_5$; K. Thaddéeff, $5\text{Bi}_2\text{O}_3 \cdot \text{H}_2\text{O} \cdot \text{CO}_2$; and H. Louis, $\text{Bi}_2\text{H}_2\text{CO}_6$, or **bismuth oxydihydroxycarbonate**,

The difference in the composition of the specimens so far described shows that the composition is very doubtful. A related mineral, from Joachimsthal, was called *waltherrite* by M. Adam, and described by J. F. Vogl, and E. Bertrand. W. Macgregor described another mineral bismuth carbonate from St. Agnes, Cornwall; W. H. Miller called it *agnesite*; and M. Adam, *gregorite*. T. Thomson's analysis said that it contained no carbonate, and only a trace of bismuth, while F. S. Beudant indicated that the assumption that the statite-like mineral is a carbonate is based on *quelque grande erreur* in W. Macgregor's analysis. The mineral may be white, yellow, green, or grey, and it occurs as an amorphous incrustation, or earth. A. Breithaupt gave 6.84-6.90 for the sp. gr.; C. F. Rammelsberg, 7.67; A. Carnot, 6.94-7.26; C. Winkler, 6.12-6.27; H. Louis, 6.84; and F. A. Genth, 6.293-7.330. The hardness is 4.0-4.5.

§ 20. The Bismuth Nitrates

When a soln. of bismuth or its oxide in hot nitric acid is allowed to crystallize at ordinary temp., **bismuth nitrate**, $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$, separates in clear, colourless, triclinic crystals. J. J. Berzelius,¹ T. Graham, J. H. Gladstone, W. Heintz, E. Ruge, A. Duflos, J. M. Ordway, G. M. Rutten, F. Chemnitz, A. de Schulten, P. Yvon, and L. Freundt prepared this salt. According to C. F. Rammelsberg, the crystals belong to the triclinic system, and have the axial ratios $a : b : c = 0.8053 : 1 : 0.6172$, and $\alpha = 90^\circ 4'$, $\beta = 104^\circ 26'$, and $\gamma = 79^\circ 6'$. The cleavage is marked on the (100)-face. G. Bodman found that the crystals are isomorphous with those of the rare earth nitrates—lanthanum, didymium, and yttrium. L. Playfair and J. P. Joule gave 2.736 for the sp. gr. of the salt, and F. W. Clarke, 2.823 at 20° . B. Powell, and L. Ditscheiner measured the refractive indices of soln. of the salt; and the effect of the nitrate on the optical rotatory power of some organic substances was studied by H. Grossmann. W. D. Bancroft and H. B. Weiser found that with a cold surface in the colourless gas-flame charged with bismuth nitrate there is deposited a bright white, metallic mirror. According to A. Quartaroli, soln. of bismuth nitrate containing an excess of nitric acid are strongly hydrolyzed even in the presence of a considerable excess of nitric acid. This was shown by the electrical conductivity of the soln., and by the conc. of the H^+ ions indicated by the catalysis of methyl acetate. The calculated ionization constant is 0.0230. Analyses by A. Duflos, J. J. Berzelius,

T. Graham, W. Heintz, W. Lüddecke, and E. Ruge show that the salt crystallizing from the nitric acid soln. at ordinary temp. is the *pentahydrate*. The conditions of equilibrium are indicated in Fig. 30. G. M. Rutten said that the *dihydrate*, $\text{Bi}(\text{NO}_3)_3 \cdot 2\text{H}_2\text{O}$, is formed by heating the pentahydrate to 75.5° . It appears as a solid phase in aq. soln. with 37.23 and 47.76 per cent. respectively of Bi_2O_3 and N_2O_5 at 72° ; 36.74 and 47.91 per cent. respectively at 75° ; and 39.75 and 45.16 per cent. respectively at 80° . According to E. Moles and E. Sellés, the *monohydrate*,

FIG. 30.—Equilibrium Conditions in the System: $\text{Bi}_2\text{O}_3\text{--N}_2\text{O}_5\text{--H}_2\text{O}$ at 21° .

$\text{Bi}(\text{NO}_3)_3 \cdot \text{H}_2\text{O}$, in nacreous, tabular crystals, is obtained when bismuth is dissolved in nitric acid at as low a temp. as possible, and the soln. evaporated at 60° to 70° . When heated in dry carbon dioxide, the anhydrous salt is formed. The *hemitrihydrate*, $\text{Bi}(\text{NO}_3)_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, was obtained by A. Ditte, and G. M. Rutten as a crystalline powder by heating the pentahydrate, or bismuth trioxide with water-free nitric acid. The hemitrihydrate rapidly attracts moisture from the air and passes into the pentahydrate. The conditions of equilibrium are indicated in Fig. 29. M. Picon said that in vacuo over phosphorus pentoxide, the normal nitrate loses 3.2 mols of water; and at 100° , the salt decomposes. This salt cannot be dehydrated by phosphorus pentoxide without decomposition. G. Bodman reported that the *hexahydrate*, $\text{Bi}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$, occurs only when associated in solid soln. with the corresponding rare earth nitrates.

W. Heintz, and E. Ruge observed that when triturated in air dried by sulphuric acid and potassium hydroxide, at ordinary temp., water, nitric acid, and bismuth hydroxydinitrate is formed. Even at 30° , the salt loses nitric acid, but it

has no definite m.p., and, according to G. M. Rutten, it forms hemihydrated bismuthyl nitrate at 75.5°, while at a higher temp. it passes into bismuth trioxide. T. Graham, and J. H. Gladstone also made some observations on this subject. K. Schäfer and F. Hein examined the absorption spectrum of nitric acid soln. of bismuth nitrate in the ultra-violet. E. Wrede studied bismuth nitrate, etc., as a target for indicating magnetic separation in a stream of hydrogen. A. Duflos said that when bismuth nitrate is treated with water, it forms dihydrated bismuthyl nitrate; and when treated with a very large excess of water, the product contains $\text{Bi}:\text{HNO}_3$ in the proportion 1:12. U. Antony and G. Gigli found that when treated with increasing proportions of water, the quantity of bismuth passing into soln. becomes less and less, until, with 50,000 parts of water to one part of nitrate, no more bismuth can be detected in soln. Following the method indicated in connection with mercurous sulphate—Fig. 37, 4. 31, 29—W. L. Miller and F. B. Kenrick represented the equilibrium conditions in the case of bismuth nitrate and water by Fig. 29. This shows the existence of the two basic nitrates with $\text{Bi}_2\text{O}_3:\text{N}_2\text{O}_5:\text{H}_2\text{O}=2:1:1$ and $6:5:9$. When normal bismuth nitrate in nitric acid is poured into water at ordinary temp. the basic nitrate $\text{BiO}(\text{NO}_3)\cdot\text{H}_2\text{O}$ is formed if the precipitate be filtered from the mother-liquid. When the crystalline precipitate is left in contact with water, it begins to change into a more basic salt. The reaction is, however, so slow that no appreciable change is produced in a few hours. At 21°, the salt $\text{Bi}_{12}\text{O}_{13}(\text{NO}_3)_{10}\cdot 9\text{H}_2\text{O}$ is in equilibrium with nitric acid soln. from 0.03 to 0.32 normality, and the salt $\text{BiO}\cdot\text{NO}_3$ with soln. from 0.425 to 0.7 normality. At 50°, the salt $\text{Bi}_4\text{O}_5(\text{NO}_3)_2\cdot\text{H}_2\text{O}$ is in equilibrium with nitric acid soln. from 0.057 to 0.285 normality; and the salt $\text{Bi}_{12}\text{O}_{13}(\text{NO}_3)_{10}\cdot 9\text{H}_2\text{O}$ with soln. from 0.285 to 0.466 normality. At 75°, the salt $\text{Bi}_4\text{O}_5(\text{NO}_3)_2\cdot\text{H}_2\text{O}$ is in equilibrium with nitric acid soln. of 0.109 to 0.314 normality.

FIG. 31.—The Ternary System: $\text{Bi}_2\text{O}_3\text{--N}_2\text{O}_5\text{--H}_2\text{O}$ at 20° and at 65°.

No signs of any basic nitrate other than these two just mentioned have been observed at 50°, although the transition of one form to another is so slow that mixtures not in equilibrium with the mother-liquid have been reported as if they were true chemical individuals. L. Vanino and F. Mussgnug showed that one of the chief difficulties in the preparation of bismuth compounds is due to the ready hydrolysis of bismuth salts except in acidic soln.; and they added that this can be prevented by working with mixtures of say bismuth nitrate and mannitol (1:1) in aq. soln. G. M. Rutten studied the ternary system $\text{Bi}_2\text{O}_3\text{--N}_2\text{O}_5\text{--H}_2\text{O}$ at different temp., and the results at 20° and 65° are summarized in Fig. 31. He found at 25°, the results indicated in Table II. J. S. Mus-

pratt studied the action of sulphur dioxide on bismuth nitrate. E. C. Franklin and C. A. Kraus observed that the nitrate is soluble in liquid ammonia, and in the presence of ammonium nitrate.

A. Libavius, in his *De natura metallorum* (Francofurti, 1600), stated that a soln. of bismuth in nitric acid gives a white precipitate when treated with water, and in that respect it differs from a soln. of zinc in the same acid. A few years later, N. Lemery, in his *Cours de chymie* (Paris, 1681), and R. Boyle, in his *Reflections on the hypothesis of alkali and acidum* (London, 1675), made some observations on the subject. B. Hepner said that the first decomposition product of bismuth nitrate is $\text{BiO}\cdot\text{NO}_3\cdot\text{H}_2\text{O}$ which furnishes scaly crystals; when this is exposed for 8 hrs. in a desiccator it furnishes $\text{Bi}_2\text{O}_3\cdot\text{N}_2\text{O}_5\cdot 1.9\text{H}_2\text{O}$. No loss of nitric acid occurs when the water is given off. The compound $\text{NO}_3\cdot\text{Bi}(\text{HO})_2\text{Bi}(\text{NO}_3)$ is obtained by heating equal parts of bismuth nitrate and water on the water-bath until the scaly crystals change, or by allowing the scaly crystals to stand in contact with a soln. of one part of bismuth nitrate and 11 parts of water; or by the continued action of a soln. of

nitric acid with less than 6 per cent. N_2O_5 . The crystals prepared in the wet way are monoclinic, and in the dry way, hexagonal plates. The final degradation produced by the action of water on bismuth nitrate, $\text{NO}_3\text{BiO}(\text{HO})\text{BiO}$, is obtained by digesting one part of bismuth nitrate with 24 parts of water on a water-bath, in 2-hour periods, rejecting the water at the end of each period. The product is an aggregate of hexagonal crystals. The *bismuticum subnitricum*—*bismuth subnitrate*—the *magisterium bismuthi*—*magistry of bismuth*—*basic bismuth nitrate*, *bismuth-white*, *pearl-white*, *blanc d'Espagne*—*Spanish white*—and *white cosmetic* are pharmaceutical or trade names for the basic nitrate or mixture of basic nitrates obtained by adding water to bismuth nitrate. Several other white powders were also called Spanish white or pearl-white. G. Kassner said the grey colours developed by a preparation of bismuth nitrate in a year was due to the separation of tellurium impurity.

The composition of the white precipitate depends on the temp. and on the proportion of water employed. According to A. Diite, and E. Ruge, the composition usually ranges between $\text{Bi}(\text{OH})(\text{BiO}_2)\text{NO}_3$, and $\text{BiO}(\text{NO}_3)$. According to G. M. Rutten, the pharmaceutical preparation cannot be $\text{BiO}(\text{NO}_3) \cdot \frac{1}{2}\text{H}_2\text{O}$ because it is washed with hot water; it may be $10\text{Bi}_2\text{O}_3 \cdot 9\text{N}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, or $6\text{Bi}_2\text{O}_3 \cdot 6\text{N}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, or a mixture of the two. If washed for a long time, its composition approximates $(\text{OH})(\text{BiO})_2(\text{NO}_3)$. The preparation and properties of the pharmaceutical oxyhydrate were discussed by A. Adriaansz, W. L. Baylor, A. Béchamp, C. Bouchet, L. A. Buchner, E. Busch, C. L. Cadet de Gassicourt, P. P. Carles, A. Carnot, A. Chapius and G. Linossier, A. Chevallier, C. E. Cornfield and G. R. A. Short, E. C. Deschamps, A. Duflos, F. P. Dulk, A. Glénard, A. Grandval, M. Grossmann, J. E. Herberger, M. Janssen, M. H. Klaproth, J. L. Lassaigne, J. Löwe, H. Reinsch, A. Riche, J. H. Salisbury, E. R. Schneider, A. T. Starting, H. Thoms, and A. Underhill. E. B. R. Prideaux and H. W. Hewis described an electrolytic process of preparation. The presence of lead as an impurity was noted by A. Carnot, A. Riche, G. Guérin, and A. Chapius and G. Linossier; the presence of ammonium nitrate, by E. Luce, E. Crouzel; and of tellurium, by J. O. Braithwaite, E. Isnard, A. Reissert, G. Brownen, and E. A. Letts. Some uses of the basic nitrate were discussed by E. C. Behrendt, C. Winkler, and U. Gayon and G. Dupetit. P. W. K. Böckmann concluded that at an acidity similar to that which prevails in the stomach, basic bismuth nitrate does not possess any neutralizing capacity. A. Böhme observed that the internal administration of the basic nitrate leads to the formation of nitrous acid which produces methæmoglobinura in men and animals. G. Gimel said that the basic nitrate is soluble in acidic liquids like musts, etc., and that it inhibits acetous fermentation.

According to G. M. Rutten, the basic salts: $5\text{Bi}_2\text{O}_3 \cdot 4\text{N}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$, reported by

E. Becker, and M. Janssen; $4\text{Bi}_2\text{O}_3 \cdot 3\text{N}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$, reported by A. Duflos, and J. E. Herberger; and $5\text{Bi}_2\text{O}_3 \cdot 3\text{N}_2\text{O}_5 \cdot 6(\text{or } 8)\text{H}_2\text{O}$, reported by A. Laurent, B. Fischer, V. Thomas, H. A. L. Wiggers, J. H. Weibel, V. A. Jacquelin, E. Frémy, J. Löwe, R. Phillips, and C. Ullgren, are non-existent. E. Isnard did not find arsenic in the commercial salt, but tellurium was present. According to B. Hepner, the compound known as *magisterium bismuthi Duflos*:

is formed by mixing one part of bismuth nitrate with 24 parts of water, and dissolving this mixture in 120 parts of water; or by heating one part of nitrate with 24 parts of water at 75° until the precipitate becomes crystalline; or by allowing scaly crystals of $\text{BiO} \cdot \text{NO}_3 \cdot \text{H}_2\text{O}$ to stand covered with water for a year when formed at ordinary temp., it furnishes large rhombic crystals, but at higher temp. the crystals are rectangular. E. Moles and E. Sellés regarded the salt $[\text{Bi}(\text{H}_3\text{NO}_4)_2(\text{H}_2\text{O})_2]\text{NO}_4$, as well as BiNO_4 , and $\text{BiNO}_4 \cdot \text{BiO} \cdot \text{OH}$ to be derivatives of orthonitric acid. The co-ordination number of bismuth is taken as 4.

Bismuth nitrate was stated by L. V. Brugnatelli to detonate slightly and emit sparks when placed on red-hot coals; and these effects are more marked when the crystals are rubbed with phosphorus. W. D. Bancroft and H. B. Weiser observed that in the Bunsen flame, bismuth nitrate decomposes and a white metallic mirror is deposited on a cold surface. Hydrogen dioxide with acid soln. of bismuth nitrate gives a yellow or orange precipitate on filtering into conc. ammonia. The precipitate dissolves in conc. nitric acid and contains but traces of active oxygen. It contains 95 per cent. Bi_2O_3 , and is probably neither a peroxide nor a basic hydroxide. E. P. Alvarez found that when an almost neutral soln. of bismuth nitrate is treated with a soln. of potassium permanganate, a white crystalline precipitate of what may be **bismuth pernitrates** is formed. Dil. nitric acid dissolves the salt completely. A. Ditte said that this occurs with a soln. containing 83 grms. HNO_3 per litre, and when this soln. is diluted it becomes turbid; it also deposits a basic salt when heated, and this re-dissolves on cooling. The presence of acetic acid in the nitric acid soln. makes it hinder the precipitation of a basic salt by water. B. Hepner and A. Likiernik, and L. Vanino and co-workers, observed a similar result in the presence of mannitol, dulcitol, or sorbitol. S. von Laszcynsky found that 100 grms. of acetone at 0° dissolve 48.66 grms. of the nitrate, and at 19° , 41.70 grms. K. A. Hofmann and K. L. Gonder observed that a complex is formed with thiourea; R. Weinland and H. Sperl, one with pyrocatechol; and J. Pastureau, one with phenylhydrazine. G. Urbain and H. Lacombe obtained complex salts with the nitrate of some bivalent metals—*vide infra*.

According to E. Ruge, if pentahydrated bismuth nitrate be kept for 2 or 3 months in dry air—over sulphuric acid and potassium hydroxide—it forms **bismuth hydroxydinitrate**, $\text{Bi}(\text{OH})(\text{NO}_3)_2 \cdot \frac{1}{2}\text{H}_2\text{O}$. The conditions of equilibrium are indicated in Fig. 29. A similar product is obtained when the normal salt is heated for 18–19 days at 50° – 78° , or until its weight during 12 hrs.' heating diminishes by only a milligram. If dried to constant weight, bismuthyl nitrate is formed. G. M. Rutten obtained a product with a similar composition by heating pentahydrated bismuth nitrate at 75.5° . If normal bismuth nitrate be treated with cold water, the gelatinous precipitate soon forms scaly crystals, which are drained on porous tiles. When dried in air, the composition is $\text{Bi}_2\text{O}_3 \cdot \text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, or **bismuth dihydroxynitrate**, $\text{Bi}(\text{OH})_2(\text{NO}_3)$. It was so prepared by F. B. Allan, E. Becker, C. F. Bucholz, W. Heintz, A. Laurent, M. Janssen, E. Ruge, G. M. Rutten, and P. Yvon. A. Quartaroli showed that the formation of this salt does not occur directly from $\text{Bi}(\text{NO}_3)_3$, but probably through the intermediate formation of the

hydroxydinitrate. A. Ditte said that the proportion of water ranges from 0.5 to 2 mols. A. de Schulten's salt, $5\text{Bi}_2\text{O}_3 \cdot 5\text{N}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$, is also considered to be identical with this salt. The conditions of equilibrium are indicated in Fig. 29. According to E. Schmidt, the same salt is precipitated by water at 60° , but with warmer water, a more basic salt is deposited. P. Yvon found that the same salt is deposited when a soln. of bismuth nitrate is neutralized with alkaline earth carbonates. E. Ruge observed the formation of the same salt by the action of an excess of nitric acid on bismuth, or of a warm conc. soln. of bismuth nitrate on powdered bismuth. B. Fischer was unable to make a definite salt by the action of bismuth nitrate on the hydroxide. The snow-white, lustrous powder contains needles, prisms, or plates. A. des Cloizeaux found the crystals prepared by P. Yvon to be triclinic. A. de Schulten gave 4.928 for the sp. gr. W. Heintz, and E. Becker said that half the water of crystallization is lost at 100° – 120° ; J. H. Gladstone, that water and acid are lost at 260° ; and at a red-heat, E. Ruge obtained the trioxide. G. M. Rutten found that when the salt $\text{Bi}_2\text{O}_3 \cdot \text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$ was kept over sulphuric acid of different conc., and therefore of different vap. press. of water vapour, it retained the following amounts of water :

Mols H_2O	9.5	8	6	5.2	2.9	0.8	0 mm.
	1.91	1.86	1.83	1.83	1.78	1.67	0.75

M. Picon studied the dehydration of this salt—over phosphorus pentoxide it forms $\text{BiO}(\text{NO}_3) \cdot \frac{5}{12} \text{H}_2\text{O}$, and at 100° , it loses 3.64 per cent. of water. A. K. Sanyal and N. R. Dhar found bismuth oxynitrate is coloured by exposure to tropical sunlight for 35 hrs. According to E. Ruge, the salt is not sensitive to light; it dissolves slightly in water and a more basic salt separates out again; hot water converts it into bismuthyl hydroxynitrate; and A. Ditte showed that boiling water containing 4.5 grms. HNO_3 per litre is without action on the salt. H. Müller and L. Kürthy observed that in certain concentrations of glycine, bismuth nitrate undergoes considerable hydrolysis which is ascribed to the interaction of the amphoteric bismuthous acid with both positively (simple) and negatively (complex) charged bismuth ions. A. Vogel said that stannous chloride gradually colours it orange-yellow, and when heated, brown or black.

According to E. Ruge, T. Graham, and E. Becker, the basic nitrate corresponding with $\text{Bi}_2\text{O}_3 \cdot \text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or **bismuthyl nitrate**, $\text{BiO}(\text{NO}_3) \cdot \frac{1}{2} \text{H}_2\text{O}$, is formed when pentahydrated bismuth nitrate, or bismuth hydroxydinitrate, or dihydroxynitrate is heated to 78° until its weight is constant. P. Yvon heated bismuth nitrate to 120° , and J. H. Gladstone to 149° . G. M. Rutten said that bismuth nitrate begins to decompose at 155° ; and P. Yvon said that the salt loses half its water at 120° . G. M. Rutten obtained bismuthyl nitrate by leaving bismuth dihydroxynitrate in contact with its mother-liquor or dil. nitric acid for some time, or by treating pentahydrated bismuth nitrate with an equal weight of water, and heating the mixture on a water-bath until it forms tabular crystals. B. Fischer made it by mixing alcoholic nitric acid, and a mixture of alcohol and bismuth hydroxide. G. M. Rutten, A. Butleroff, and F. B. Allan said that the hexagonal, prismatic crystals are probably monoclinic. They are not decomposed when washed with nitric acid containing 10 per cent. N_2O_5 .

If bismuth nitrate be treated with hot or cold water until no more nitric acid is extracted, and the hydrolysis is completed, F. B. Allan, A. Butleroff, A. Ditte, W. Lüddecke, E. Ruge, G. M. Rutten, and P. Yvon said that a snow-white, microcrystalline powder, $2\text{Bi}_2\text{O}_3 \cdot \text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or **bismuthyl hydroxynitrate**, $(\text{BiO})_2(\text{NO}_3)(\text{OH})$, is formed. E. Ruge said that the crystals obtained with hot water belong to the cubic system. One mol. of water is retained at 100° ; and the salt suffers no further change when boiled with water. The conditions of equilibrium are indicated in Fig. 29. F. B. Allan said that the salt is in equilibrium with 0.057N- to 0.285N- HNO_3 at 30° ; with 0.109N- to 0.314N- HNO_3 at 75° . If heated in a sealed tube at 200° – 205° with water, often renewed, G. Rousseau

and G. Tite said that it finally passes into bismuth trioxide. If the mother-liquor remaining after the deposition of the scaly crystals of $\text{Bi}_2\text{O}_3 \cdot \text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, be allowed to stand a couple of days at ordinary temp., G. M. Rutten found that crystals of $6\text{Bi}_2\text{O}_3 \cdot 5\text{N}_2\text{O}_5 \cdot 8$ (or 9) H_2O , or **bismuthyl hydroxypernitrate**, $(\text{BiO})_6(\text{NO}_3)_5(\text{OH}) \cdot 3\frac{1}{2}$ (or 4) H_2O , are formed. The crystals are probably rhombic. The salt is also formed when pentahydrated bismuth nitrate is heated with 24 times its weight of water until crystals begin to form. The conditions of equilibrium are indicated in Fig. 29. F. B. Allan said that at 21° this salt is in equilibrium with 0.5*N*- to 0.32*N*- HNO_3 ; and at 50° with 0.235*N*- to 0.446*N*- HNO_3 . Salts prepared by E. Becker, W. Heintz, M. Janssen, and E. Ruge are probably identical with this salt. K. H. Butler and D. McIntosh said that the nitrate is insoluble in liquid chlorine.

H. L. Wells and co-workers prepared **cesium bismuth nitrate**, $2\text{CsNO}_3 \cdot \text{Bi}(\text{NO}_3)_3$, in long, colourless prisms from a soln. of the constituents. It melts at 102° . G. Urbain obtained **ammonium bismuth nitrate**, $2\text{NH}_4\text{NO}_3 \cdot \text{Bi}(\text{NO}_3)_3 \cdot 4\text{H}_2\text{O}$, from a soln. of the component salts. A. C. Vournasos prepared white crystals of **methylamine nitratobismuthate**, $\text{NH}_3(\text{CH}_3[\text{Bi}(\text{NO}_3)_4])$, in white crystals—*vide* 8. 49, 21. G. Urbain and H. Lacombe prepared a number of complex salts $3\text{M}''(\text{NH}_3)_2 \cdot 2\text{Bi}(\text{NO}_3)_3 \cdot 24\text{H}_2\text{O}$, where M stands for Mg, Zn, Mn, Co, or Ni. The salts are isomorphous with the complex nitrates of the rare earths; they effloresce in dry air, but deliquesce in moist air—the manganese salt being the most, and the nickel and magnesium salts least deliquescent; and the salts are all decomposed by water. It was not found possible to prepare *copper bismuth nitrate*. The colourless **magnesium bismuth nitrate** has a sp. gr. 2.32 at $16^\circ/16^\circ$, and melts with decomposition at 71° . Colourless **zinc bismuth nitrate** has a sp. gr. 2.75 at $16^\circ/16^\circ$, and melts with decomposition at 67.5° . The *cadmium bismuth nitrate* could not be made. Pale red **manganese bismuth nitrate** is the most unstable member of the series, and it does not exist in contact with the solid phase of either constituent; its sp. gr. is 2.42 at $16^\circ/16^\circ$; and it melts without decomposition at 43 – 44° . They could not make *ferrous bismuth nitrate*. Red **cobalt bismuth nitrate** has a sp. gr. 2.48 at $16^\circ/16^\circ$, and melts without decomposition at 58° . Green **nickel bismuth nitrate** has a sp. gr. 2.51 at $16^\circ/16^\circ$, and it melts with decomposition at 69° .

§ 21. The Bismuth Phosphates

According to C. F. Wenzel,¹ an aq. soln. of phosphoric acid forms with bismuth hydroxide a white insoluble powder, and a soluble phosphate. According to C. Montemartini and U. Egidi, the pharmaceutical preparation *bismuthum phosphoricum solubile* contains bismuth oxide, prepared by the addition of an alkali phosphate to a soln. of bismuth nitrate or chloride, and always contains some basic nitrate or chloride. It may, however, be obtained free from these compounds by taking advantage of the fact that bismuth oxide is soluble in a soln. of potassium hydroxide which contains glycerol. Bismuth nitrate is intimately mixed with glycerol, water is added until the salt is entirely dissolved, and then potassium hydroxide until the precipitated oxide is redissolved. If dil. sulphuric acid is then added, a precipitate of bismuth oxide is produced, which is entirely free from any combined acid, and after drying in air, or in a vacuum over sulphuric acid, or at 100°–105°, has the composition Bi₂O₃·H₂O.

According to C. Montemartini and U. Egidi, **bismuth orthophosphate**, BiPO₄, is the only phosphate stable towards water which is obtainable from soln. of bismuth salts by precipitation and subsequent washing. W. Heintz obtained this phosphate by precipitating a soln. of bismuth nitrate with sodium hydrophosphate, and washing the product with nitric acid of decreasing conc. G. Chancel said that the composition of the precipitate is the same if an excess of either salt be present, but the soln. should be free from hydrochloric or sulphuric acid; M. M. P. Muir

said that a varying conc. of nitric acid makes very little difference. A. de Schulten obtained microscopic crystals of the orthophosphate by heating on a water-bath a mixture of 15 grms. of pentahydrated bismuth nitrate, 7 grms. of hydrated sodium hydrophosphate, and conc. nitric acid, and adding water slowly drop by drop. L. Vanino and F. Hartl treated a soln. of bismuth nitrate and mannitol with phosphoric acid or a phosphate; and C. Braun fused metaphosphoric acid with bismuth. In both cases, bismuth orthophosphate was formed. L. S. T. Rügheimer and E. Rudolf found the mol. wt. of bismuth orthophosphate in soln. in bismuth trichloride to be normal. C. Haushofer described the orthophosphate as a white crystalline powder containing spherical, stellar, or octahedral aggregates; and A. de Schulten said that the clear crystals are monoclinic prisms of sp. gr. 6.323 at 15°. G. Chancel, W. Heintz, M. M. P. Muir, and A. de Schulten said the phosphate is anhydrous; the product obtained by L. Vanino and F. Hartl was the *trihydrate*, $\text{BiPO}_4 \cdot 3\text{H}_2\text{O}$. W. Heintz, and G. Chancel found that the phosphate is reduced when heated to redness in hydrogen; but not in carbon monoxide. R. M. Caven and A. Hill said that this phosphate is not hydrolyzed by water even when boiled for a long time; and C. Montemartini and U. Egidi added that it is relatively stable towards water, but suffers a little decomposition when the water is allowed to act for a long time. W. Heintz, M. M. P. Muir, and G. Chancel said that the phosphate is but sparingly soluble in water, and in dil. nitric acid, while boiling with dil. nitric acid does not alter the salt. L. Vanino and F. Hartl found that warming with potassium iodide does not change the phosphate, but hydrogen sulphide blackens it, forming the trisulphide; a boiling soln. of potassium hydroxide was found by R. M. Caven and A. Hill to decompose the phosphate easily and completely. R. H. Brett found the freshly precipitated phosphate to be readily soluble in a soln. of ammonium chloride. F. Paneth and W. Thimann studied the adsorption of aniline dyes by the phosphate.

According to A. Cavazzi, when a soln. of 10 grms. sodium hydrophosphate in 100 grms. of water and 55 c.c. of aq. ammonia is treated with a dil. ammoniacal soln. of 6 grms. of bismuth citrate, the basic salt, $4\text{Bi}_2\text{O}_3 \cdot \text{P}_2\text{O}_5$, or *bismuth enneaoxydiorthophosphate*, $3\text{Bi}_2\text{O}_3 \cdot 2\text{BiPO}_4$, is precipitated; and conversely, if the soln. of the bismuth citrate be added to the soln. of the sodium hydrophosphate, the precipitated basic salt is mixed with citrate. The white powder is insoluble in water, and soluble in hydrochloric, nitric, and citric acids.

According to A. Schwarzenberg, a boiling soln. of sodium pyrophosphate readily dissolves bismuth trioxide; and A. Stromeyer obtained **bismuth pyrophosphate**, $\text{Bi}_4(\text{P}_2\text{O}_7)_3$, by adding sodium pyrophosphate to a soln. of bismuth nitrate; the same precipitate was obtained by G. Chancel when the bismuth salt is in excess. K. A. Wallroth obtained this phosphate by dissolving bismuth trioxide in molten microcosmic salt at a bright red-heat, and keeping the glass in a state of fusion until crystallization occurs. The cold mass is extracted first with water, and then with dil. hydrochloric acid. Hexagonal plates are formed which are decomposed by water. G. Chancel said that if the salt be boiled with an acid soln. of bismuth nitrate, it rapidly forms the orthophosphate; F. Passerini said that the salt is sparingly soluble in water, and acetic acid, and freely soluble in hydrochloric or nitric acid; A. Stromeyer, and A. Brand said that the salt is soluble in a soln. of sodium pyrophosphate, but F. Passerini found it to be insoluble in that menstruum, as well as in a soln. of ammonium citrate. C. Raspe made **alkali bismuth pyrophosphates** by melting bismuth trioxide with the secondary alkali phosphates. A. Rosenheim and T. Triantaphyllides found that **sodium bismuth pyrophosphate**, $\text{Na}(\text{BiP}_2\text{O}_7) \cdot 3\text{H}_2\text{O}$, forms microscopic crystals.

J. Persoz obtained **bismuth metaphosphate** by mixing a nitric acid soln. of bismuth nitrate with metaphosphoric acid, and then adding ammonia. The white precipitate is insoluble in an excess of ammonia. When boiled with water, G. Chancel found that it slowly passes into the orthophosphate. According to T. Fleitmann, bismuth trioxide dissolves in molten phosphoric acid, forming a clear

glass, which, when slowly cooled, forms crystals of **bismuth tetrametaphosphate**, $\text{Bi}_4(\text{P}_4\text{O}_{12})_3$. It is insoluble in water, and when treated with sodium sulphide, it forms sodium tetrametaphosphate.

E. Glatzel prepared **bismuth orthosulphophosphate**, BiPS_4 , by heating bismuth trichloride with phosphorus pentasulphide. The dark grey crystalline mass furnishes a red powder. It burns with a pale flame when heated in air. It furnishes hydrogen sulphide when treated with hydrochloric acid; with conc. sulphuric acid it forms sulphur dioxide, but the dil. acid is without action; it is decomposed by aq. ammonia, by nitric acid, and by aqua regia with the separation of sulphur; it is insoluble in water, carbon disulphide, benzene, alcohol, ether, and acetic acid; and it is decomposed by aq. soln. of alkali hydroxides.

CHAPTER LIV

VANADIUM

§ 1. The History of Vanadium

In a letter to *l'Academie des Sciences de Paris*, A. von Humboldt¹ announced the discovery of a new metal by A. M. del Rio in 1801. The element was found in a plumbiferous mineral from Zimapan, Mexico, and it was called *erythronium*—from *ἐρυθρός*, red—in allusion to the red colour furnished by its salts when treated with acids. Both A. M. del Rio, and H. V. Collet-Descotils examined the mineral and announced that erythronium was nothing but a basic lead chromate; and the idea of a new element was abandoned. In 1830, N. G. Sefström described a new element which he found in the iron ores of Taberg, Sweden, and he observed that the properties of the iron prepared from these ores were peculiar, and he traced the anomaly to the presence of a new element. He suggested that it be named **vanadium**—from *Götting Freya Vanadin*, a Scandinavian goddess. Immediately afterwards, F. Wöhler established the identity of A. M. del Rio's erythronium with N. G. Sefström's vanadium. Thus erythronium was rediscovered, but its baptismal name was disregarded. F. Wöhler came near to the re-discovery, for he said that he had found something strange in a lead ore from Zimapan, Mexico, before N. G. Sefström's announcement of the discovery of vanadium, but he put it on one side for future examination. As J. J. Berzelius expressed it:

In the far north, there lived a goddess Vanadin, as beautiful as she was gracious. One day there came a knock at the door. The goddess was in no hurry and thought, "They can knock again"; but there came no further knocking, for he who knocked had passed on. The goddess wondered who it could be who cared so little to be let in and ran to the window, and recognized the departing one in the person of Wöhler. Some days afterwards some one else knocked repeatedly and loud. The goddess opened the door herself to Sefström, and vanadium was discovered.

In 1831, J. J. Berzelius² published a memoir: *Om vanadin och dess egenskaper*, describing some properties of the new element; but he overlooked the fact that what he supposed to be the element was really vanadous oxide, VO, and the trichloride was an oxychloride, VOCl₃. This was established by the work of H. E. Roscoe. The relationship between phosphorus and vanadium was brought out by the work of C. F. Rammelsberg,³ and J. Schabus. The monographs on vanadium include:

G. J. Rockwell, *Index to the Literature of Vanadium—1801–1877*, *Ann. New York Acad.*, 1. 133, 1879; V. von Klecki, *Analytische Chemie des Vanadins*, Hamburg, 1894; W. Prandtl, *Die Literatur des Vanadins—1804–1905*, Hamburg, 1906; F. Ephraim, *Die Vanadin und seine Verbindungen*, Stuttgart, 1904; H. Brearley, *A Bibliography of Steel-works Analysis*, *Chem. News*, 83. 163, 1901; P. Nicolardot, *Le vanadium*, Paris, 1905.

The element *vesbium*—named after an ancient name for Vesuvius—reported by E. Bechi,⁴ and A. Scacchi in some crevices in the lava flows of the 1631 Vesuvian eruption, was shown by F. Zambonini, and L. de Luise to be probably impure vanadium oxide—*vide infra*, vesbine. Similar remarks apply to M. Websky's *idunium* found in a vanadium ore from Aquadita.

§ 2. The Occurrence of Vanadium

Elemental vanadium does not occur in nature. Vanadium was once regarded as a scarce element, actually it is amongst one of the more abundant of the minor constituents of the earth's crust, for it is more abundantly distributed than nickel, nitrogen, copper, zinc, or lead. Estimates have been made by F. W. Clarke,¹ and J. H. L. Vogt. According to F. W. Clarke and H. S. Washington, vanadium constitutes 0.038 per cent. of the ten-mile crust—zirconium constitutes 0.048 per cent. and strontium, 0.032 per cent. J. H. L. Vogt gave 0.00n per cent. According to F. W. Clarke, the igneous rocks contain an average of 0.026 per cent. V_2O_3 , or 0.041 per cent. of vanadium. Analyses of 235 samples of Mississippi delta silts showed 0.02 per cent. of V_2O_3 ; and 52 samples of marine clays, 0.03 per cent. of V_2O_3 . W. Vernadsky gave 0.0034 for the percentage amount and 0.01 for the atomic proportion of antimony on the earth's crust.

J. N. Lockyer² showed that vanadium is probably contained in the sun. This was confirmed by H. A. Rowland, A. de Gramont, F. W. Dyson, W. M. Mitchell, W. S. Adams, G. E. Hale and co-workers, and C. C. Hutchins and E. L. Holden. The presence of vanadium in meteorites has been reported by R. Apjohn,³ and B. Hasselberg. The last-named found vanadium in thirty-one stony meteorites which he examined, but not in meteoric iron, but he could not confirm J. N. Lockyer's report that vanadium occurs in the meteoric iron of Nejed, and Obernkirchen.

The occurrence of vanadium has been discussed by C. Czudnowicz,⁴ D. T. Day, L. Dieulafait, I. Domeyko, C. R. Fletcher, A. A. Hayes, M. W. Iles, C. F. Rammelsberg, H. E. Roscoe, F. M. Turner, R. Wagner, etc. The vanadium minerals include :

Sulphide ores.—*Patronite*—a vanadium sulphide with the varieties rizopatronite, and vanadiferous asphaltite containing asphaltic carbon. *Bravoite* is an iron nickel sulphide containing vanadium. *Sulvanite* has the composition $V_2S_5 \cdot 3Cu_2S$.

Oxidized ores.—*Alaite*, $V_2O_5 \cdot H_2O$; *ardennite* or *devalquite*, a complex iron aluminium vanadate-silicate, $10(Mn, Mg, Ca, Fe)O \cdot 5(Al, Fe)_2O_3 \cdot 5(V, As)_2O_5 \cdot 10SiO_2 \cdot 6H_2O$; *roscolite*, vanadium-mica; *pucherite*, $BiVO_4$; *deschenite*, and *eusynchite* varieties of lead vanadate; *vanadinite*, $Pb_4(VO_4)_3 \cdot PbCl$ —with the variety *endlicheite*; *descloizite*, $(Pb, Zn)_4V_2O_8(OH)_2$ —with the varieties *cuprodescloizite*, *aræoxene*, *ramirite*, *tritochorite*; *calciovolborthite*, $(Cu, Ca)_4V_2O_8(OH)_2$; *brackebuschite*, $(Pb, Fe, Mn)_3V_2O_8 \cdot H_2O$; *psittacinite*, $(Pb, Cu)_4V_2O_8(OH)_2 \cdot H_2O$; *motttramite*, $(Cu, Pb)_6V_2O_{10} \cdot 2H_2O$; *eosite*, a lead vanadate; and molybdate; *chileite*, a lead copper vanadate; *vanadiolite*, a siliceous lead vanadate; *wicklowite*, a lead vanadate; *volborthite*, $(Cu, Ca, Ba)_3V_2O_8(OH)_2 \cdot 6H_2O$; *carnotite*, $(KO)_2 \cdot U_3O_8 \cdot V_2O_5 \cdot 3H_2O$; *ferganite*, $U_2(VO_4)_2 \cdot 6H_2O$; *uranite*, $5CuO \cdot V_2O_5 \cdot 2H_2O$; *hewettite*; and *metahewittite*— $CaH_2V_6O_{17} \cdot 8H_2O$ —*pascoite*, $Ca_2V_6O_{17} \cdot 11H_2O$ —and *fernandinite*,

$\text{CaO} \cdot \text{V}_2\text{O}_4 \cdot 5\text{V}_2\text{O}_5 \cdot 14\text{H}_2\text{O}$; *tyuyamunite*, uranium calcium vanadate; *minasragrite* is a vanadium sulphate; *fritscheite*, a vanadiferous autunite—it is coloured red by manganese; *lawrowite* or *taffroffite*, a vanadiferous pyroxene; *vanadiferous augite*; *vanadiferous gummitz*; *vanadium ochre*. G. P. Tschernik⁵ studied the urano-vanadium ores of the Ferghan territory, Russia; and S. Kurbatoff, in Minusinsk.

Vanadium is very widely distributed on the earth's crust, but this fact is of little economic importance. The specialized deposits, where the element is sufficiently concentrated to enable it to be extracted for commercial purposes, were classified by L. de Launay⁶ somewhat as follows: (i) Segregations from basic magmas—*e.g.* in association with ilmenites and titaniferous magnetites. (ii) In veins of hydrothermal origin—*e.g.* in association with uranium ores or gold tellurides. (iii) Sulphide ores associated with hydrocarbons—*e.g.* the patronite deposit of Minasrag and the asphaltites of Peru and Nevada. (iv) The oxidized upper levels of lead and copper lodes—*e.g.* the vanadium minerals—vanadinite, descloizite, chileite, etc. (v) Deposits in sedimentary rocks—*e.g.* the carnotites of Colorado and Utah; the French bauxites and laterites; the minette ores of Lorraine, etc. The geographical distribution is illustrated by the map, Fig. 1.

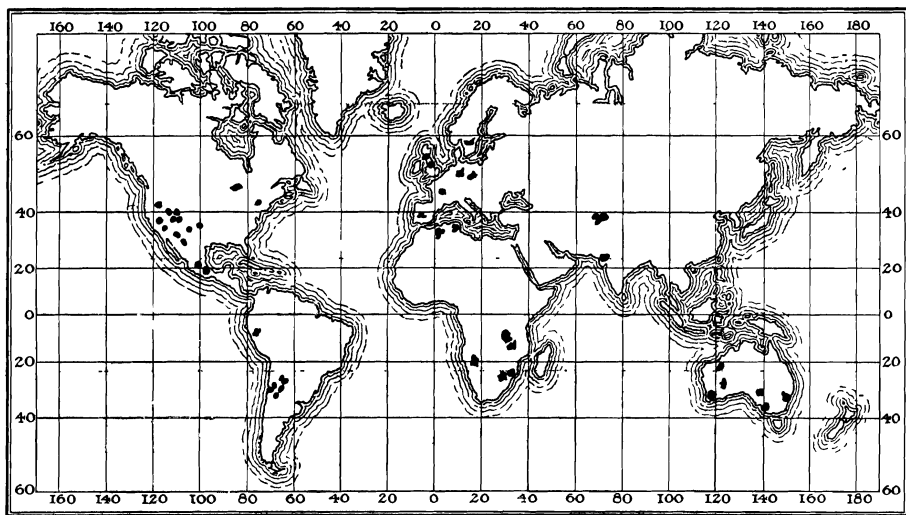

FIG. 1.—The Geographical Distribution of the Vanadium Ores.

Europe and Asia.—In *England*,⁷ vanadiferous minerals occur at Mottram St. Andrew, and Alderley Edge in Cheshire; and associated with the lead-copper-cobalt deposits of Staffordshire and Shropshire. None of the deposits are of commercial value as sources of vanadium. In *Czechoslovakia*, vanadium is associated with the silver and other ores of Joachimsthal. In *Germany*,⁸ vanadium has been found associated with the Kupferschiefer of Mansfield. In *Luxemburg*, and *France*,⁹ vanadium is found in bauxites, shales, clays, and the minette iron ores. At Le Creusot, vanadium has been extracted commercially from the slags derived from the smelting of the volcanic ores of Mazonay, Saône-et-Loire. In *Spain*,¹⁰ much of the world's supply was obtained from the vanadate ores of Santa Marta, Estremadura. In *Sweden*,¹¹ vanadium occurs in the titaniferous ores of Taberg, and in the ash of the coal in Billingen Skaraborg Län. In *Russia*,¹² vanadium ores have been reported from some parts of the Ural Mountains. Vanadium ores have been obtained from the Altai Mountains in the north of Russian *Turkestan*. One deposit is said to have been formerly worked by the Chinese for copper.

Africa.—In northern *Rhodesia*,¹³ vanadium ores are found associated with the oxidized lead and zinc ores of the Broken Hill district; some mottramite has been mined in the *Tanganyika Territory*; and there are a number of workable deposits in the northern part of *South-West Africa* near a line running N.W. to S.E. between Uris and Berg Ankas. In the *Transvaal*, there are deposits at the Doornhoek lead mine, Marico district; at Kafferskraal, near Ottoshoop; and at Messina. Vanadate minerals occur in North Africa at Oran in *Algeria*, in *Tunis*, etc. There is a deposit at Ruwe in the *Congo Free State*.

America.—Vanadium ores occur in the *United States*¹⁴ in the area comprising the states of Colorado and Utah; and in the southern regions of the Rocky Mountain chain in the states of Arizona, and New Mexico. Some carnotite occurs near Mauch Chunk, Pennsylvania; and vanadium ores have been reported from Baraga Co., Michigan; Eastern Oregon; Sangre de Cristo Range, Colorado; San Bernardino Co., California; and Good Springs, Nevada. The asphaltites of Oklahoma and Arkansas are vanadiferous. There are numerous ores of the vanadate class associated with the deposits of lead ores in the northern and central portions of *Mexico*.¹⁵ There is a small output of vanadium from *Argentina*.¹⁶ It occurs in the provinces of Mendoza, San Luis, and Cordoba. Vanadium minerals have been reported from several places in the provinces of Coquimbo, *Chili*—Arqueros, and Mina Grande near Marqueza. There are deposits of vanadium in *Peru*.¹⁷

Australia.—Small quantities of vanadium have been reported in coal ashes, ironstones, etc., in the vicinity of Sydney, *New South Wales*.¹⁸ Carnotite has been reported from Radium Hill, and Mount Painter; vanadium ore has also been found in a few other localities—Leigh's Creek District, Booleroo Springs, and Apoinga—in *South Australia*. Vanadium is said to be of widespread occurrence in the greenstones, laterites, coal-ashes, and clays of *Western Australia*. Roscoelite occurs at Kalgoorlie, Niagara, Coolgardie, Menzies, and Pinyalling.

Up to the end of the nineteenth century, only a small amount of vanadium was used in commerce. A little of this was obtained from Joachimsthal, Bohemia, from the vanadiferous slags of the ironworks at Creusot, France, from Spain, and from Mexico. The discovery of the vanadium ores at Minasraga, Peru, in 1904, led to the commercial development of vanadium. These deposits are the main source of the world's supply, and this is supplemented by supplies from Colorado, and Utah. The following data are abridged from the monograph on *Vanadium Ores* by the Imperial Institute, London:

	1909	1912	1915	1918	1920	1922
Peru . . .	392	684	804	371	1110	none
United States . . .	—	300	569	250	462	100

where the concentrate is expressed in metric tons of metal. In 1912, Argentina produced 14, and Spain 199 metric tons of concentrate; in 1913, 40 and 30 metric tons respectively; and in 1914, none. For 1926, Northern Rhodesia produced 171 long tons; South-West Africa Territory, 5058; and United States, 275 long tons. The price of ferrovanadium in 1909–10 was about \$5.00 per pound of contained vanadium; in 1915–16, about \$2.50; in 1920, \$6.00–\$7.00; and in 1921, \$5.00–\$5.50.

The occurrence of vanadium in a number of minerals and rocks has been reported. Thus, C. Porlezza and A. Donati¹⁹ found vanadium in the tufa of Fiuggi; A. Donati found it in the 1916-eruption products of Stromboli; G. Carobbi, in a boric acid fumarole on Vesuvius; and L. Ricciardi found 0.0063–0.0081 per cent. V_2O_3 in lava from Vesuvius and Etna; and 0.0105–0.13 per cent. in *basaltic rocks*. W. F. Hillebrand found up to 0.08 per cent. V_2O_3 in the more basic eruptive and metamorphic rocks, and vanadium was generally absent from rocks rich in silica. He supposed that *biotite*, *pyroxene*, and *amphibole* carry the vanadium, and he found 0.012–0.127 per cent. of V_2O_3 in biotites and amphiboles. The vanadium is supposed to be present as V_2O_3 , in isomorphous association with alumina and ferric oxide. This subject was discussed by J. H. L. Vogt. Vanadium was also found by E. Bechi to occur in many Italian rocks—basalt, *travertine*, *calcite*, and *sandstone*. T. Engelhardt observed up to 0.012 per cent. of V_2O_5 in some German basalts, and *dolerites*. V. Roussel found vanadium in some French basalts; J. C. H. Mingaye, in some basalts of New South Wales; and R. Apjohn, and E. Sonstadt, in some trap-rocks. W. F. Hillebrand found very small quantities of vanadium in a number of limestones, and sandstones; and W. F. Hillebrand and F. L. Ransome observed that the binding agent of some Colorado sandstones—designated by C. Friedel and E. Cumenge, carnotite—is a cryptocrystalline potassium vanadatoaluminosilicate. The occurrence of vanadium in the *clays* of Gentilly has been observed by P. Beauvallet; in the clays of Forges-les-Eaux, and Dreux, by A. Terreil; in London clay (0.02–0.06 per cent. V_2O_3), Sussex gault clay (0.06–0.07 per cent.), and in a white

Belgian clay (0.03 per cent.), by T. L. Phipson : in the Keuper clay of Bornholm, by G. Forchhammer ; the clay of Lindener Mark, by C. Huber ; in lignitic clays, by H. Seger, O. Kallauner and I. I. Hruda, and F. Stolba, in the clays of New South Wales, by J. C. H. Mingaye. Nearly all British fireclays contain some vanadium. Naturally, also, vanadium occurs in goods made from titaniferous clays, and if such are under-fired, the vanadium is liable to work its way to the surface in wet weather, and it then produces a yellowish-green scum of alkali vanadate. This was observed by H. Seger, F. Stolba, and J. C. H. Mingaye.

Vanadium has been reported in many *iron ores* of the magnetite type ; and J. Walz found the largest proportion in the titaniferous ores. F. J. Pope obtained between 0.23 and 0.63 per cent. V_2O_5 in some titaniferous magnetites. Many secondary iron ores, like limonite (*q.v.*), contain vanadium. This was established by the observations of C. Bödeker, T. Bodemann, R. Böttger, F. W. Daw, I. Deck, H. St. C. Deville, J. Fritzsche, R. J. Hodges, L. l'Hôte, C. Kersten, A. Müller, T. L. Phipson, E. Riley, N. G. Sefström, R. von Seth, A. Schultz, C. M. Stillwell, L. F. Svanberg, and A. Terreil. As a consequence of the presence of vanadium in iron ores, vanadium has also been frequently found in *raw iron* as well as in the *slags* from blast furnaces—*e.g.*, by L. Blum, I. Deck, J. Fritzsche, C. Kersten, A. Müller, E. Riley, A. Schrötter, N. G. Sefström, R. von Seth, A. Terreil, and G. Witz and F. Osmond. C. Kersten found vanadium to be present in the *copper schists* of Mansfield ; while H. E. Roscoe, P. Krusch, D. J. Planer, C. Czudnowicz, and H. Credner found the element present in other cupriferos ores. A. R. Alderman observed up to 0.84 per cent. V_2O_5 in some titaniferous ores of South Australia.

H. St. C. Deville, L. l'Hôte, and L. Dieulafait reported vanadium to be present in *barzite* ; H. St. C. Deville, in *cerite* ; A. Breithaupt and F. W. Fritzsche, in *conichalcite* ; C. F. Rammelsberg, in *crednerite* ; H. St. C. Deville, in *cryolite* ; A. Jorissen, in *delvauxite* ; E. S. Larsen and W. F. Hunt, in *ægirite* ; A. E. Fersman, in *vanadiolaumontite* ; C. Bergmann, in *ehlite* ; C. Kersten, in *gummite* ; G. A. Koenig, in *garnet* ; L. F. Svanberg, in *hydrophite* ; F. Wöhler, C. F. Rammelsberg, and C. Czudnowicz, in a yellow *lead ore* ; W. F. Hillebränd, in *mica* ; I. Domeyko, N. von Kokscharoff, and W. P. Blake, in *mimetesite*, and in *pyromorphite* ; A. Patera, C. Kersten, C. von Hauer, L. l'Hôte, H. D. A. Ficinus, F. Wöhler, L. F. Svansberg, C. Giseke, and H. C. Bolton, in *pitchblende*, *uraninite*, and other *uranium ores* ; C. Huber, H. Laspeyres, and C. F. Rammelsberg, in *psilomelane* ; C. F. Naumann, in *pyrolusite* ; H. St. C. Deville, O. F. von der Pfordten, C. B. Hasselberg, and W. B. Giles, in *rutile* ; C. Palache and E. V. Shannon, in *higginsite* ; G. A. Koenig, in *schorlomite* ; H. D. A. Ficinus, and A. Vogel, in *serpentine* ; E. F. Smith and F. F. Exner, in *woframite* ; J. L. Smith, C. F. Rammelsberg, and F. Wöhler, in *wulfenite* ; R. Klemm, in *zircon* ; and F. Zambonini, in *vestine*.

Vanadium has been reported to occur in the ash or flue-dust of numerous *lignites* and *coals* by C. Baskerville, H. Ramage, A. Jorissen, J. Kyle, T. y Meca, J. C. H. Mingaye, and A. Mourlot ; and the occurrence of vanadium in Mexican *petroleum* was observed by J. E. Hackford, E. de Golyer ; in Egyptian oil, by W. A. Guthrie ; and in Persian petroleum, by A. E. Dunstan. The Standard Development Co. extracted vanadium from petroleum ash. According to E. S. Porter, the fact that vanadium is found in peat, lignite, and coal in small percentages, indicates that the vanadium was a constituent of the plant life from which these deposits originated ; and this view is supported by the presence of vanadium in the ashes of many plants. On the other hand, in the asphaltitic deposits of Peru, where comparatively high percentages of vanadium occur, it is probable that the element has been concentrated by some means other than the inspissation of petroleum (*vide infra*). A. A. Hayes, and G. Witz and F. Osmond found vanadium occurring in certain *natural waters*. A. A. Bado observed it in the subterranean waters of Bellville, Cordova, Argentine. E. Demarçay found vanadium in the ashes of some *plants*—*e.g.* horn-beam, poplar, vine, oak, silver fir, and Scotch fir. E. O. von Lippmann, and A. von Wachtfl found vanadium in beet

vinasse, or in potassium hydroxide derived therefrom; E. F. Smith also found it in commercial potassium hydroxide; A. Baumgarten, T. E. Thorpe, A. Scheurer-Kestner, E. Donath, and H. L. Robinson found it in commercial sodium hydroxide; C. F. Rammelsberg, in the mother-liquors of a soda-works; A. Baumgarten, in alkali phosphate; H. C. Bolton, in uranium oxide.

The vanadium cycle in nature.—Water charged with atmospheric gases can dissolve vanadium in soluble alkali vanadates; if such water comes in contact with natural ores of lead—galena, anglesite, cerussite—lead vanadate will be formed, and such an ore is the chief natural source of vanadium. According to W. Lindgren,²⁰ during the process of the weathering of rocks and ores, a part of the vanadium passes into soln., and becomes concentrated in the limonite like phosphorus, but in smaller proportions. This is illustrated by the fact that bog-iron ores usually contain vanadium. Much of the vanadium is concentrated in sediments as shown by the wide distribution of vanadium in many sandstones. Vanadium also accumulates in silts and muds more than it does in the coarser sediments. This is illustrated by the common occurrence of vanadium in clays. It may be carried along with alumina in colloidal suspensions. Finally, a small proportion of vanadium is taken into soln. by surface waters, probably as calcium vanadate, and is carried to the sea. While vanadium has not been reported as a constituent of sea-water, it seems to be there, for it is absorbed from this source by holothurians and ascidians as a substitute for copper or phosphorus in their blood. After the death of the animal, the vanadium returns to the sea-water, or becomes buried in the sediments. It is not unlikely that vanadium is concentrated in sea-water by other animals.

W. Lindgren continued: "It is strongly suspected that plants use vanadium as a substitute for phosphorus. The ashes of plants, coals, and asphaltic substances in many localities contain vanadium. This element seems to have been gradually concentrated during the formation of asphaltum. Coaly substances may precipitate vanadium from meteoric waters, but it is more probable that vanadium formed part of the original organism from which asphaltum is derived. Bituminous shales often contain vanadium. The mesozoic sediments of Peru represented by black shales, contain 0.12–0.41 per cent. When sedimentary rocks containing vanadium are percolated by underground waters, at considerable depths, some of the element passes into soln. and is again precipitated as vanadium mica—roscoelite—or potassium uranium vanadate—carnotite. The ores are formed later than the beds, and are characterized by a very strange assortment of elements, among which, besides the two already mentioned, are copper, lead, silver, barium, chromium, nickel, molybdenum, and selenium. Igneous rocks are absent. Thus far no entirely satisfactory explanation of the mode of origin of these deposits has been formulated. Most of the elements just referred to are such as are known to be relatively concentrated in sediments. To sum up, it is believed that vanadium was first moderately conc. in fine sediments, and that a second conc. has been effected by biochemical processes followed by a third conc. by meteoric waters and reprecipitation at suitable places. It is held that the second conc. and perhaps the third resulted in finely disseminated 'patronite,' owing to the combination of vanadium with sulphur likewise of organic origin. Still later processes of alteration resulted in such minerals as carnotite and roscoelite." The formation of vanadium minerals in nature has been also discussed by L. Dieulafait, J. H. L. Vogt, F. B. Notestein, and A. Ditte.

§ 3. The Extraction of Vanadium

Vanadium is extracted from the sulphide ores typified by patronite; from the silicates typified by roscoelite; from uranium-vanadium ores typified by carnotite; and from vanadate ores typified by descloizite and volborthite. It can also be extracted from slags and other substances—clays, iron ores, *etc.* Vanadium is also produced as an alloy with iron—ferrovanadium.

The extraction of vanadium salts as ammonium vanadate, *etc.*—In the wet processes for the extraction of vanadic oxide from minerals opened up by nitric acid the soln. is treated with aq. ammonia, and ammonium sulphide. Lead sulphide is precipitated, and the dark red filtrate gives a precipitate of vanadium sulphide when treated with acids. The sulphide is roasted in air, fused with potassium nitrate, and the aq. soln. of potassium vanadate is treated with ammonium chloride, and the ammonium vanadate crystallizes out. J. F. W. Johnston¹ dissolved vanadinite in nitric acid, precipitated the lead and arsenic by hydrogen sulphide; evaporated the filtrate to dryness; and boiled the residue with a sat. soln. of ammonium carbonate. On cooling the liquid, he obtained crystals of ammonium vanadate which were purified by recrystallization. F. Wöhler treated vanadinite with fuming hydrochloric acid and alcohol; evaporated the filtrate from lead chloride with an excess of acid; decomposed the product with an excess of sodium hydroxide; oxidized the liquid with chlorine; and precipitated ammonium vanadate by the addition of ammonium chloride.

A number of dry processes have been employed. In L. l'Hôte's process, the powdered mineral was mixed with four times its weight of lamp-black, made into a pasty mass with oil, heated, and then exposed at 300° to a current of chlorine. Vanadium oxychloride distils off at 210°, and is collected in a suitable receiver. H. Herrenschildt fused a mixture of vanadinite with sodium carbonate to convert all the vanadium into sodium vanadate by the oxidizing action of the air. H. P. Smith melted the vanadinite with potassium nitrate; the aq. extract was warmed with steam, while iron plates were immersed in the liquid. The mixed iron and vanadium hydroxides were precipitated from the dark green liquid by means of soda-lye, and the washed precipitate used for the manufacture of ferro-vanadium. The sodium vanadate was washed out with boiling water and converted into vanadic acid by treatment with sulphuric acid.

To extract vanadium from clays, slags, *etc.*, the powdered product is opened up by fusion in air with potassium nitrate (F. Wöhler); sodium nitrate (G. Forchhammer); a mixture of potassium nitrate and sodium hydroxide (R. Böttger); a mixture of potassium nitrate and sodium carbonate (N. G. Sefström, J. J. Berzelius, F. Wöhler, C. Kersten, and A. Patera); sodium chloride and sulphuric acid (H. T. Koenig); or a mixture of alkali and a sulphide (Electrometallurgical Co.). E. Classen treated powdered magnetite with sulphuric acid and drove off the excess of acid by heat; the residue was fused with six times its weight of sodium carbonate alone or in admixture with potassium nitrate. This treatment converts the vanadium into soluble alkali vanadate. A. Wittig used a mixture of sulphuric acid and sulphurous acid or a sulphite. N. G. Sefström thoroughly extracted the mass with boiling water, and neutralized the liquor with nitric acid free from nitrites to avoid reducing the vanadic acid. The silica is removed by filtration. If the silica has a red colour, it is freed from vanadium by digestion with ammonia and washing with water. The filtrate is treated with lead nitrate or acetate. The precipitated lead vanadate is washed; and repeatedly agitated with conc. hydrochloric acid; mixed with alcohol; and heated for some hours nearly to the b.p. of the alcohol. The blue filtered liquid is evaporated to dryness, dissolved in water, mixed with nitric acid, sat. with potassium carbonate,

evaporated to dryness, and fused. The cold product is dissolved in the smallest possible quantity of water; and the vanadic acid precipitated as ammonium vanadate by the addition of solid ammonium chloride. The phosphoric acid is removed by washing this salt with a soln. of ammonium chloride, and then with alcohol. J. J. Berzelius said that silica is removed by treating the soln. in sulphuric acid with hydrofluoric acid, evaporating the mixture to dryness, etc. B. W. Gerland showed that it is easy to remove soda from the ammonium vanadate, but potash is retained very tenaciously. Modifications of the process for iron ores and slags were used by J. J. Berzelius, B. P. F. Kjellberg, K. B. Thews, J. A. Norblad, R. von Seth, H. Nagell, E. Petersen, G. Witz and F. Osmond, and L. Blum. F. L. Hahn and W. Franke heated at 250°–300° a vanadate under press. with carbon tetrachloride and extracted the product with acids. J. E. Conley described the extraction of vanadium from descloizite and vanadinite.

In Peru, patronite is mixed with the necessary fluxes and roasted in a reverberatory furnace. The heavy metals form a matte, and the vanadium and gangue pass into the slag. The slag is granulated in water, dried, and reduced to ferrovanadium in a blast furnace. In general, the vanadates are fused with sodium salts when the vanadium passes into the slag as sodium vanadate, while the lead, copper, or zinc separates as metals. The slag is crushed, mixed with sulphuric acid, and baked so as to form a dry cake. This is crushed, leached with boiling water, and the soln. of vanadium sulphate is evaporated. This is roasted and reduced to ferrovanadium by the thermite process. J. E. Conley described a process for the recovery of vanadium from lead vanadate, etc. The extraction of vanadium from iron slags was described by R. H. von Seth and G. Hult; from iron and copper slags, by J. Fritzsche, E. Riley, R. H. von Seth, and C. Kersten; from ferruginous and calcareous bauxites, by H. St. C. Deville, and E. E. Dutt; from tufa, lava, and granite, by C. Porlezza and A. Donati; from clays, by P. Beauvallet, H. St. C. Deville, H. A. Doermer, and G. Forchhammer; from ilmenite, by the Radium and Rare Earths Treatment Co.; from sandstone, by H. E. Roscoe; and from petroleum residues, by A. Oberle. B. D. Saklatwalla roasted roscoelite with salt and pyrites; leached the product with hot water; and added ferrous sulphate to the cold soln. to precipitate the vanadium as iron vanadate. B. P. F. Kjellberg described a process for recovering vanadium from titaniferous ores; and H. G. C. Fairbanks, for the purification of vanadates.

The extraction of vanadium from pitchblende, and carnotite was described by F. Wöhler, C. Giseke, W. F. Blecker, J. E. Conley, C. von Hauer, A. Safarik, A. Patera, A. T. Elliott, K. B. Thews, K. B. Thews and F. J. Heinle, C. Lallemand, and J. Ohly. G. Gin decomposed carnotite by fusion with potassium hydrosulphate. After soln. in water, concentration, and cooling, the uranium and vanadium separate as the double potassium sulphate. On treatment with zinc the vanadium is reduced, and is then precipitated by neutralization with ammonia and addition of ammonium carbonate; the uranium is obtained on boiling the filtrate. Another method is based on heating to redness in the vapour of ferric chloride, when vanadyl chloride VOCl_3 , which is readily volatile, is formed. B. D. Saklatwalla boiled the ore with dil. sulphuric acid (1 : 1), and added ammonium persulphate to the soln. After a prolonged boiling, vanadium separates as a red hydroxide, which forms the pentoxide when heated. H. Fleck and W. G. Haldane patented a method in which the crushed ore is agitated with 15–20 per cent. sulphuric acid, and the acidic soln. containing the uranium, vanadium, iron, and copper brought into contact with fresh ore until neutral, when some of the required constituents will be precipitated upon it as basic sulphates or carbonates; the enriched ore is then treated with fresh acid, and the neutral soln. clarified by filtration; powdered limestone added until the uranium, vanadium, and copper fractions just commence to separate; the soln. is then freed from calcium sulphate, and the required fraction completely precipitated by further treatment with limestone. The product (a complex mixture) may be dried, ignited, or else further purified by any of the known methods.

J. H. Haynes believed that no method employing sulphuric acid can be commercially successful. It is considered that the best method of separating the uranium and vanadium of carnotite is founded on the fact that both elements can be dissolved by a hot soln. of sodium carbonate as sodium uranium carbonate, $2\text{Na}_2\text{CO}_3 \cdot \text{UO}_2\text{CO}_2$, and sodium vanadate, NaVO_4 , and thus separated from calcium and iron. The uranium is then precipitated as sodium uranate, $\text{Na}_2\text{O} \cdot 3\text{UO}_2$, with sodium hydroxide, and the vanadium subsequently separated from the filtrate as calcium vanadate or as ferrous vanadate. The metallurgy of the lead vanadates was discussed by W. Baughman. In the case of carnotite, the radium is first extracted, and the vanadium recovered as a by-product. In the process described by C. L. Parsons and co-workers :

The ore is first leached with conc. nitric acid heated to 100° by steam. The soln. is neutralized with sodium hydroxide, and treated with barium chloride and sulphuric acid to precipitate radium and barium sulphates. The precipitate settles in about 3 or 4 days. The clear liquor is decanted into tanks, and treated with an excess of a boiling soln. of sodium carbonate so as to precipitate iron, calcium, and most of the aluminium. The soln. containing sodium uranyl carbonate, and sodium vanadate is nearly neutralized with nitric acid and treated with sodium hydroxide so as to precipitate uranium as sodium uranate. The remaining soln. is treated with nitric acid and ferrous sulphate so as to precipitate the vanadium as iron vanadate. It is said that 90 per cent. of the radium, nearly all the uranium, and 50 per cent. of the vanadium, are recovered from the ore by this process. Summarizing the operations :

The isolation of vanadium metal.—In 1831, J. J. Berzelius² thought that he had isolated vanadium by heating vanadium oxytrichloride in ammonia gas, but A. Safarik, E. Uhrlaub, and H. E. Roscoe showed that the product was probably vanadium nitride; and if the nitride be heated in hydrogen, H. E. Roscoe said that no metal is formed. The crystals obtained by A. Safarik by passing the vapour of vanadium oxytrichloride and hydrogen through a red-hot tube were shown by H. E. Roscoe to be a mixture of lower oxychlorides. The product obtained by J. J. Berzelius by heating vanadium pentoxide with potassium was found by H. E. Roscoe to be a mixture of oxides; and he was unable to prepare the metal by heating white-hot vanadium trioxide alone or mixed with sodium in a current of hydrogen, by heating the trioxide mixed with magnesium in a graphite crucible; or by passing the vapour of vanadium oxytrichloride over heated sodium. He also showed that the product obtained by J. F. W. Johnston by heating vanadium pentoxide with carbon was probably vanadium silicide; with a mixture of vanadium trioxide and silicon-free carbon, a mixture of oxides is produced. M. A. Hunter and A. Jones obtained a metal of sp. gr. 5.97 by heating the anhydrous chloride with sodium in a steel bomb. H. von Wartenberg said that the trioxide at 2500° can be reduced to the metal by hydrogen at 5 atm. press. H. Moissan obtained a vanadium-aluminium alloy by heating vanadium pentoxide and aluminium;

K. Héroult obtained a mixture of oxides by reducing the pentoxide with aluminium; and H. Kunzel and E. Wedekind, with calcium. H. Goldschmidt obtained a regulus which W. Hittorf found to be vanadium hemioxide; and J. Koppel and A. Kaufmann were unable to make vanadium by the thermite process alone or in the presence of calcium fluoride, carbon, or calcium carbide. A. Wittig used the thermite process, but first heating to redness the vanadium compound with an ammonium salt before it is mixed with aluminium in the usual way.

H. E. Roscoe obtained vanadium by heating to redness vanadium di- or tri-chloride, contained in a platinum boat, in a current of hydrogen free from traces of oxygen, and after 40–80 hrs. raising the temp. to whiteness for a short time. The product contained 95.8 per cent. vanadium, and occluded hydrogen. The operation is difficult to carry out successfully, and H. E. Roscoe has given a full description of the experimental minutiae. R. Edson and D. McIntosh made vanadium on a small scale by passing a current of hydrogen through vanadyl chloride past a glowing platinum wire filament heated electrically, a silver-grey coating of vanadium is deposited smoothly on the platinum. The metal was also obtained by H. E. Roscoe by reducing the solid chloride by sodium, at a red-heat in hydrogen. The product was separated from admixed trioxide by levigation, and after washing in water, contained 91.1 per cent. metal. W. Prandtl and H. Manz, and C. Setterberg obtained 98.7 per cent. vanadium by this process. M. Billy prepared what he regarded as pure vanadium by passing the vapour of the chloride over sodium hydride at about 400°. The sodium chloride is extracted by acid and water, and the metal dried at 100° in a current of carbon dioxide. Attempts to prepare vanadium by reducing the oxide with aluminium by H. Goldschmidt and C. Vautin's process, were failures in the hands of J. Koppel and A. Kaufmann, and gave only an impure metal in the hands of R. Vogel and G. Tammann. W. Muthmann reduced vanadium pentoxide by rare earth metals in the form of *mischmetal*. L. Weiss and O. Aichel recommended heating a mixture of 25 grms. of vanadium pentoxide, 49 grms. of *mischmetal* in a fireclay crucible lined with magnesia, and ignited by a mixture of 40 parts of barium dioxide, 7 parts of potassium chlorate, and 10 parts of aluminium powder. The reaction proceeds very rapidly, and the regulus of 10 grms. is vanadium of a high degree of purity. H. Moissan heated a mixture of vanadium oxide with sugar charcoal for 2 mins. in an atm. of hydrogen in a carbon tube furnace, vanadium containing 4.4–5.3 per cent. of carbon was obtained—if the heating be too long continued, a carbide is formed. According to W. Prandtl and B. Bleyer, calcium reduces vanadium oxide vigorously, but owing to the absence of a fusible slag, the metal remains in isolated particles. A mixture of calcium (3 gram atoms) and aluminium (2 gram atoms) acts readily, and yields a fusible, crystalline slag and a homogeneous regulus. If large quantities are used, it is advisable to moderate the violence of the reaction by dil. with slag or previously prepared metal. According to O. Ruff and W. Martin, vanadium trioxide gives better results than the pentoxide on account of the greater fusibility of the latter which causes it to pass into the slag; on the other hand, W. Prandtl and H. Manz said that the better results are obtained with the pentoxide. A. S. Cachemaille heated to 800°–1000° a mixture of vanadium oxide with an excess of calcium and an alkali or alkaline earth halide in an iron bomb lined with lime. The cold product was washed with water, dil. acid, or alcohol. J. W. Marden and M. N. Rich recommended reducing vanadium pentoxide by a mixture of calcium and calcium carbide with a small piece of potassium or sodium on top of the charge placed in a bomb. The function of the alkali metal is to clean up any moisture present. The sealed bomb is heated to 900°–950°.

W. von Bolton prepared the metal by passing an electric current through thin rods of vanadium trioxide contained in a vacuum furnace. O. Ruff and W. Martin obtained vanadium by pressing a mixture of aluminium, vanadium trioxide, and 2 per cent. of carbon into a crucible lined with magnesia. The crucible is covered and heated to redness after adding a layer of ignition mixture. The product contains

95 per cent. of vanadium. Reduction with carbon in an arc gives a less pure product. Products containing from 95 to 97 per cent. of vanadium are obtained by moulding mixtures of the trioxide and carbon with starch into rods, sintering in an electric furnace at 1750° , and finally in an arc. The impurity consists of carbon or oxygen, according to the proportions employed. They also obtained vanadium by heating vanadium trioxide and carbide in a zirconia crucible at 1950° . W. Prandtl and H. Manz said that the presence of alkali in the aluminothermite process is harmful because of the passage of alkali vanadate into the slag. Attempts to remove oxygen from the product by adding the hydride, were not successful.

According to G. Gin, vanadium can be obtained by the electrolysis of fused calcium fluoride, to which some fluoride of iron is added. The anode consists of a mixture of vanadium trioxide and carbon; compressed and roasted in the way used in making anodes of carbon alone, the cathode is a bath of fused steel. In making alloys containing more than 25 per cent. of vanadium, a current density of 2 amps. per sq. cm. at the anode and 6 amps. per sq. cm. at the cathode is used; 11–12 volts are required. It is supposed that iron fluoride is electrolyzed, the fluorine liberated reacting with the anode, thus: $6F + V_2O_3 + 3C = 2VF_3 + 3CO$, the vanadium fluoride dissolves in the fused calcium fluoride and is then itself electrolyzed. According to S. Cowper-Coles, vanadium can be obtained as a brilliant, metallic deposit by the electrolysis of a soln. of 1.75 parts of vanadium pentoxide, 2 parts of sodium hydroxide, 160 parts of water, and 32 parts of hydrochloric acid, using a current of 18–20 amps. per sq. ft., and an e.m.f. of 1.88 volts at the terminals of the electrolytic cell—the anode is of carbon, the cathode of platinum. C. Setterberg was unable to obtain the metal by the electrolysis of aq. soln. If a soln. of ammonium vanadate be electrolyzed, a reddish-brown mass containing nitrogen, oxygen and vanadium is deposited on the anode; and if a soln. of vanadium tetroxide in hydrochloric acid be electrolyzed in a compartment cell, the blue liquid becomes brown, and a black deposit of vanadium trioxide collects on the cathode, and flecks of vanadium pentoxide collect on the anode. The electrical conductivity of vanadyl chloride or vanadium tetrachloride is too small to enable it to be electrolyzed. P. Truchot found that vanadium is deposited as oxyhydrate when hot, slightly ammoniacal soln. of sodium vanadate are electrolyzed. R. E. Myers obtained a reduction but no deposition of vanadium by the electrolysis of an acidified soln. of sodium vanadate using a mercury cathode. It may be said that all attempts to obtain the metal vanadium from aq. soln. by electrolysis have failed. L. Schicht, and G. Gore obtained a reduction but no metal. Neither W. Borchers nor S. Fischer could succeed in verifying S. Cowper-Coles' statement. S. Fischer showed that the reduction is limited in most cases to the blue V_2O_4 -stage, but at 90° , the reduction can go to the lavender V_2O_2 -stage. Lead electrodes reduce the soln. to the green V_2O_3 -stage at temp. below 9° , but above that temp. the lavender V_2O_2 -stage appears. Carbon electrodes reduce the electrolyte to the sesquioxide form (V_2O_3), green colour. Platinum cathodes at temp. below 90° C. reduce the electrolyte to the blue vanadyl state only (V_2O_4), and the current density seemingly has no further effect. At temp. of 90° C. and above the lavender state (V_2O_2) is reached only when porous cells are used; otherwise not. The black deposit on platinum cathodes is not a vanadium compound.

The preparation of vanadium alloys.—The preparation of vanadium is so difficult that the metal of a high degree of purity has not been obtained. It is, however, comparatively easy to prepare alloys of vanadium with other metals. Thus, by reducing a mixture of the metal oxides with carbon in the electric furnace, H. Moissan³ prepared **ferrovanadium**, and **cuprovanadium**; and H. Herrenschildt obtained ferrovanadium, cuprovanadium, **nickelovanadium**, and **cobaltovanadium** by heating in an electric furnace the precipitate obtained by mixing a soln. of sodium vanadate with, say, the requisite proportions of ferrous, cupric, or cobaltous sulphate and sodium carbonate, or by heating, say, a mixture of vanadium pentoxide and nickel oxide. F. R. Carpenter obtained ferrovanadium by heating

a mixture of the vanadium ore with ferric oxide, dolomite, and a reducing agent at a high temp. An electric furnace, lined with magnesia, is charged with steel turnings; when those are melted, vanadium pentoxide is added, and this is followed by a mixture of silicon or ferrosilicon and lime. The pentoxide is reduced by the silicon: $2V_2O_5 + 5Si = 4V + 5SiO_2$, and the silica forms a slag with the lime. D. W. Berlin, and K. Nishida, also prepared these alloys; and R. Vogel and G. Tammann obtained them by the aluminothermite reduction of a mixture of ferric oxide and vanadium pentoxide. L. F. Vogt, and H. P. Smith reduced a mixture of vanadium and ferric oxides (*vide supra*) with charcoal and aluminium in an electric furnace, or treated the mixed oxides by the thermite process. G. Gin obtained vanadium alloys as indicated above. H. Moissan prepared **aluminovanadium** by melting fluorspar in the electric furnace, then dropping in aluminium, and finally adding a thermite mixture of vanadium pentoxide and aluminium shot. C. Matignon and E. Monnet obtained ferrovanadium by reducing a mixture of vanadium pentoxide and ferric oxide by aluminium; and aluminovanadium by similarly reducing a mixture of vanadium pentoxide and alumina. Cuprovanadium is prepared by heating a mixture of vanadium pentoxide, copper oxide, and aluminium shot with lime, soda-ash, and fluorspar in a crucible lined with magnesite. J. J. Boericke prepared some alloys by the thermite process.

§ 4. The Properties of Vanadium

Owing to the fact that most of the observations on the physical properties of vanadium have been made with the element containing more or less impurity, it is necessary to affix to the following record *cum grano impuritiae*. H. E. Roscoe's¹ vanadium was described as a silver-white, crystalline powder; C. Setterberg's, as a grey powder containing acicular crystals; L. Weiss and O. Aichel's, as a regulus of hexagonal crystals. W. Prandtl and B. Bleyer described it as a steel-grey metal which can take a high polish. W. C. Brögger and G. Flink said that the crystals obtained by C. Setterberg often have an olive-green or a bluish-green film, and are combinations of the dodecahedron and cube, and the tabular crystals are often twinned. According to A. W. Hull, the **X-radiogram** of vanadium agrees with a body-centred cubic lattice. The side of unit cube is 3.04 Å., and there are two atoms per unit cube. H. E. Roscoe gave 5.5 at 15° for the **specific gravity** of vanadium; C. Setterberg, 5.866–5.875 at 15°; W. Muthmann and co-workers, 6.025 at 15°/15°; O. Ruff and W. Martin, 5.688 at 18.7°; J. W. Marden and M. N. Rich, 6.0 at 22° for cold-worked wire; and W. Prandtl and H. Manz found

aluminothermic, 95 per cent. vanadium has a sp. gr. 5.987 at 20°, while that prepared from sodium and the chloride had a sp. gr. 5.819 at 20°. H. G. Grimm made observations on the ionic radius. According to W. Prandtl and B. Bleyer, vanadium is hard enough to scratch quartz; and L. Weiss and O. Aichel say that the **hardness** of vanadium exceeds that of any other metal, being very nearly 7 on Mohs' scale; J. R. Rydberg gave 6. Consequently, it is scratched neither by the hardest steel, nor by quartz. W. Muthmann and co-workers gave 7.5 for the hardness, and said that it is as brittle as glass. G. W. Bridgman found the cubic **compressibility** calculated from the linear compressibility of a mass of cubic crystals is, at 30°, $\delta v/v_0 = -6.090 \times 10^{-7}p + 2.58 \times 10^{-12}p^2$; and at 75°, $\delta v/v_0 = -6.117 \times 10^{-7}p + 2.55 \times 10^{-12}p^2$. J. Laissus discussed the **diffusion** of vanadium in iron.

C. Setterberg gave 0.1259 for the **specific heat** and 6.46 for the **atomic heat** of vanadium; W. Muthmann and co-workers gave 0.124; H. Mache, 0.1153 from 0° to 100°; J. W. Marden and M. N. Rich, 0.120 from 20° to 100°; and C. Matignon and E. Monnet calculated 0.1258 for the sp. ht. from the value for ferrovandium, and 0.1235 for the value for aluminovanadium. E. Donath and J. Mayrhofer studied the relations between the at. ht., at. wt., and sp. gr. of vanadium and some other elements. O. Ruff and W. Martin found that the presence of either oxygen or carbon raises the **melting point** of vanadium, and by extrapolation they found the m.p. of the pure metal to be 1715°. G. K. Burgess and R. G. Waltenberg gave 1720°; W. von Bolton, 1680°; and J. W. Marden and M. N. Rich, 1700°; and W. R. Mott gave 1750° for the m.p., and calculated 3400° for the **boiling point**. J. W. Marden and M. N. Rich found vanadium to be one of the least volatile of metals at its m.p. A sample may be kept molten in a high vacuum for a long time without appreciable blackening of the glass container. The **heat of combustion** of a gram of metal to the pentoxide is 2456 cal.; W. Muthmann and co-workers gave 31.303 Cals. per equivalent; W. G. Mixer found that (2V, 5O) exceeds 441 Cals., and O. Ruff and L. Friedrich gave 437 ± 7 Cals.

H. von Wartenberg² found 3.03 for the **index of refraction** of vanadium for light of wave-length 0.579 μ ; 0.351 for the **absorption coefficient**; and 58 per cent. for the **reflecting power**. W. W. Coblenz found that the reflecting power rises gradually from 58 per cent. in the yellow to 92 per cent. at 9 μ . In this respect it resembles iron and chromium. He gave:

λ	0.5	0.6	0.8	1.0	2.0	4.0	7.0 μ
R	57	58	60	61	69	79	88 per cent.

W. Biltz³ discussed the relationship between the colour of vanadium and the magnetic properties of the element—*vide* chromium. K. Someya stated that the violet colour obtained by reducing ammonium vanadate soln. fades on dilution, showing that the vanadous ions are probably colourless. The colour is restored by conc. hydrochloric acid or potassium thiocyanate, showing that the colour is due to non-ionized molecules or complex ions. The **spark spectrum** of vanadium was examined by R. Thalén,⁴ H. A. Rowland, J. Parry and A. E. Tucker,

FIG. 2.—Spark Spectrum of Vanadium.

E. Demarçay, W. N. Hartley and H. W. Moss, O. Lohse, F. Exner and E. Haschek, J. H. Pollock, C. E. Gissing, M. Eppley, A. de Gramont, A. Hagenbach and H. Konen, A. M. Kilby, and J. M. Eder and E. Valenta. The more important lines have wave-lengths 6120, 6090, 6040 Å. in the orange-yellow; 5726 Å. in the yellow; 4407, 4384, and 4379 Å. in the indigo-blue—Fig. 2. The **arc spectrum**

was examined by H. A. Rowland and C. N. Harrison, B. Hasselberg, A. Frerichs, M. Eppley, J. N. Lockyer and F. E. Baxandall, F. Exner and E. Haschek, A. S. King, W. F. Meggers, H. Shaw, A. M. Kilby, J. M. Eder and E. Valenta, and R. Rossi. C. C. Kiess and W. F. Meggers measured the red, and ultra-red lines exceeding 5500 Å., and W. Ludwig the lines between 2207–4646 Å. in the arc spectrum of vanadium. C. Porlezza and A. Donati discussed the detection and determination of vanadium in ores from the arc spectrum. The **band spectrum** was examined by H. Konen, E. Demarçay, J. M. Eder and E. Valenta, A. Hagenbach and H. Konen and F. Exner and E. Haschek; the *enhanced lines*, by J. N. Lockyer, and M. Kimura and G. Nakamura; the effect of *pressure*, by W. J. Humphreys, and R. Rossi; the effect of a strong *magnetic field*—the **Zeeman effect**—by J. E. Purvis, W. F. Meggers, and H. D. Babcock. C. C. Kiess and O. Laforte, A. S. King, and R. J. Lang examined the **ultra-violet spectrum**; and the influence of an *electric field*—the **Stark effect**—by H. Nagaoka and Y. Sugiura. G. A. Hemsalech excited the spectrum by thermoelectronic currents. The **series spectrum** was studied by M. A. Catalan, R. C. Gibbs and M. E. White, K. Bechert and M. A. Catalan, R. Frerichs, T. Okaya, K. Bechert and L. A. Sommer, R. J. Lang, O. Laporte, R. Mecke, H. N. Russell, S. Goudsmit, and W. F. Meggers. H. Gieseler and W. Grotrian measured the lines in the **absorption spectrum** of vanadium vapour at 2000°. H. Gieseler and W. Grotrian studied the absorption spectrum of the vapour of vanadium. According to J. Formanek, the greenish-blue aq. soln. of vanadium dichloride has an absorption spectrum with a band in the red; and the green alcoholic soln. absorbs the red and violet. If tincture of alkanna be present, the soln. becomes blue, and the absorption spectrum has bands at 6099 and 5643 with a feeble band at 5250. The position of the bands does not change when the soln. are allowed to stand some time. A trace of ammonia does not alter the absorption spectrum, but an excess of ammonia renders the liquid turbid and red; it then shows the absorption spectrum of alkanna.

The K-series in the **X-ray spectrum** was examined by V. Dolejšek,⁵ A. Leide, D. Coster, M. Levi, M. J. Druyvesteyn, K. Chamberlain, H. Fricke, D. M. Bose, A. E. Lindh, B. B. Ray, G. Wentzel, O. Stelling, B. Walter, E. Hjalmar, N. Sten-son, N. Seljakoff and co-workers, and M. Siegbahn. There are: $\alpha_2\alpha'$, 2·50212; α, α , 2·49834; $\alpha_3\alpha_4$, 2·4846; β, β , 2·27968; and $\beta_2\gamma$, 2·26537. S. B. Hendricks and R. W. C. Wyckoff, R. Thoraues, and D. Coster studied the L-series; and D. M. Bose the M-series and the N-series. K. H. Kingdon gave 7·69 volts for the **ionizing potential** of vanadium vapour; H. N. Russell gave 6·76 volts; and R. N. Ghosh, 6·5 volts. R. Robl observed no fluorescence when vanadium is exposed to ultra-violet light.

K. F. Herzfeld⁶ studied the metallic conduction of vanadium. J. W. Marden and M. N. Rich gave 0·000026 ohm per c.c. for the sp. **electrical resistance** of cold-worked vanadium; and for the effect of temp. from 20° to 150°, $R=R_0(1+0·0028\theta)$. L. Marino found that the **electromotive force** of vanadium is not analogous to that of chromium, but is more related with the behaviour of phosphorus and arsenic. When an electrolyte, which has no action on vanadium at the ordinary temp., is electrolyzed with a vanadium anode, a complex vanadium anion is produced, the vanadium going into soln. as a quadrivalent ion. The loss of weight of the anode is always greater than that corresponding with the amount of silver separated in the voltameter; this is attributed to the oxidation of some carbon to carbon dioxide. In alkaline soln., vanadium dissolves vanadate, independently of conc., temp., and current density. Potential measurements were made according to the scheme, $V | MX | NaNO_3 | AgNO_3 | Ag$, where X=Cl, Br, OH, and M=Na, K, Zn, Mg, etc.; with the exception of the cases of sodium and potassium hydroxides, the e.m.f. was independent of the nature of the electrolyte. The e.m.f. of the combination $V | MX | H_2CrO_4 | Pt$ was also determined. In no case did the vanadium become passive. G. C. Schmidt measured the electrode

potential of vanadium in $N\text{-KCl}$. G. Tamman and J. Hinnüber studied the cell $V_n\text{Hg} | V_2(\text{SO}_4)_3, \text{HgSO}_4 | \text{Hg}$. A. Thiel and W. Hammerschmidt found the **overtoltage** in $2N\text{-H}_2\text{SO}_4$ at 25° to be 0.1352 volt. W. Muthmann and F. Fraunberger, and G. C. Schmidt examined the **passivity** of vanadium. They found that with purified vanadium in $N\text{-KOH}$, the potential at the beginning is -0.13 volt, and after ten minutes, it has attained the maximum value 0.737 volt. The passivity is shown when the metal is treated with oxidizing agents, or after anodic polarization. T. F. Rutter measured the **oxidation and reduction potentials** of vanadium salts, or the e.m.f. of the chains $V^{II} \rightarrow V^{III}$; of $V^{III} \rightarrow V^{IV}$; and of $V^{IV} \rightarrow V^{V}$ from soln. containing di- and ter-valent vanadium salts, ter- and quadrivalent vanadium compounds, and quadri- and quinquevalent compounds in variable quantities. The soln. were referred to a mercurous sulphate electrode in $0.5N\text{-H}_2\text{SO}_4$ of potential 0.679 volt.

He found for (1) $V^{II} \rightarrow V^{III}$, with $0.1N\text{-V}^{II}$ salt and $0.5N\text{-H}_2\text{SO}_4$ free from V^{III} -salt, a potential of 0.909 volt with $0.05N\text{-V}^{II}$ -salt, $0.05N\text{-V}^{III}$ -salt, and $0.5N\text{-H}_2\text{SO}_4$, 0.889 volt; $0.033N\text{-V}^{II}$ -salt, $0.066N\text{-V}^{III}$ -salt, and $0.5N\text{-H}_2\text{SO}_4$, 0.881 volt; $0.025N\text{-V}^{II}$ -salt, $0.075N\text{-V}^{III}$ -salt, and $0.5N\text{-H}_2\text{SO}_4$, 0.875 volt; and $0.1N\text{-V}^{III}$ -salt, and $0.5N\text{-H}_2\text{SO}_4$, free from V^{II} -salt, 0.464 volt—the mercury electrode was positive. (2) For $V^{III} \rightarrow V^{IV}$, with $0.1N\text{-V}^{III}$ -salt free from V^{II} - and V^V -salts, 0.462 volt; with $0.075N\text{-V}^{III}$ -salt and $0.025N\text{-V}^{IV}$ -salt, 0.0397 volt; with $0.05N\text{-V}^{III}$ -salt and $0.05N\text{-V}^{IV}$ -salt, 0.0373 volt; with $0.025N\text{-V}^{III}$ -salt, and $0.075N\text{-V}^{IV}$ -salt, 0.363 volt; and $0.1N\text{-V}^{IV}$ -salt free from V^{III} - and V^V -salts, 0.051 volt—the mercury electrode was positive. (3) For $V^{IV} \rightarrow V^V$, with $0.1N\text{-V}^{IV}$ -salt free from V^{III} - and V^V -salts, 0.051 volt—mercury electrode positive; with $0.05N\text{-V}^{IV}$ -salt, and $0.05N\text{-V}^V$ -salt, 0.241 volt; and $0.1N\text{-V}^V$ -salt, and $0.05N\text{-H}_2\text{SO}_4$ free from V^V -salt, 0.462 volt—mercury electrode negative.

T. F. Rutter also found that vanadium of its own accord could form ions of the type VO^+ from V^{III} ; VO_2^+ , VO_3^+ , and $\text{V}_6\text{O}_{17}^{IV}$. Also if the ratio of $(V^{II} \cdot V^{III} = 0.05 : 0.05)$ and $(V^{III} \cdot V^{IV} = 0.05 : 0.05)$ existed, then the single potentials are respectively $+0.21$ and -0.30 . This means that the tendency to form V^{II} to V^{III} is greater than the tendency to change H to H^+ , and the potential to change V^{III} to V^{IV} is greater than that to change Ag to Ag^+ : therefore, vanado-salts liberate hydrogen, and vanadi-salts liberate silver or copper of the soln. of copper sulphate used is concentrated and heat applied. Vanadyl salts are said to be very weak reducing agents, but they are quickly oxidized by permanganic acid, chromic acid, and hydrogen dioxide; slowly by persulphates; and only slightly by iodine and bromine. T. F. Rutter also established the fact that various oxides of vanadium immediately come to an equilibrium.

The electrolytic reduction of quadri- and quinque-valent vanadium salts was studied by A. Stahler and H. Wirthwein, A. Piccini and N. Brizzi, A. Bültemann, E. Renschler, R. Luther, W. F. Bleecker, L. Pissarjewsky, P. Truchot, R. E. Myers, and S. Fischer—*vide infra*, vanadium trioxide.

K. Honda⁷ showed that the **magnetic susceptibility** of vanadium is 1.5×10^{-6} units at 18° , and 1.8×10^{-6} units at 1100° ; M. Owen gave 2.4×10^{-6} units at ordinary temp. P. Weiss and H. K. Onnes showed that the magnetic properties of vanadium are not intensified by cooling the element down to the temp. of solid hydrogen. W. Biltz associated the colour of unsaturated vanadium compounds with the magnetic power. E. Wedekind compared the magnetic susceptibility of vanadium compounds with those of the other elements. R. Dieterle investigated the magnetic susceptibility of the iron vanadium alloys; and D. M. Bose and H. G. Bhar, I. Tamm, and P. Pascal, of vanadium salts. N. Perrakis found the paramagnetic susceptibility constant of quinquevalent vanadium to be 44.0×10^{-6} mass units. According to P. Pascal, when the chemical properties of a metal become masked by its entry into a complex ion or colloid, the magnetic properties are similarly affected and to the same degree. For example, vanadium pentoxide dissolves in conc. sulphuric acid to a red soln., which on dilution, becomes first yellow and then colourless. The pentoxide in the red soln. has the mol. magnetic susceptibility $-2 \times 85.7 \times 10^{-5}$; in the yellow soln., $-2 \times 31.5 \times 10^{-5}$; and in the

colourless soln., $-2 \times 30 \cdot 2 \times 10^{-5}$. From these values, it is permissible to conclude that the strongly acid soln. contain red sulphovanadic compounds which dissociate on dilution. These complexes doubtless include $\text{VO}_2(\text{SO}_4)_3$; $\text{V}_2\text{O}_5 \cdot 3\text{H}_2\text{SO}_4$; and $\text{K}_2\text{O} \cdot 4\text{SO}_3 \cdot \text{V}_2\text{O}_5$.

F. Fischer and F. Schrötter⁸ observed no reaction occurs when vanadium is sparked beneath liquid **argon**. H. E. Roscoe found that vanadium prepared by reducing the chloride in **hydrogen** contains some of that occluded gas. H. Huber and co-workers found that vanadium which has been heated in vacuo to 1100° readily absorbs hydrogen and the equilibrium is rapidly attained from either side. They measured the *pv*-curves between 300° and 800° ; and observed no evidence of the ageing of the metal. According to W. Muthmann and co-workers, finely divided vanadium at 1300° unites with 16.1 per cent. of hydrogen, forming a stable **vanadium hydride** as a black powder which is not affected by water or by boiling hydrochloric acid, but is oxidized by nitric acid. W. Prandtl and H. Manz were unable to prepare a hydride by heating electrolytically disintegrated vanadium in hydrogen at 1000° . The sp. gr. is 5.30. The hydride was studied by A. Sieverts and A. Gotta. According to H. E. Roscoe, vanadium in the cold is not changed by moist or dry **air**. When warmed gently in air, it forms brown hemioxide, which when heated further passes into black trioxide, then to blue tetroxide, and finally to yellowish-red pentoxide. When vanadium is heated in **oxygen**, or strewn into a flame, it burns brilliantly with the emission of sparks. Vanadium can be repeatedly moistened with **water** and dried in vacuo without the slightest increase in weight. Vanadium containing occluded hydrogen is gradually oxidized in air; and the cold, powdered metal, prepared by the sodium reduction process, and dried by heating it to dull redness in vacuo or in hydrogen, may ignite like a pyrophorus when brought into air or oxygen. When vanadium is heated with an excess of dry **chlorine**, it forms the dark brown tetrachloride, but it is not attacked by **bromine** water. The powdered metal is not attacked by cold or hot, dil. or conc. **hydrochloric acid**; it is slowly dissolved by **hydrofluoric acid** with the evolution of hydrogen, and the formation of a green soln. L. Marino found that the metal with 8.66 per cent. carbon is not attacked by the **halide acids**. Vanadic acid is produced by the action of **chloric, perchloric, and bromic acids** on vanadium. Sat. soln. of **potassium chlorate, bromate, iodate, and perchlorate** oxidize vanadium to vanadic acid: $6\text{V} + 5\text{KClO}_3 = 5\text{KCl} + 3\text{V}_2\text{O}_5$. N. Domanicky saw that **sulphur monochloride** in the presence of ether will probably form a higher chloride. H. E. Roscoe found that dil. **sulphuric acid**, or the cold conc. acid, is without action on vanadium, but the hot, conc. acid dissolves the metal, forming a greenish-yellow soln. L. Marino found vanadium to be soluble in hot sulphuric acid (2 : 1), and when the temp. is raised to 330° , vanadic acid is formed and some sulphur dioxide is set free. The metal is attacked by a warm soln. of **ammonium persulphate**, and the liquid becomes strongly acid owing to the formation of monopersulphuric and sulphuric acids. H. E. Roscoe found that when vanadium is heated in **nitrogen**, a bronze-coloured nitride is formed, and W. Muthmann and co-workers obtained the nitride by the direct union of the elements at a red-heat. I. I. Tschukoff studied this subject. H. E. Roscoe found that vanadium is converted into vanadium tetranitrate by **nitric acid** of sp. gr. 1.18, and vanadic acid is produced by nitric acid of sp. gr. greater than 1.35. According to H. E. Roscoe, nitric acid of any conc. attacks vanadium in the cold, forming brown fumes and a blue soln.; **aqua regia** attacks the metal very vigorously. M. Wunder and B. Janneret found that ferrovanadium is rapidly dissolved by **phosphoric acid** of sp. gr. 1.75. G. Tammann and K. Schönert found that **carbon** does not diffuse in vanadium at temp. up to 750° . H. W. Underwood, and O. Schmidt studied vanadium as a catalyst in the hydrogenation of organic substances. L. Marino found that vanadium remains unchanged in soln. of **alkali acetates, oxalates, sulphates**, etc. O. Schmidt discussed the catalysis hydrogenation of organic substances in the presence of vanadium salts.

H. Giebelhausen found that vanadium reacts with **silicon** to form silicides (*q.v.*). According to H. E. Roscoe, and L. Weiss and O. Aichel, when the metal is heated in **glass** or **porcelain** vessels, the silicate is attacked and vanadium silicide is formed. C. Setterberg also observed that the metal readily reacts with **silica** at an elevated temp. H. E. Roscoe found that neither hot nor cold soln. of **alkali hydroxides** attack vanadium, but, when exposed to air, molten alkalis, **sodium carbonate** or **potassium nitrate**, gradually oxidize the metal to a vanadate. L. Marino observed that a soln. of **mercuric chloride** is reduced by vanadium to mercurous chloride: **cupric chloride** is likewise reduced to cuprous chloride; and **ferric chloride** to ferrous chloride. Vanadium also reduces soln. of **silver nitrate**, **gold chloride**, and of **platinum and iridium tetrachlorides**.

The **vanadides** of the metals have not been closely investigated. H. Giebelhausen⁹ showed that *vanadium-copper alloys* form two immiscible liquids at 1800°. A sample with 92 per cent. vanadium freezes at 1084°; and likewise also the end of the freezing of that metal with 2.8–21.0 per cent. of copper freezes at the same temp. The regulus consists of two layers, one vanadium and the other copper; each layer carries only traces of the other element. The f.p. diagram assumes the form shown in Fig. 3. R. M. Keeney discussed these alloys.

Similar results were obtained by H. Giebelhausen with *vanadium-silver alloys*. The two elements are immiscible at 1800°, and the alloy has two f.p., one corresponding with vanadium, the other with silver, Fig. 3, with the 1884°-line at 961°. Silver does not dissolve appreciably in vanadium or vanadium in silver. According to R. J. Dunn and O. F. Hudson, the critical point at about 460° in brass and alloys of copper and zinc, containing the β -phase, is only slightly affected by vanadium, for 1 per cent. raises it only about 10°.

Vanadium is practically without influence on the resolution of the β -phase. R. Hohage and A. Grützner described some *vanadium-iron alloys*. When added to mild steels with 0.10–0.17 per cent. carbon, vanadium increased the yield-point and maximum strength, and reduced the elongation, reduction of area, and impact values, proportionally to its content, and exerted these effects to a greater degree as the quenching temp. was raised. With rising vanadium content, the critical cooling velocity was diminished and a tendency to air-hardening produced. E. Maurer said that there is only a slight increase in hardness of vanadium steels with a rise in the quenching temp. Additions of vanadium to a steel containing 0.74 per cent. of carbon reduce the specific resistance, but, in the absence of carbon, the resistance is increased. Vanadium steels, in which the ratio vanadium; carbon is 5.17 or lower, have their specific resistance markedly raised by quenching at 950°, but not when the ratio is 6.20 or higher. This is in agreement with the formula, V_4C_3 , for the carbide, which was confirmed by analysis. Vanadium carbide dissolves gradually with rise of temp. like cementite, the degree of solubility depending on the amount of vanadium already in the matrix. The coercive strength of 10 per cent. vanadium steel shows a 37 per cent. increase when carbon-free, and 80 per cent. increase with 1 per cent. carbon, when the steel is quenched at 1300°. This alteration in property is attributed to the passing into soln. of carbon according to the equation $V_4C_3 \rightleftharpoons 4V + 3C$ (dissolved). The decomposition of vanadium carbide at higher temp. (1400°) has no bearing on high-speed or tool steel as these are quenched at 1280° and 800° respectively. J. O. Arnold and A. A. Reid discussed these iron-vanadium alloys—*vide*, iron; and G. Tammann and G. Siebel investigated their temper colours. Alloys containing more than 0.5 per cent. of vanadium contain hard, blue inclusions, possibly an oxide. G. Tammann and J. Hinnüber prepared an alloy with **mercury** by the electrolysis of vanadium sulphate, $V_2(SO_4)_3$; but the solubility of vanadium in mercury is too small for measurement. H. E. Roscoe found that vanadium attacks the

FIG. 3. — Freezing-point Curve of Vanadium-Copper Alloys.

platinum vessels in which it is heated. J. Aloy and A. Valdiguié studied the catalytic action of vanadium in hydrogenations.

Some reactions of analytical interest.—If vanadium pentoxide or vanadic acid be boiled with conc. **hydrochloric acid**, chlorine is given off, and mixed chlorides or oxychlorides are formed. An acid soln. of a vanadium salt gives no precipitate with **hydrogen sulphide**, but soln. of vanadic acid are reduced to blue vanadic tetroxide. Many other reducing agents—sulphur dioxide, hydrobromic acid, oxalic and tartaric acids, and sugar—act similarly: $V_2O_5 + SO_2 = SO_3 + V_2O_4$; others—*e.g.* hydriodic acid—reduce vanadic acid to green vanadium trioxide: $V_2O_5 + 4HI = 2H_2O + 2I_2 + V_2O_3$ —the iodine is removed by boiling; and **metals**—zinc, cadmium, and aluminium—reduce the vanadic acid to violet or lavender vanadium dioxide so that the soln. becomes blue, then green, and then violet. A soln. of vanadic acid is coloured brown by **ammonium sulphide** owing to the formation of sulpho-salts, and vanadium pentasulphide—soluble in alkalis, and alkali carbonates and sulphides—is precipitated on adding an acid. The precipitation is not complete. A cold acidic soln. of a vanadate gives with **ammonia** a yellow coloration until the soln. is neutral; soln. of **alkali hydroxides** give a brown precipitate soluble in excess, forming a yellowish-green soln. If a piece of solid **ammonium chloride** be added to a soln. of an alkali vanadate, colourless ammonium vanadate is precipitated, and this is but sparingly soluble in a conc. soln. of ammonium chloride. When an acid soln. of a vanadate is treated with a few drops of **hydrogen dioxide**, and shaken, the soln. becomes reddish-brown—*vide* titanium salts—this reaction is very sensitive. When a neutral soln. of a vanadate is treated with **mercurous nitrate**, white mercurous vanadate is precipitated, and the precipitate is soluble in nitric acid; **lead acetate** under similar conditions gives a yellow precipitate of lead vanadate, also soluble in nitric acid; **barium chloride**—not strontium or calcium chloride—gives a yellow precipitate which soon becomes colourless when warmed; **copper salts** give a bluish-yellow precipitate with metavanadates, and a green precipitate with orthovanadates. A soln. of vanadate containing acetate and free ammonia or acetic acid, gives a precipitate of ammonium uranyl vanadate when treated with a soln. of a **uranium salt**; and a boiling soln. of a vanadate, mixed with ammonium chloride and ammonia, gives manganous vanadate when treated with **manganous chloride**. A soln. of vanadic acid gives a green, flocculent precipitate when treated with **potassium ferrocyanide**; and **tannic acid**, a bluish-black precipitate. When a conc. sulphuric acid soln. of vanadic acid is treated with **strychnine sulphate** it gives a bluish-violet coloration which soon becomes rose-coloured—this reaction is very sensitive; with **aniline hydrochloride**, aniline black is formed. For reactions with salts of the lower oxides of vanadium, *vide infra*.

The physiological action of vanadium salts.—According to J. Priestley,¹⁰ vanadium salts are poisonous, producing paralysis, convulsions, sleepiness, falling temp., and slow pulse. D. E. Jackson found that vanadium produces gastrointestinal irritation, increased intestinal peristalsis, and a rise of blood-pressure, more lasting but less pronounced than that caused by adrenaline. Constriction of the arterioles is present in kidney, intestine, and spleen, but not in the leg. This action is peripheral, not central. W. F. Dutton described the effects of the absorption of fumes from vanadium on workers. An early symptom of the effects is anæmia accompanied by emaciation and irritation of the throat and eyes, and the disease often terminates fatally. He advises thorough ventilation and the use of respirators as protective measures. J. Priestley found that with dogs the lethal dose is 0.00918–0.01466 grm. of the pentoxide per kilogram. The antidote is potassium ferrocyanide, and substances containing tannin. A. Gamgee and L. Larmuth studied the action of vanadium salts on frogs, and it was found that the toxicity of alkali orthovanadate is smaller than that of the pyro- or metavanadate. C. Binz and H. Schulz suggested that the members of the arsenic family owe their poisonous nature to the alternate oxidization and reduction which destroys

the albumen. S. Suzuki found that the presence of 0.1 per cent. of vanadium in a water-culture medium acts banefully on barley, but 0.01 per cent. does no harm. H. Weber said that the vanadium salts are antiseptic, and recommended a mixture of sodium chlorate and a vanadium salt to which he applied the trade name *vanadin*, but T. Bokorny said that the vanadium salts have no special antiseptic power. F. Laran, and B. L. Lyonnet and co-workers recommended vanadium salts as a therapeutic agent in tuberculosis, and anæmia.

The uses of vanadium.—Up to the early 'sixties of the nineteenth century vanadium was a chemical curiosity. About that time, vanadic acid was found to be more suitable than chromic acid as an oxidizing agent in some dyeing processes;¹¹ in the production of various shades of aniline dyes;¹² as a catalyst in the oxidation of aniline hydrochloride to a fixed black for an indelible ink; and as a mordant in the transformation of vegetable cellulose to oxycellulose. The last-named application, however, was superseded owing to the deleterious effect on the fabric. It has been used as a photographic developer and sensitizer;¹³ as a reducing agent;¹⁴ as a dryer for linseed oil paints;¹⁵ as a contact catalyst in the oxidation of sulphur dioxide,¹⁶ and other substances; in the purification of hydrochloric acid from arsenic,¹⁷ for the addition of vanadium dichloride causes the precipitation of arsenic; and vanadium carbide has been used in the preparation of incandescent¹⁸ filaments. There are also some therapeutic applications—*vide supra*, the physiological action of arsenic.¹⁹ Perhaps the most important application of vanadium is in the addition of a small proportion of that element to steel, brass, etc. The general effect of vanadium is to toughen the alloy and increase its resistance to repeated shocks, or varying stresses—*vide supra*;²⁰ and it is used in some rectifiers.²¹

§ 5. The Atomic Weight and Valency of Vanadium

Naturally, the at. wt. of vanadium was unknown so long as J. J. Berzelius¹ hypothesized that vanadium dioxide, V₂O₂, was vanadium, was in vogue. From H. E. Roscoe's work on vanadium, it is possible to calculate from J. J. Berzelius' value for the ratio V₂O₅ : V₂O₃, the at. wt. 52.46; from his value for VOCl₃ : 3AgCl, 51.56; and from C. Czudnowicz's value for V₂O₅ : V₂O₃, 54.7. These numbers are too high. H. E. Roscoe showed that the error is most probably due to the presence of phosphoric acid in the vanadic acid employed, for this prevents the complete reduction of the pentoxide to the trioxide.

Vanadium acts in well-defined ways as a bi-, ter-, quadri-, and a quinquavalent element; but less clearly as a univalent element—*vide infra*, vanadium hemioxide—and as an element of a higher valency as a pentad—*vide infra*, the pervanadates. The compounds of bivalent vanadium show analogies with the salts of bivalent magnesium, chromium, manganese, iron, cobalt, and nickel—*e.g.* $\text{RSO}_4 \cdot 7\text{H}_2\text{O}$, and some complex salts prepared by A. Piccini and L. Marino. The compounds of trivalent vanadium are analogous with the salts of trivalent aluminium, chromium, manganese, iron, and cobalt as exemplified by the alums prepared by A. Piccini, the complex fluorides of the type $(\text{NH}_4)_3\text{RF}_6$; and $\text{CoRF}_5 \cdot 7\text{H}_2\text{O}$, prepared by E. Petersen, and A. Piccini and G. Giorgis. Quadrivalent vanadium furnishes an amphoteric oxide which can act both as a base and as an acid, forming hypovanadates; and the quadrivalency of the element is evident from H. E. Roscoe's determination of the vapour density of the tetrachloride, VCl_4 . The subject was discussed by F. Parisi. Quinquevalent vanadium furnishes an oxide which acts as an acid radicle to form salts—vanadates—which C. F. Rammelsberg, J. Schabus, G. A. Kennigott, and A. Schafarik showed were, in many cases, isomorphous with the phosphates, and the arsenates. T. E. Thorpe's determination of the vapour density of the oxytrichloride, VOCl_3 ; and J. A. Hall's determination of the vapour density of the ester, $\text{VO}(\text{C}_2\text{H}_5\text{O})_3$, agreed with this. According to D. I. Mendeléeff, the true analogies of vanadium are chromium and titanium on one hand, and columbium and tantalum on the other; vanadium exhibits a greater resemblance to the latter than to phosphorus.

H. E. Roscoe's value for the ratio $\text{V}_2\text{O}_5 : \text{V}_2\text{O}_3$ furnishes the at. wt. 51.382 (oxygen 16); and the ratio $\text{VOCl}_3 : 3\text{Ag}$ (107.88) gives, with chlorine 35.46, the at. wt. 51.046, and the ratio $\text{VOCl}_3 : 3\text{AgCl}$, 51.253. B. Brauner's best representative value from the early work so far considered is 51.33. W. Prandtl and B. Bleyer obtained from the ratio $\text{VOCl}_3 : 3\text{AgCl}$, 51.133, 50.965, and 51.069, and they considered that 51.069 was the best representative value; they also computed 51.356 from the ratio $\text{V}_2\text{O}_5 : \text{V}_2\text{O}_3$. F. W. Clarke's best representative value for the work so far considered is 51.037. D. J. McAdam decomposed anhydrous sodium metavanadate with hydrogen chloride and chlorine, and determined the residual sodium chloride; they calculated from the ratio $\text{NaVO}_3 : \text{NaCl}$, 50.966 for the at. wt. of vanadium. H. V. A. Briscoe and H. F. V. Little obtained 50.941 from the ratio $\text{VOCl}_3 : 3\text{Ag}$, and 50.947 from the ratio $\text{VOCl}_3 : 3\text{AgCl}$. The general results show that with chlorine 35.457, the at. wt. of vanadium by H. E. Roscoe lies between 50.38 and 52.33; by W. Prandtl and B. Bleyer, between 50.87 and 51.2; by D. J. McAdam, between 50.94 and 50.99; and by H. V. A. Briscoe and H. F. V. Little, between 50.93 and 50.97. The best representative value is taken to be between 50.95 and 50.96; or **50.96**. The International Table for 1925 gives 51.

The **atomic number** of vanadium is 23. According to F. W. Aston,² vanadium has no **isotopes**, being a simple element with an at. mass of 51. The **electronic structure**, according to N. Bohr's scheme, is (2) (4, 4) (4, 4, 3) (2); R. Samuel and E. Markowicz gave (2) (2, 6) (2, 6, 3) (2). The subject was discussed by L. A. Sommer, M. L. Huggins, R. Ladenburg, C. D. Niven, D. M. Bose, S. Meyer, and H. Lessheim and co-workers; and G. Kirsch and H. Pettersson obtained no evidence of **atomic disintegration** when vanadium is bombarded with the long-range particles from the active-deposit of radium. H. Collins made some speculations on the structure of the atom of vanadium.

§ 6. Vanadium Hemioxide, Dioxide, and Trioxide

Vanadium furnishes the following well-defined oxides :

Vanadium dioxide, or hypovanadous oxide, V_2O_2 , **vanado**-oxide.

Vanadium trioxide, or vanadous oxide, V_2O_3 , **vanad**-oxide.

Vanadium tetroxide, or hypovanadic oxide, V_2O_4 , **vanade**-oxide.

Vanadium pentoxide, or vanadic oxide, V_2O_5 , **vanadan**-oxide.

A hemioxide has been reported, and also a series of pervanadates. As indicated below, there is some confusion in the nomenclature. The colour of the salt derived from the dioxide is lavender or violet; from the trioxide, green; from the tetroxide, blue; and from the pentoxide, yellow.

J. J. Berzelius¹ reported a *purple oxide* to be formed by shaking vanadous hydroxide with water for 24 hrs. in a vessel from which air is not all excluded; a *green oxide*, by melting a mixture of vanadium trioxide with six times its weight of the pentoxide, or a mixture of equimolar parts of the tetra- and penta-oxides; a *greenish-yellow oxide* by the action of a neutral vanadous salt on a hypovanadic salt; and an *orange-yellow oxide* by exposing one of the previous oxides to air. These products doubtless represent intermediate stages in the oxidation of vanadium trioxide and one of the higher oxides. A. Ditte reported the intermediate oxide, V_4O_7 , *vanadium heptatetritoxide*, or $V_2O_3 \cdot V_2O_4$, or $V_2O_3 \cdot V_2O_5$, as a dark blue crystalline mass formed by heating to redness in a porcelain crucible lined with carbon a mixture of vanadium pentoxide, or ammonium metavanadate and arsenic trioxide; or by reducing ammonium vanadate with sulphur dioxide at a red-heat. There is nothing to show that this oxide is a chemical individual. O. Manasse reported the oxide, V_5O_{17} , or $3V_2O_4 \cdot V_2O_5$, to be formed by dissolving in alkali-lye the tetroxide mixed with pentoxide; A. Ditte reported V_4O_9 , or $V_2O_4 \cdot V_2O_5$, by heating ammonium metavanadate in air until the residue is almost melted, and by C. F. Rammelsberg, by heating the pentoxide with lithium carbonate. J. T. Brierley obtained the hydrate $V_2O_4 \cdot V_2O_5 \cdot 2\frac{1}{2}H_2O$, by gently heating the salt $(NH_4)_2O \cdot 2V_2O_4 \cdot 2V_2O_5 \cdot 14H_2O$; and J. J. Berzelius, and J. T. Brierley also reported $V_3O_7 \cdot 4H_2O$, or $V_2O_4 \cdot 2V_2O_5 \cdot 8H_2O$, by slowly heating vanadium trioxide in air. In all these cases, there is nothing to show that the products are not intermediate stages in the oxidation of a lower to a high vanadium oxide.

H. E. Roscoe² suggested that the brown oxide which first forms on the surface of vanadium when the finely divided metal is exposed to air for a long time, may be *vanadium suboxide*, or **vanadium hemioxide**, V_2O , or, according to A. Werner's nomenclature, *vanada*-oxide. According to W. Hittorf, the same oxide is formed when vanadium pentoxide is reduced by the aluminium thermite process. J. Koppel and A. Kaufmann, however, showed that the alleged suboxide is probably a mixture of vanadium dioxide and vanadium.

According to H. E. Roscoe,³ *hypovanadous oxide*, or *vanadium monoxide*, VO or **vanadium dioxide**, V_2O_2 , or VO, or, in A. Werner's nomenclature, *vanado*-oxide, was regarded by J. J. Berzelius as elemental vanadium. By analogy with

the chromium oxides, A. Piccini called this compound *vanadous oxide*. There is therefore some confusion in the naming of these oxides. The analogy between chromic oxide, Cr_2O_3 , and vanadium trioxide, V_2O_3 , is not sufficient to overshadow the closer analogy between the vanadium compounds and those of, say, phosphorus, or nitrogen. The dioxide was prepared by A. Safarik, and H. E. Roscoe, by reducing the higher oxides with potassium, or by passing the vapour of vanadium oxytrichloride, mixed with an excess of hydrogen, through a combustion tube containing red-hot carbon. The dioxide remains as a grey metallic powder admixed with carbon. It is freed from chlorine by heating it to redness in hydrogen. L. Pauling discussed the space-lattice. The sp. gr. given by E. Wedekind and C. Horst is 5.758 at 14° . From W. G. Mixter's $(2\text{V}, 5\text{O}) > 441$ Cals.; and $(\text{V}_2\text{O}_5, 3\text{O}) = 87.8$ Cals., it follows that $(2\text{V}, \text{O}_2) > 209$ Cals. E. Wedekind and C. Horst found the magnetic susceptibility to be 50.06×10^{-6} units. In the compressed state, it conducts electricity. The dioxide is insoluble in water; but it dissolves in dil. acids, forming a lavender or violet soln. of a **hypovanadous salt** without giving off hydrogen. A similar liquid is obtained by reducing a soln. of vanadium pentoxide in, say, sulphuric acid, with sodium amalgam, zinc or cadmium; in the latter case the soln. should be warm, and a little platinum present. L. Schlucht reduced a soln. of vanadium pentoxide in dil. sulphuric acid electrolytically to the lavender-blue liquid; J. T. Brierley similarly reduced a soln. of vanadium tetroxide; and A. Piccini and L. Marino, a soln. of vanadium trichloride or pentoxide, with a platinum cathode, in which case, according to L. Marino, the yield is good in sulphuric acid soln. The results are not so good in hydrochloric acid or neutral soln.; in the latter case, oxy-salts are formed. T. F. Rutter recommended a mercury cathode. If the lavender-blue soln. be treated with potassium or sodium hydroxide, brown or purple-red **hypovanadous hydroxide**, $\text{V}(\text{OH})_2$, is precipitated. The hypovanadous salts are among the most powerful reducing agents of inorganic chemistry. The neutral and acidic soln. absorb oxygen very energetically; they decompose water; and rapidly bleach litmus, indigo-blue, and other vegetable colours. The hypovanadous hydroxide which is precipitated by alkali-lye immediately begins to decompose the water with the evolution of hydrogen and the formation of vanadous hydroxide, $\text{V}(\text{OH})_3$. According to A. Piccini and L. Marino, when the soln. of a hypovanadous salt is treated with sodium carbonate, it gives a violet precipitate which decomposes at once. Sodium sulphide gives a violet precipitate which decomposes with evolution of hydrogen and hydrogen sulphide. With potassium

FIG. 4.—The Electro-metric Titration of Hypovanadous Salts with Potassium Permanganate.

nitrate and hydrochloric acid, there is an evolution of nitric oxide. From salts of tin, silver, gold, and platinum, the metal is precipitated by a soln. of a vanadous salt; in the same way, copper is deposited quantitatively from its soln. It is worthy of note that chromous salts reduce cupric salts only to cuprous oxide. A. Piccini and L. Marino recommended the reducing action on a soln. of a copper salt as a test for hypovanadites; T. F. Rutter, the reducing action on silver sulphate. L. Marino held that the latter test is not conclusive since vanadous salts also give a precipitate with silver sulphate whereas copper salts do not. T. F. Rutter, however, found that copper salts can be reduced by vanadous salts in acid soln. Hypovanadous salts precipitate arsenic from its soln. in hydrochloric acid—*vide supra*, the uses of vanadium. T. F. Rutter measured the oxidation potential—*vide supra*. E. Müller

and A. Flath, R. Lang, and R. G. Gustavson and C. M. Knudson studied the electro-metric titration of salts of bivalent vanadium with potassium permanganate. Results by the former, with 10 c.c. of a soln. containing about 0.1 grm. vanadium per litre, 85 c.c. of water, and 4 c.c. of conc. sulphuric acid,

are indicated in Fig. 4. N. H. Furman titrated the salts with soln. of ceric sulphate.

J. J. Berzelius⁴ obtained **vanadium trioxide**, *vanadous oxide*, or *vanadium sesquioxide*, V_2O_3 , which, by analogy with chromic oxide, Cr_2O_3 , was called by A. Piccini, *vanadic oxide*. A. Werner called it *vanadi-oxide*. J. J. Berzelius prepared this oxide by reducing vanadium pentoxide by hydrogen, at a red-heat, or, according to H. E. Roscoe, at a white-heat. If the pentoxide be crystalline, J. J. Berzelius said that the trioxide will also be crystalline; and H. E. Roscoe added that the presence of one per cent. of phosphoric acid hinders the reduction. A. Ditte, A. Safarik, and C. Czudnowicz employed this process. J. J. Berzelius also obtained the trioxide by fusing the pentoxide in a carbon crucible; A. A. Read, by heating the pentoxide to 1750° ; A. Ditte, by melting the pentoxide with an excess of potassium cyanide and extracting the mass with water; A. Ditte, by heating ammonium metavanadate out of contact with air, either alone, or mixed with an excess of sulphur or of ammonium oxalate; H. E. Roscoe, by passing a mixture of vanadium oxytrichloride, $VOCl_3$, and hydrogen through a red-hot tube; E. Friederich and L. Sittig, by heating the pentoxide in hydrogen; and E. Wedekind and C. Horst, by heating the solid oxychloride, $VOCl$, to a red-heat in a current of hydrogen until the brown mass is quite black in colour, and free from chlorine. The operation requires 12–16 hrs. G. Wegelin obtained a colloidal form by a prolonged grinding in an agate mortar.

Vanadium trioxide occurs a black powder, or in black lustrous crystals. V. M. Goldschmidt and co-workers said that the crystals are like those of corundum. A. Safarik gave 4.72 for the sp. gr. at 16° ; and W. Prandtl and B. Bleyer, 4.870. H. E. Roscoe said that this oxide is infusible, meaning, of course, that the m.p. is above the temp. of the ordinary furnaces available in his time. O. Ruff and W. Martin gave the m.p. at about 2000° ; and E. Friederich and L. Sittig, 1970° . E. Tiede and E. Birnbräuer made observations on this subject. W. G. Mixer's data ($2V,5O$) > 441 Cals.; ($V_2O_3,2O$) = 87.8 Cals., corresponds with ($2V,3O$) > 353 Cals. H. E. Roscoe and L. Bleekrode said that the oxide is a good electrical conductor; E. Friederich and L. Sittig gave 55×10^{-4} ohm for the resistance at 1100° . E. Wedekind and C. Horst found the magnetic susceptibility to be 13.88×10^{-6} units. N. Perrakis studied this subject. When the trioxide is heated in air, it oxidizes and burns like tinder. J. J. Berzelius said that it oxidizes the most readily in air, the lower the temp. at which it has been prepared, and after some months it forms small indigo-blue crystals of the tetroxide.

O. Schmidt studied the adsorption of hydrogen, argon, oxygen, nitrogen, ammonia, methane, ethane, ethylene, carbon monoxide, and carbon dioxide. H. von Wartenberg and co-workers found that at 2500° , vanadium trioxide is reduced by hydrogen at about 5 atm. press. H. Müller found that the values of $K = p_{H_2O}/p_{H_2}$ in the V_2O_4/V_2O_3 -reaction: $V_2O_3 + H_2O \rightleftharpoons V_2O_4 + H_2$, at 493° , 538° , and 606° , are respectively 2.20, 2.63, and 5.03; and the calculated thermal values, respectively 121.8, 122.7, and 121.3. The trioxide colours water green; and H. E. Roscoe represented the reaction which occurs when the trioxide is heated in chlorine: $3V_2O_3 + 6Cl_2 = V_2O_5 + 4VOCl_3$; ammonia transforms the white-hot trioxide into the nitride, VN. H. E. Roscoe said that the trioxide is insoluble in most acids and in alkali-lye. A. Safarik found that hot, dil. hydrochloric acid forms a dark green liquid; and J. J. Berzelius said that with the exception of nitric acid, boiling acids do not dissolve the trioxide; nitric acid forms a blue soln. and gives off nitric oxide. P. Sabatier and J. B. Senderens found that vanadium trioxide below 500° is not affected by nitrous oxide; nor is it oxidized by nitric oxide; but between 300° and 400° , nitrogen peroxide converts it into yellow pentoxide. E. Müller and H. Barck said that vanadium trioxide completely decomposes nitric oxide at 500° , forming vanadium tetroxide. P. Sabatier and A. Mailhe, and J. N. Pearce and A. M. Alvarado studied the catalytic activity of vanadium trioxide on the vapour of ethyl alcohol in forming ethylene. In the presence of sulphuric

acid, the trioxide is oxidized to the pentoxide by potassium permanganate. J. J. Berzelius found that a mixed soln. of mercuric chloride and a vanadous salt gives with ammonia a mixed precipitate of *mercuric vanadite* and mercury diamminochloride. The precipitation is quantitative.

The analogies between **vanadium trioxide** and the oxides of trivalent aluminium, chromium, and iron have been indicated above. Salts of this basic trioxide oxide—**vanadous salts**—were obtained by H. E. Roscoe by reducing a sulphuric acid soln. of vanadium pentoxide by magnesium, or zinc; by F. A. Gooch and R. W. Curtis, by reducing a soln. of vanadium pentoxide with hydriodic or hydrobromic acid; by J. Locke and G. H. Edwards, by reducing vanadium oxydichloride with sodium amalgam; and by A. Cioci, A. Piccini and N. Brizzi, E. Renschler, A. Bültemann, and T. F. Rutter, by the electrolytic reduction of a soln. of vanadium tetroxide or pentoxide in sulphuric acid. K. Someya discussed the violet colour of vanadous salt soln. The green soln. readily oxidizes in air, and it reduces soln. of silver and mercuric salts. L. Marino said that it does not reduce soln. of copper salts, but T. F. Rutter found that it does so. T. F. Rutter's observations are indicated in Table I. The vanadous salts are considered to be among the most powerful reducing agents in inorganic chemistry. They unite with oxygen with unusual vigour, and they decompose water with evolution of hydrogen even in the presence of acids and alkalis—these agents indeed accelerate the speed of the reaction. The vanadous salts relate vanadium with the magnesium series and with the chromium compounds. In the series, Ti, V, Cr, Mn, Fe, Co, Ni, titanous chloride is more difficult to prepare than the vanadous salt, and this in turn is more difficult to prepare than the chromous salt. Vanadous compounds are very unstable in aq. soln., while titanous salts decompose in the presence of water. When the green soln. is treated with aq. soln. of ammonia, or with the hydroxides or carbonates of the alkalis or alkaline earths, a flocculent, green precipitate of **vanadous hydroxide**, $V(OH)_3$, is produced. The presence of tartaric acid hinders the precipitation. The green hydroxide is oxidized to a brown hydroxide on exposure to air; it is insoluble in an excess of alkali-lye, and with acids, it furnishes vanadous salts. Thus, E. Petersen found that with hydrofluoric acid it forms a soln. of vanadium trifluoride. A. Rogers and E. F. Smith prepared **ammonium vanaditotungstate**, $3(NH_4)_2O \cdot V_2O_3 \cdot 8WO_3 \cdot 10H_2O$, in crystals freely soluble in water; no precipitation occurs with an ammoniacal soln. of cupric sulphate. O. W. Gibbs obtained **mercurous vanaditotungstate** with a soln. of mercurous nitrate and ammonium divanaditotungstate, and he anticipated the existence of *platinum vanaditomolybdate* and a *platinum vanaditotungstate* analogous to the arsenitotungstate.

§ 7. Vanadium Tetroxide and the Hypovanadates

J. J. Berzelius¹ obtained **vanadium tetroxide**, V_2O_4 , and it has also been called *vanadyl oxide*, $(VO)O$, or *vanadium dioxide*, VO_2 , *hypovanadic oxide*, and, according to A. Werner, *vanade-oxide*. J. J. Berzelius prepared this oxide by heating to redness an intimate mixture of equimolar parts of vanadium tri- and pentoxides in the absence of air; or by heating the hydrated tetroxide in vacuo, or, according to J. K. Crow, in an atm. of carbon dioxide. H. Buff and F. Wöhler made the tetroxide by the electrolysis of molten vanadium pentoxide, and removing the excess of pentoxide by boiling soda-lye. W. Prandtl heated the pentoxide in a gas furnace for some hours, and found that a crust of the tetroxide is produced by the reducing action of the gas. The unchanged pentoxide can be removed by washing the product with aq. ammonia. A. Guyard reduced the pentoxide to tetroxide by melting it with oxalic acid; E. Friederich and L. Sittig, by heating it with carbon; A. Ditte, by heating it with phosphorus—but here a phosphate is formed; A. Ditte, by heating the pentoxide in a current of sulphur dioxide—the reaction is slow; and J. J. Berzelius, A. Ditte, and H. E. Roscoe, by heating ammonium metavanadate out of contact with air. K. Someya found that bismuth amalgam reduces vanadates to hypovanadates. H. E. Roscoe said that this oxide is formed when the trioxide is exposed to air for some months. J. K. Crow obtained the tetroxide by heating the oxychloride, $V_2O_4 \cdot 4HCl \cdot 3H_2O$, in a current of carbon dioxide. According to J. Koppel and E. C. Behrendt, quinquevalent is reduced to quadrivalent vanadium by hydroxylamine hydrochloride, dextrose, formaldehyde, alcohol, oxalic acid, hydrogen sulphide, and, best of all, by sulphur dioxide.

Vanadium tetroxide obtained from the fused pentoxide appears as a black earthy mass; otherwise, it may appear as a dark blue crystalline powder. V. M. Goldschmidt examined the crystals, and found that the X-radiogram agreed with a space-lattice of the rutile type with $a=4.54$ A., $c=2.88$ A., or $a:c=1:0.633$. E. Wedekind and C. Horst gave 4.339 for the sp. gr. W. Prandtl said that in the absence of air it does not fuse at the m.p. of platinum, but in air, it slowly forms the pentoxide. K. Friederich gave 1967° for the m.p.; and E. Friederich and L. Sittig, 1640° . W. G. Mixer gave for the heat of formation $(V_2O_3, O)=59.6$ Cals.; and since $(2V.5O)>441$ Cals., and $(V_2O_4, O)=28.2$ Cals., $(2V, 4O)>413$ Cals. He also gave $(V_2O_2, O_2)=204.2$ Cals. H. Müller gave $(V_2O_3, O)=61$ Cals.; K. Friederich gave 55 ohms for the electrical resistance per sq. mm., and E. Friederich and L. Sittig, for the sp. resistance, gave 450×10^{-4} ohms at 1100° . T. F. Rutter studied the oxidation and reduction potentials—*vide supra*. E. Wedekind and C. Horst found the magnetic susceptibility to be 3.73×10^{-6} units. N. Perrakis studied this subject. J. J. Berzelius found that when the tetroxide is heated to redness in a current of dry hydrogen it forms the trioxide. H. Müller found the equilibrium constant, K , in the reaction: $V_2O_4 + H_2 = V_2O_3 + H_2O$ to be $K = \frac{[H_2O]}{[H_2]} = 2.5$ over the range 500° – 600° —*vide supra*, vanadium trioxide. He found for the values of $K = \frac{p_{H_2O}}{p_{H_2}}$ in the V_2O_5/V_2O_4 -reaction: $V_2O_4 + H_2O \rightleftharpoons V_2O_5 + H_2$, at 496° , 530° , and 600° , respectively 7.6, 21.2, and 23.3; and the calculated thermal values of the reaction, respectively 118.2, 116.2, and 116.0 Cals. H. Buff and F. Wöhler found that exposure in air, or treatment with nitric acid, converts the tetroxide into the pentoxide. The tetroxide was found by J. K. Crow gradually to absorb water and oxygen from the air, and to be easily soluble in acids and alkali-lye. According to G. Gain, when an aq. soln. of vanadium sulphite is boiled, sulphur dioxide is evolved, and a pale red, crystalline powder is deposited, which, when dried on a porous tile, is the so-called *hypovanadic acid*, $H_4V_2O_6$; or *vanadyl hydroxide*, $VO(OH)_2$; or *dihydrated vanadium tetroxide*, $V_2O_4 \cdot 2H_2O$. There are two isomeric forms of the dihydrate: one is the stable green hydrate, the other is unstable and red. When the red form is kept out of contact with the moisture of the air, it becomes olive-green. Each form loses a mol. of water at 140° – 150° , forming a bluish-black monohydrate, $V_2O_4 \cdot H_2O$, and in hydrogen at 200° – 250° , it forms the black tetroxide. The red dihydrate dissolves in sulphuric acid, forming an azure-blue soln., and the green dihydrate a green soln. The heats of soln. are respectively 12.62 and 10.89 Cals. Each soln. becomes colourless when neutralized with alkali-lye, and the heats of neutralization of the blue and green soln. are respectively 16.92 and 18.56 Cals. In passing from the red to the green dihydrate, there is therefore an absorption of 1.64 Cals. of energy. E. Parisi said that the transformation of the pink vanadyl compound into the olive-green modification is a consequence of the conversion of a part of the vanadium from the quadrivalent to the quinquevalent condition. The pink compound remains unchanged as regards colour and reducing power for potassium permanganate if it be kept in a tightly-stoppered bottle filled with water previously boiled, and sat. with carbon dioxide.

If a salt of the tetroxide, say the sulphate, or chloride, free from the pentoxide, be treated with a cold soln. of sodium carbonate, J. J. Berzelius found that a greyish-white precipitate, which when washed and dried out of contact with air—say in vacuo—consists of *hydrated vanadyl hydroxide*, $(VO)(OH)_2 \cdot 2\frac{1}{2}H_2O$, or *heptahydrated vanadium tetroxide*, $V_2O_4 \cdot 7H_2O$. The supernatant liquid should be colourless. If it is blue, insufficient sodium carbonate has been added; if brown, too much sodium carbonate has been added, and some oxide has passed into soln.; and if green, vanadic acid is present. C. Czudnowicz said that the vanadyl salts are not precipitated by sodium carbonate; and A. Guyard, that the precipitate is sodium hypovanadate.

J. J. Berzelius found that the grey heptahydrate may contain a trace of carbon

dioxide ; if any oxidation has occurred, it acquires a brown tinge, and then reddens blue litmus owing to the formation of vanadic acid. When heated in vacuo, it loses all its water, forming the anhydrous tetroxide. J. K. Crow showed that at 100°, in a current of carbon dioxide, the hydrate loses 4 mols. of water. The hydroxide is soluble in acids, forming vanadyl salts, and in alkali-lees, forming hypovanadates. Vanadium tetroxide is thus an amphoteric oxide. V. Auger found that when a mixture of sulphuric acid and vanadium tetroxide is heated, sulphur dioxide is evolved until one-third the vanadium is oxidized. J. Locke complains that vanadium tetroxide is sometimes compared with nitrogen tetroxide, and nitrous acid, NO.OH, with vanadous hydroxide, VO.OH, for little reason other than because they have similar formulæ. If this be sufficient for chemical analogy, why not put AlO.OH in the same class—for both hydroxides unite with alkalis, and both aluminium and vanadium form the alums ?

While anhydrous vanadium tetroxide dissolves slowly, the hydrated oxide dissolves quickly in acids, forming **hypovanadic or vanadyl salts**. Quadrivalent vanadium is amphoteric, for it unites either with bases or with acids to form salts. It acts as a base in the form of the bivalent radicle, VO, vanadyl, which is analogous with the bivalent radicle, UO₂, uranyl. The oxide of quadrivalent vanadium possesses very feeble acidic properties, and by a polymerization of many molecules the acidity seems to be so increased that it can form salts with bases ; as a result, a unimolecular anion of quadrivalent vanadium has not been obtained, and the vanadites hitherto investigated have the formula R₂V₄O₉. Quinquevalent vanadium compounds can be reduced to the quadrivalent form by hydroxylamine hydrochloride, formaldehyde, oxalic acid, sulphur dioxide, hydrogen sulphide, etc. J. J. Berzelius obtained the acidic soln. by reducing a soln. of vanadium pentoxide in acids by hydrogen ; nitrous acid ; sulphur dioxide ; phosphorous acid ; hydrogen sulphide—with the separation of sulphur ; hydrochloric, hydrobromic, or hydriodic acid—with the development of chlorine, bromine, or iodine ; and by the lower oxides of some metals, or the metals themselves. A. Guyard used oxalic, citric, or tartaric acid, sugar, alcohol, or methyl alcohol as reducing agent ; alcohol, hydrochloric acid, glucose, and formaldehyde act slowly, while hydroxylamine acts quickly. J. Koppel and E. C. Behrendt showed that the reaction : $V_2O_5 + SO_2 \rightleftharpoons SO_3 + V_2O_4$, in sulphuric acid soln. is reversible. The reaction was examined by H. E. Roscoe, and C. Czudnowicz. H. E. Roscoe found that in acid soln., the lower oxides of vanadium are oxidized to the tetroxide by a current of air. The anhydrous salts are brown or green, the hydrated salts are blue. Most of them are soluble in water, forming blue soln., which on oxidation becomes green. Many of them were prepared by J. J. Berzelius, C. Czudnowicz, J. Koppel and co-workers, and A. Guyard. According to J. J. Berzelius, soln. of the salts become colourless when treated with ammonia, giving a brown precipitate which forms a brown soln. with water ; alkali hydroxides or carbonates, as indicated above, precipitate the hydroxide. Ammonium sulphide gives a dark brown precipitate of vanadium sulphide, which forms a purple soln. with an excess of the precipitant. Potassium ferrocyanide gives a yellow precipitate insoluble in acids ; potassium ferricyanide, a yellowish-green gelatinous precipitate ; and tincture of galls, a bluish-black precipitate resembling ink. Hydrogen sulphide has no action on soln. of hypovanadic salts ; and zinc does not precipitate vanadium. T. F. Rutter's observations are indicated in Table I. A. Kurtenacker and F. Werner found that vanadyl sulphate quantitatively reduces hydroxylamine in strongly alkaline soln. to ammonia ; in neutral soln., nitrous oxide and nitrogen are formed ; in feebly acid soln., the catalytic decomposition furnishes ammonia, nitrous oxide, and nitrogen ; and in strongly acid soln. the action ceases. G. Canneri studied the complexes with citric and tartaric acids.

Vanadium tetroxide unites with the salifiable bases, forming **hypovanadates**—also called *vanadites*. The alkali hypovanadates are made by dissolving the tetroxide in alkali-lye ; the others, insoluble in water, are obtained as precipitates

TABLE I.—SOME REACTIONS WITH VANADOUS, HYPOVANADIC, AND VANADIC SALTS.

Reagent.	Vanadous, V ⁺⁺⁺	Hypovanadic, V ⁺⁺	Vanadic, V ⁺
Hydrogen dioxide	fast	fast	fast
Potassium permanganate	fast	fast	slow
Chromic acid	fast	fast	none

Vanadous sulphate	none	fast	fast

by double decomposition. The salts are dark brown, and when covered with water, or dissolved in it, they assume a green colour—the alkali salts soln. becomes colourless—being then oxidized to the vanadic state. The insoluble salts generally become soluble during the oxidation. The alkali hypovanadates in soln. are coloured blue by acids, forming double salts; purple-red, by hydrogen sulphide; and bluish-black, by tincture of galls. J. K. Crow found that lead acetate gives a brown precipitate; with lead nitrate the precipitation is incomplete and a blue soln. is produced. Silver nitrate gives a black, crystalline precipitate—according to J. Koppel and R. Goldmann, the precipitate contains silver hypovanadate and vanadate, and silver.

A. Ditte reported that **ammonium hypovanadate**, $(\text{NH}_4)_4\text{V}_2\text{O}_6$, is formed in green crystals by treating a soln. of the oxyiodide, $\text{V}_2\text{O}_3\text{I}_2 \cdot 2\text{HI} \cdot 3\text{H}_2\text{O}$, with ammonia; the green soln. becomes colourless when oxidized. J. J. Berzelius prepared **ammonium trihydroypovanadate**, $(\text{NH}_4)_3\text{V}_2\text{O}_6$, *i.e.* $(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$, by adding an excess of aq. ammonia to a warm soln. of a hypovanadous salt so as to dissolve the precipitate first formed, and allowing the liquid to cool slowly. The crystals are redissolved in water, and the brown soln. again treated with ammonia. The crystalline ammonium trihydroypovanadate is washed rapidly with ammonia and dried in vacuo. J. K. Crow washed the salt first with aq. ammonia, then with alcohol containing some acetic acid, and dried it over conc. sulphuric acid. The salt is readily oxidized. If the aq. soln. be evaporated in vacuo over calcium chloride, J. J. Berzelius observed that the brown product is insoluble in water. J. Koppel and R. Goldmann obtained the salt in glistening, brown needles or scales by adding a boiling soln. of the blue hypovanadous salt to aq. ammonia. The salt is soluble in water, but not soluble in alcohol, ether, or aq. ammonia. It readily gives off ammonia when exposed to air. J. Koppel and R. Goldmann prepared $\text{Na}_2\text{O} \cdot 2\text{V}_2\text{O}_4 \cdot 4\text{H}_2\text{O}$, or **hemihydrated sodium trihydroypovanadate**, $\text{Na}_3\text{V}_2\text{O}_6 \cdot \frac{1}{2}\text{H}_2\text{O}$, in golden-yellow needles or scales by the method employed for the ammonium salt, or by cooling a hot soln. of the ammonium salt mixed with sodium hydroxide. J. K. Crow obtained the *dihydrate*, $\text{Na}_3\text{V}_2\text{O}_6 \cdot 2\text{H}_2\text{O}$, and also **potassium trihydroypovanadate**, $\text{K}_2\text{H}_3\text{V}_2\text{O}_6$ with $\frac{1}{2}\text{H}_2\text{O}$ (I. Koppel and R. Gold-

mann) or $2\text{H}_2\text{O}$ (J. K. Crow), by J. J. Berzelius' process, in which a hot soln. of vanadyl sulphate or chloride is mixed with a slight excess of alkali-lye, and left to cool in a closed vessel. Brown, scaly crystals are deposited. They are washed first with potash-lye, then with alcohol, and dried in vacuo. Instead of alcohol, J. K. Crow used alcohol mixed with a little acetic acid. I. Koppel and R. Goldmann recommended the method employed for the ammonium salt. The brown product is permanent in air; is very soluble in water, forming a brown, opaque liquid—possibly a colloidal soln. The soln. is decolorized by exposure to air, forming potassium vanadate. An excess of potash-lye precipitates potassium vanadate from the brown soln. A. Ditte reported that when warm soln. of potassium iodide and soluble vanadium pentoxide are mixed together, iodine is liberated, and green lustrous crystals of the hypovanadate, $\text{K}_2\text{O} \cdot 2\text{V}_2\text{O}_4 \cdot \text{H}_2\text{O}$, are precipitated. If the mother-liquor is boiled and then conc. it deposits yellow crystals of potassium vanadate. If the iodide and vanadium pentoxide are fused together in a crucible out of contact with oxygen, iodine is liberated, and a brilliant black residue is left, which, when treated with warm water, yields a reddish-yellow soln., which deposits dark green crystals of the anhydrous hypovanadate, $\text{K}_2\text{O} \cdot 2\text{V}_2\text{O}_4$, leaving a yellow liquid, from which potassium vanadate can be crystallized.

J. Koppel and R. Goldmann were unable to prepare **silver hypovanadate**, but J. K. Crow obtained a black crystalline precipitate, $\text{Ag}_2\text{O} \cdot \text{V}_2\text{O}_4$, by the action of silver nitrate on potassium hypovanadate. J. K. Crow, and I. Koppel and R. Goldmann obtained **barium trihydrohypovanadate**, $\text{Ba}(\text{H}_3\text{V}_2\text{O}_6)_2 \cdot \text{H}_2\text{O}$, by adding baryta-water to a soln. of vanadium tetroxide in hydrochloric acid until the liquid had an alkaline reaction. The brown precipitate is washed by decantation with hot water, and then on a filter-paper, and drying the product in a current of carbon dioxide at 120° . J. K. Crow said that the brown, amorphous compound is freely soluble in hydrochloric or nitric acid. J. K. Crow prepared what he regarded as **lead hypovanadate**, $\text{PbO} \cdot \text{V}_2\text{O}_4$, by adding a soln. of lead acetate to a soln. of potassium hypovanadate—*vide supra*. A Rogers and E. F. Smith prepared **ammonium dihypovanadatoheptadecatungstate**, $5(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_4 \cdot 14\text{WO}_3 \cdot 13\text{H}_2\text{O}$, in black octahedral crystals freely soluble in water; no precipitation occurs with an ammoniacal soln. of cupric sulphate. O. W. Gibbs obtained **mercurous dihypovanadatoheptadecatungstate** from a soln. of mercurous nitrate and ammonium dihypovanadatoheptadecatungstate. J. J. Berzelius obtained a brown **manganese hypovanadate** by double decomposition; the product is oxidized by air to a yellow vanadate.

§ 8. Vanadium Pentoxide

The end-product of the oxidation of vanadium, the lower oxides, the nitride or the sulphide, by roasting in air is vanadium pentoxide, V_2O_5 , or *vanadic anhydride*, or, according to A. Werner,¹ *vanadan-oxide*. The pentoxide was also obtained by J. J. Berzelius and others, by oxidizing these substances with nitric acid or aqua regia, or by fusion with potassium nitrate, and washing the product with a dil. acid; it is formed by the hydrolysis of vanadium oxytrichloride, or oxytribromide; and by heating compounds of vanadium pentoxide with the volatile acids or bases. J. E. Teschemacker said that an impure vanadite occurs as *vanadium ochre* in the Cliffe Mine, Lake Superior; but W. T. Schaller said that the supposed mineral is cuprous oxide—a variety of cuprite or hydrocuprite. F. L. Hess described an opaque black mineral which he called **vanoxite**—compounded from vanadium oxide—occurring in the Utah-Colorado carnotite region. Its composition approximates *vanadyl vanadate*, $2V_2O_4 \cdot V_2O_5 \cdot 8H_2O$.

The extraction of vanadium pentoxide from various minerals has been already discussed. H. E. Roscoe recommended purifying the dried pentoxide by moistening it with sulphuric acid, mixing it with hydrofluoric acid to remove the silica, and heating the mixture so as to drive off the sulphuric acid; to remove phosphates, the oxide is deflagrated with an equal weight of sodium in an iron crucible, and the residue washed with water until free from soluble alkali. The residue is treated with nitric acid, and converted into ammonium vanadate, which is purified by repeated crystallization. A. Safarik found that the pentoxide of a high degree of purity is produced when the oxytrichloride is decomposed by water; F. J. Pope described the preparation of a pure pentoxide from ammonium metavanadate. According to C. Matignon, in the decomposition of ammonium metavanadate by heat, any reduction of the resulting vanadium pentoxide may be avoided by proper working. The pure salt should be roasted in an oxidizing muffle with slowly-rising temp., and care exercised to prevent melting until the decomposition of the ammonium salt is complete. A platinum dish must be employed, since silicates are attacked and iron causes reduction. In the decomposition, an intermediate product may be isolated. By slow heating of a thin layer, the colour is seen to pass through yellow, brown, ruby-red, and a metallic steel-blue, and finally to become brick-red. The metallic-looking body had the formula $5V_2O_5 \cdot 2VO_3 \cdot NH_4$.

A. Ditte assumed that there are three **allotropic forms** of the pentoxide. (1) A reddish-yellow, ochreous powder formed by heating ammonium vanadate in a closed vessel, treating the product with nitric acid, evaporating to dryness, and gently heating the residue. It absorbs water readily from the air, forming red $V_2O_5 \cdot H_2O$, and afterwards $V_2O_5 \cdot 2H_2O$. The hydrates form a blood-red soln. with water. (2) A pale yellow powder obtained by heating ammonium vanadate at 440° for several hours in a current of dry air. It does not absorb moisture from the air, and is only slightly soluble in water with which it forms a yellow soln. A similar oxide, but with a reddish-yellow colour, is obtained by boiling ammonium vanadate with dil. nitric acid, and heating the resulting dihydrate to 350°–440°. (3) A dark brownish-red mass of needle-like crystals is obtained by heating ammonium vanadate out of contact with air, treating the residue with nitric acid, and heating the product until fused. The resulting pentoxide can be left in contact with water for several months when only 0.05 grm. per litre passes into soln. F. Ephraim doubted whether these different varieties are real allotropes; the differences may be a question of the average grain size.

The pentoxide prepared by roasting the hydrate, or the ammonium salt, is a reddish-yellow powder, and when hot, the powder is brick-red. J. J. Berzelius added that the colour is lighter the finer the grain-size of the powder. The molten oxide is yellowish-red, according to N. G. Sefström, and dark brown, according to J. F. W. Johnston. On cooling the fused pentoxide to the temp. at which it no longer appears red-hot in diffused daylight, J. J. Berzelius observed that heat is again developed and a glowing ring appears to pass inwards from the circumference to the centre of the mass, where the light is longest visible. The cold mass is reddish-brown, and, according to A. E. Nordenskjöld, it consists of a mass of acicular **crystals** belonging to the rhombic system. A. E. Nordenskjöld said that the crystals obtained by J. J. Berzelius were rhombic prisms with the axial ratios $a : b : c = 0.3832 : 1 : 0.9590$; and with the cleavages on the (100)- and (010)-faces perfect; and the cleavage on the (001)-face distinct. F. Rinne studied the X-radiogram. According to J. J. Berzelius, if the pentoxide contains the tetroxide or a heavy metal oxide, it does not crystallize after fusion, but forms a cauliflower-like mass and appears black; if it contains only a little tetroxide, it may crystallize, but has then a darker colour, inclining to violet.

A. Safarik gave 3.49–3.56 for the **specific gravity** of crystallized vanadium pentoxide at 20°; W. Prandtl and B. Bleyer, 3.359; and E. Wedekind and C. Horst, 3.320. D. Balareff, and C. del Fresno studied the mol. vol. W. Prandtl gave for the **melting point** 690°, and T. Carnelley, 658°. J. J. Berzelius said that the pentoxide can be heated white-hot without losing oxygen provided no reducing gases have access to the compound; and A. A. Read found that the pentoxide is decomposed at 1750°, forming the trioxide. According to J. A. Norblad, the molten pentoxide contaminated with tetroxide may spit on cooling owing to the evolution of some oxygen. P. Hautefeuille said that the **spitting** is conditioned by the presence of alkali; the quantity of oxygen given off is proportional to the quantity of contained alkali. E. Tiede and E. Birnbräuer said that the pentoxide does not volatilize or melt when heated. W. Prandtl showed that the spitting which occurs when the molten alkali acid vanadates solidify is due to the reversible change of the acid vanadate to vanadylvanadate on solidification: $mM_2O \cdot nV_2O_5 \rightleftharpoons mM_2O \cdot (n-p)V_2O_5 \cdot pV_2O_4 + \frac{1}{2}pO_2$, for oxygen is again absorbed and the acid vanadate regenerated on heating the vanadylvanadate in air. W. Prandtl showed that only the acid vanadates of the first group in the periodic system spit on solidification. The presence of a moderate proportion of boric oxide does not affect the spitting, but if much phosphate be present, no spitting occurs. J. J. Berzelius observed that vanadium pentoxide exhibited a calorescence when the undercooled liquid crystallizes. H. Moissan and A. Holt found that the pentoxide volatilizes when heated in the electric furnace. W. G. Mixer gave for the **heat of formation** $(2V,5O) > 441$ Cals; $(V_2O_3, O_2) = 87.8$ Cals.; $(V_2O_4, O) = 28.2$ Cals.; and $(V_2O_2, 3O) = 232.4$ Cals.; H. Müller calculated $(V_2O_4, O) = 117$ Cals.; O. Ruff and L. Friedrich gave $(2V,5O) = 437 \pm 7$ Cals.; and O. Ruff and W. Martin gave 2456 Cals. for the heat of combustion, and W. Muthmann and co-workers, 31.303 Cals. per eq. W. W. Coblenz examined the **ultra-red emission spectrum** of the pentoxide. According to J. Gibbons, alkali vanadates become green when in contact with organic substances and exposed to light, and as in the case of chromates (*q.v.*), glue under these conditions becomes insoluble in water. C. Renz found that brown vanadium pentoxide is **photosensitive**, for it becomes black with greater or less rapidity when exposed to light beneath glycerol, benzaldehyde, cinnamaldehyde, cuminol, or aqueous mannitol soln.; a lower oxide, initially vanadium tetroxide, is produced. Soln. of citric or tartaric acid in absolute alcohol become green and ultimately blue when illuminated in the presence of vanadium pentoxide; carbon dioxide is evolved freely. Similar decomposition is observed with mandelic acid, but, in this instance, the vanadium pentoxide is blackened. A. Karl said that vanadium oxide is triboluminescent. J. J. Berzelius found that the **electrical conductivity** of vanadium pentoxide is nil, but H. Buff and F. Wöhler,

and L. Bleekrode said that when molten, the pentoxide is a good conductor; and on electrolysis it forms the tetroxide. K. Friederich gave 31,000 ohms per sq. mm. for the electrical resistance of the pentoxide. The **electrolytic reduction** of vanadium pentoxide was examined by J. T. Brierley, A. Cioci, A. Bültemann, A. Piccini and N. Brizzi, and T. F. Rutter. A. C. Chapman and H. D. Law found that with a platinized platinum cathode the reduction did not reach the trioxide stage, but with a cathode of zinc, cadmium, or lead, the dioxide stage is reached. H. H. Willard and F. Fenwick studied the electrometric titration of vanadic acid when reduced by ferrous sulphate. For T. F. Rutter's observations on the **reduction potential**, *vide supra*, vanadium. E. Wedekind and C. Horst found the **magnetic susceptibility** to be 0.16×10^{-6} units. S. Meyer gave 0.95×10^{-6} , and S. Berkman and H. Zocher, 0.39×10^{-6} .—*vide supra*, vanadium. N. Perrakis found that quinquevalent vanadium has a paramagnetism independent of temp. between 17° and 77° in vanadium pentoxide and in sodium vanadate, and between 17° and 45° in ammonium vanadate. The mean value (to within 10 per cent.) of the coefficient of atomic magnetization of quinquevalent vanadium derived from these determinations is 44.0×10^{-6} . Vanadium pentoxide has the same paramagnetism in the solid state as in soln. Like the atomic moment, the paramagnetism may have many different values in the same atom.

W. Biltz² triturated ammonium vanadate with dil. hydrochloric acid, and after washing the reddish-brown product with water found that the compound begins to pass through the filter. When the residue is treated with purified water, a reddish-yellow **colloidal solution** of vanadium pentoxide is formed. Soln. were also prepared by W. Biltz and W. Geibel, and H. Kuzel. E. Müller prepared the colloidal soln. by pouring molten vanadium pentoxide into distilled water. If the soln. is evaporated to dryness on the water-bath, the residue obtained is insoluble in water, but is much more reactive than the ordinary form of the acid. It is supposed that the production of the colloidal acid in the above manner is due to the rapidity with which the transition from the liquid to the solid state is effected. According to G. Wegelin, if the vapour of vanadium oxytrichloride is led into distilled water and the aq. soln. heated to its b.p., vanadic acid separates out in the form of reddish-brown flakes. If the precipitated acid is filtered and washed, it yields a colloidal soln. on further treatment with distilled water. If the soln. is evaporated to dryness at low temp., a resinous substance is obtained, which redissolves in water, forming a clear colloidal soln. J. D. Riedel obtained the colloidal soln. by gradually adding 50 grms. of isoamylorthovanadate to a litre of boiling water, and boiling the mixture until a homogeneous dark red soln. is obtained. When cold, the amylene is extracted with ether, and the ether removed by a current of air. About 8 per cent. of the vanadic acid is a non-colloidal soln. S. Ghosh and co-workers prepared colloidal gels by dialyzing soln. of the pentoxide. W. Prandtl and L. Hess prepared colloidal sols by the hydrolysis of butyl orthovanadate. G. Wegelin obtained the colloidal pentoxide by a prolonged grinding in an agate mortar. D. N. Chakravarti and N. R. Dhar found that colloidal soln. of vanadium pentoxide become more and more viscous, and finally set to a jelly as dialysis proceeds.

A. V. Dumansky found that the red, colloidal soln. contains negatively charged particles which gradually become smaller as the soln. ages. The electrical conductivity at first gradually falls and reaches a certain minimum value after some days, whilst the viscosity of the soln. increases; there is, however, no constant relationship between these two properties. Dilution causes a gradual rise in the conductivity, which finally assumes a constant value; this is doubtless due to the hydrolysis of the colloidal particles with the production of ions. The red colour of the sol finally changes to yellow, and yellow soln. are found to contain no colloidal particles when viewed in the ultra-microscope. The effect of temp. on the conductivity has also been studied. A rise of temp. is shown to produce an increase in conductivity; on cooling, the conductivity of the soln. does not immediately

regain its former value. According to H. Freundlich and W. Leonhardt, the colloidal particles carry a relatively large negative charge; the colloidal soln. coagulates ferric and aluminium hydroxide hydrosols. When the colloidal soln. is stirred, it presents the appearance which would be observed by a liquid in which a mass of fine crystals is suspended. If examined between crossed Nicols, the slightest disturbance of the soln. causes illumination of the dark field. The anisotropy or birefringence of the hydrosol of vanadium pentoxide was examined by H. Freundlich and co-workers, H. R. Kruyt, and A. V. Dumansky. W. Reinders inquired whether the colloidal particles are themselves anisotropic, or whether the anisotropy is due to differences in the elastic properties of the soln. in different directions. He showed that freshly prepared colloidal soln. of vanadium pentoxide are not birefringent; on keeping the soln. they slowly develop double refraction, and this is apparently due to the formation and increase in size of ultra-microscopic, crystalline needles. Hence, the colloidal particles of vanadium pentoxide are in reality micro-crystalline. H. Gessner assumed that the hydrosol prepared by W. Biltz has the constitution $(\text{HVO}_3)[\text{V}_2\text{O}_5 \cdot \frac{1}{2}\text{NH}_4 \cdot \text{H}_2\text{O}](\text{NH}_4\text{VO}_3)$. The conc. of molecularly dispersed vanadium pentoxide is always less than the solubility of crystalline vanadic acid, and furthermore decreases with increasing age of the sol; at the same time, changes occur in the viscosity and conductivity. An equilibrium value is finally attained, and in a series of sols the equilibrium conc. of molecularly dispersed vanadium pentoxide decreases rapidly with increasing conc. of colloid. These phenomena are ascribed to the growth of rod-like particles in the original sol, which contains an unstable form of condensed vanadic acid in particles of irregular size. The larger particles adsorb dissolved vanadic acid and build it into their crystal structure, thus growing at the expense of the smaller particles. The coagulation experiments show that ageing increases the sensitivity of a sol towards electrolytes. Sols prepared by E. Müller's method of pouring fused vanadium pentoxide into water have the constitution $[\text{V}_2\text{O}_5 \cdot \text{H}_2\text{O}]\text{VO}_3 \cdot \text{H}$; they behave in a very similar manner to the Biltz sols. J. Böhm examined the X-radiograms of aged sols. According to G. Wiegner and co-workers, vanadium pentoxide sols contain ultra-microns of elongated rod-like structures similar to fibrin sols; in course of time these ultra-microns grow, this being accelerated by an increase in conc. of the sol. The tendency to coagulate is much increased after this growth, and can be brought about by filter-paper, boles, carbon, silk threads, and silicic acid and gelatin gels. This gelatinization is favoured or perhaps conditioned by vanadyl salts formed by the reduction of the vanadium pentoxide. The serum obtained from the gel coagulates more sol; this is accounted for by its high content of vanadyl salts. Salts (contained in filter-paper) favour the reduction to vanadyl salts and therefore accelerate the coagulation. Vanadic acid stabilizes the sol. The dilution of the sol and consequently decreasing the conc. of the active vanadic acid ions brings about gelatinization. These results show a close analogy to fibrin sols. H. Zocher and K. Jacobssohn showed that some sols of vanadium pentoxide spontaneously separate into two phases—one isotropic and dilute, the other anisotropic and concentrated. J. Jochims observed that during the illumination, under the ultra-microscope, of a drop of a 1–2 per cent. of vanadium pentoxide sol, radially disposed, angular, rod-like particles appear, and the viscosity of the sol increases. The effect does not occur if the heat rays are filtered from the light. The same change is brought about by small quantities of sodium or calcium chloride, or potassium sulphate. Higher concentrations of the electrolyte cause the formation of a thixotropic gel—*i.e.* of a gel which can be liquefied by agitation. This subject was studied by J. Jochims.

D. N. Chakravarti and N. R. Dhar found that on the dialysis of soln. of vanadium pentoxide, the liquid becomes more and more viscous and finally gelatinizes. H. R. Kruyt showed that with an electric field parallel to the direction of the luminous beam, very little dispersion takes place, and the elongated particles apparently disappear. On the other hand, when the field is perpendicular to the luminous

beam, the Tyndall effect is very pronounced. The optical properties were studied by R. H. Humphry, H. Freundlich and co-workers, H. Mottsmith and I. Langmuir, T. Schwedoff, S. Horiba and T. Kondo, etc. J. Errera found that a freshly made soln., containing 31 parts of oxide per 1000, had a sp. inductive capacity of 74.7, and this increased with age. A soln. five years old, containing 14 parts per 1000, had a sp. inductive capacity of 400. The liquid remaining after ultra-filtration gave a value of 82.9. After dilution the sol does not reach immediately a state of equilibrium, but a portion gradually passes into the molecular disperse state and, at the same time, diminution of the sp. inductive capacity takes place. By increasing the intensity of the oscillating circuit used as a source of alternating current, and therefore the strength of the electric field, the sp. inductive capacity increases, whereas for water under the same conditions it remains constant. With rise of temp. the sp. inductive capacity diminishes. The phenomena observed have the same origin as the optical anisotropy of vanadium pentoxide sols. R. Fürth and O. Blüh found that for a wave-length of 70 cms. a vanadium pentoxide sol three years old showed an increase in dielectric constant with increase in conc., but the converse was found in the case of a freshly made sol. The dielectric constant does not increase with the field strength; it is the polarization which increases. H. Freundlich and co-workers measured the rate of crystallization of sols of vanadium pentoxide; Wo. Ostwald, the viscosity; H. Freundlich and W. Seifriz, the elastic modulus; B. Lange, the polarization of light by sols; H. Freundlich and co-workers, R. H. Humphry, G. I. Pokrowsky, D. N. Chakravarti and N. R. Dhar, and A. Frey, the double refraction; A. Szegevari and E. Wigner, the electrical phenomena; H. Zocher, the structure of the sol; and H. Gessner, W. Reinders and G. van der Lee, N. R. Dhar and S. Ghosh, the ageing. H. Freundlich and co-workers showed that the ageing of the sol is dependent on a process of crystallization which proceeds according to a reaction of the second order; it is retarded by arsenic acid, while phosphoric acid is without influence. H. Lachs studied the scintillation effects with vanadium pentoxide as an ultra-microscopic colloid, and found that the effect diminishes with long standing owing to the development of crystals. A. Ivanitzkaja and M. Proskurnin studied the cataphoresis of the colloid. N. R. Dhar and S. Ghosh found that the hydroxide is peptized by alkali-lye with sugar, starch, or glycerol. The coagulation of the colloid by electrolytes, etc., was studied by W. Ostermann, G. Wiegner and co-workers, Wo. Ostwald, and N. G. Chatterji and N. R. Dhar.

Vanadium pentoxide is tasteless, and poisonous—*vide supra*, physiological action of vanadium. H. Lessheim and co-workers³ discussed the electronic structure. The oxide reddens moist blue-litmus paper. J. J. Berzelius, and A. Ditte showed that the oxide is reduced to the trioxide when heated to redness in **hydrogen**; and E. Newbery and J. N. Pring, that it is reduced to the monoxide, at 2000° and 150 atm. press. H. Müller found the equilibrium constant, K , in the reaction $V_2O_5 + H_2 = V_2O_4 + H_2O$ to be $K = \frac{[H_2O]}{[H_2]} = 7.6-23.3$ over the range 540°-600°—*vide supra*, vanadium tetroxide. H. W. Underwood described the use of vanadium oxide as an oxidation catalyst. According to C. Reichard, soln. of vanadic acid, which are sulphur-yellow, are reduced only in the presence of a larger quantity of acid, and give first a pale bluish-green, then a pale green, and finally a dark green coloration. When the evolution of hydrogen is very feeble, a bluish coloration is first observed, which then passes through violet into green, a green precipitate finally being formed. Vanadates in concentrations above 1 per cent. give at first a violet, then a pale blue, and finally a greyish-blue coloration. J. J. Berzelius found that 100 parts of **water** at ordinary temp. dissolve 0.1 part of the pentoxide; and he added that if the powdered oxide be agitated with water, a yellow, turbid liquid is obtained from which the undissolved particles of acid are not deposited until after several days, and without being converted into the hydrate. When the yellow, turbid liquid is evaporated, it deposits most of the pentoxide in red rings round the sides of the basin, and a few crystals of a lower oxide of an orange

colour are produced owing to the reducing action of the dust of atm. air. A. Ditte gave for the solubility of the fused oxide, 0.05 grm. per litre. J. Fritzsche mixed a boiling conc. soln. of an alkali vanadate with an excess of acid, dried the washed precipitate in air freed from ammonia, and obtained pale yellow, pulverulent *dihydrated vanadium pentoxide*, $V_2O_5 \cdot 2H_2O$, or *pyrovanadic acid*, $H_4V_2O_7$. A similar product was obtained by C. von Hauer. The fresh precipitate dissolves in ammonia. According to A. Ditte, there are two forms of the dihydrate: (i) is obtained by exposing the reddish-yellow pentoxide (*vide supra*) to air, and it furnishes a blood-red limpid soln. with water; (ii) is obtained by boiling a soln. of ammonium vanadate with a little nitric acid, and drying the washed precipitate in air. This form of the dihydrate does not alter in contact with water, and is only slightly soluble in water at 100° . According to B. W. Gerland, if copper vanadate be treated with an excess of sulphurous acid, orange-yellow crystals of *monohydrated vanadium pentoxide*, $V_2O_5 \cdot H_2O$, or *metavanadic acid*, HVO_3 , are formed. K. A. Nenadkewitch found dark red aggregates of monohydrated vanadium pentoxide, $V_2O_5 \cdot H_2O$, at Tyuya-Mayum, Alai Mts., Turkestan. He called the mineral *alaite*. The same product is obtained by treating ammonium vanadate with copper sulphate, and washing the precipitate free from copper by sulphurous acid. A. Guyard suggested that B. W. Gerland's pentavanadic acid is really an ammonium vanadate. P. Düllberg reported that *ditriahydrated vanadium pentoxide*, $3V_2O_5 \cdot 2H_2O$, or *hexavanadic acid*, $H_4V_6O_{17}$, can exist in aq. soln. in a very unstable form which readily furnishes the brown dihydrate. V. Auger found that vanadic acid incompletely reduces **hydrogen dioxide**—*vide infra*, pervanadic acid. The double reduction of V_2O_5 to V_2O_4 , and of H_2O_2 to H_2O was studied by J. R. Cain and J. C. Hostetter, who attributed it to the formation of a persulphide and as catalyst in the sulphuric acid soln. The reaction was also studied by A. W. Hother-sall, and A. C. Robertson.

For some chemical properties of the pentoxide see Table I. Vanadium pentoxide readily dissolves in the strong acids, forming **vanadic salts**—*vide infra*, the vanadium halides. Vanadium pentoxide and its salts are reduced to the tetroxide by **hydrogen chloride, bromide, or iodide**. Conc. **hydrochloric acid** slowly reduces the pentoxide and gives off chlorine, and F. A. Gooch and co-workers found that in aq. soln., the tetroxide is formed. The reaction was studied by J. J. Berzelius, E. Campagne, A. Ditte, C. Czudnowicz, R. Bunsen, C. F. Mohr, R. Holverscheit, A. Rosenheim, L. Milch, O. W. Gibbs, F. Ephraim, R. Finkener, F. A. Gooch and co-workers, A. Safarik, and E. F. Smith and J. G. Hibbs—*vide infra*. The reduction with **hydrobromic or hydriodic acid** was studied by P. E. Browning, A. Ditte, C. Friedheim and H. von Euler, A. E. Stoppel and co-workers, and R. Holverscheit. H. Ditz and F. Bardach said that the reduction with hydriodic acid proceeds to the trioxide stage, but G. Edgar could obtain only the tetroxide stage. F. Ephraim, and E. B. Auerbuch and K. Lange found that some vanadium volatilizes when the pentoxide is heated with hydrochloric acid. A. Ditte, and F. Ephraim found that when a mixture of vanadium pentoxide and **potassium chloride, bromide, or iodide** is fused, the halogen escapes and potassium hypovanadate is formed; if **potassium fluoride** be employed and the residue extracted with water, potassium fluovanadate (*q.v.*) is produced; similarly also with **sodium fluoride**; while a soln. of sodium or **ammonium fluoride** dissolves vanadium pentoxide, and the soln. furnishes a series of fluovanadates. The reduction of vanadic acid by potassium iodide was found by T. Warynsky and B. Mdivani to be more readily affected in the presence of acetic acid than in the presence of the chloroacetic acids, and most readily affected in the presence of trichloroacetic acid. According to W. Prandtl and H. Manz, when a mixture of vanadium pentoxide and **calcium fluoride** is heated to redness, some vanadium is volatilized probably as a fluoride or oxyfluoride. This volatilization of vanadium from the fluoride was noted by A. Guyard, and by W. Manchot and H. Fischer.

A. Ditte said that the pentoxide is reduced to the trioxide when heated with

sulphur. The reduction of soln. of the pentoxide to the tetroxide stage by **hydrogen sulphide** was examined by G. Edgar, F. A. Genth, O. Manasse, B. W. Gerland, R. Holverschreit, C. Czudnowicz, A. Safarik, and C. F. Rammelsberg. The soln. is also reduced to the tetroxide stage by **sulphurous acid** as shown by J. J. Berzelius, A. Ditte, C. F. Rammelsberg, F. A. Genth, O. Manasse, B. W. Gerland, R. Holverschreit, and I. Koppel and E. C. Behrendt. Sulphur dioxide slowly reduces the vanadic-sulphuric acid soln. In the presence of sulphur, the reduction of quinquevalent vanadium gives at first a blue soln. of the hypovanadyl salt, and then at a later stage anhydrous vanadous sulphate is deposited and the soln. is entirely free from vanadium. According to V. Auger, a soln. of vanadic acid in **sulphuric acid** begins to decompose before the b.p. is reached. It loses oxygen, and after boiling for several hours an equilibrium is reached, two-thirds of the vanadium being reduced to the quadrivalent state, if the soln. contains less than one part of vanadium per thousand. With more conc. soln., as soon as the reduction has commenced, vanadyl hydrosulphate is first deposited and then vanadyl sulphate until the conc. is reduced to 1 : 1000. In all cases, reduction is incomplete. For the action of sulphuric acid, *vide infra*, the sulphates. J. R. Cain and J. C. Hostetter found that sulphuric acid soln. of quinquevalent vanadium are reduced to the quadrivalent form by soln. of the **persulphates**. B. W. Gerland studied the dialysis of soln. of the pentoxide in sulphuric acid. C. Matignon and F. Bourion observed that when the pentoxide is heated in the vapour of **sulphur monochloride**, vanadium tetrachloride and oxytrichloride are formed. G. Darzens and F. Bourion found that thionyl chloride forms an oxychloride when heated with **thionyl chloride**. A. Ditte showed that when the pentoxide is heated in a current of **ammonia**, it is reduced to the tetroxide stage. G. Gore found that vanadium pentoxide is insoluble in liquid ammonia; and F. Ephraim and G. Beck observed that when exposed to ammonia gas, **vanadium monaminopentoxide**, $V_2O_5 \cdot NH_3$, is formed—possibly $NH_4(NH_2V_4O_{10})$. A. Ditte showed that in aq. soln., **ammonium salts**—chloride, perchlorate, iodate, carbonate, acetate, oxalate, nitrate, phosphate, arsenate, sulphate, chromate, molybdate, tungstate, and borate—form complex salts. I. Koppel and E. C. Behrendt found that **hydroxylamine** reduces soln. of vanadium pentoxide to the tetroxide stage; and the reduction with hydroxylamine and **hydrazine** was studied by K. A. Hofmann and F. Küsspert, K. A. Hofmann and V. Kohlschütter, and G. von Knorre and K. Arndt. J. J. Berzelius found that vanadium pentoxide is reduced by **nitrous acid**. Red **phosphorus** was found by A. Ditte to reduce the pentoxide to the tetroxide stage; and by L. Rosenstein, to the tervalent state. J. J. Berzelius found that vanadium pentoxide is reduced by **phosphorous acid**. A. Guyard found that when the pentoxide is fused with **phosphoric acid**, it forms a glassy mass. O. Kallauner and I. Hrudá found that the fusion point of china clay was lowered by admixture with vanadium pentoxide :

V_2O_5 .	0	1	5	10	20	40	60	80	100 per cent.
Fusion	1770°	1750°	1730°	1710°	1670°	1435°	1180°	940°	675°

Vanadium pentoxide forms a series of heteropoly-acids and salts with **silicates** (6. 40, 47), **chromates**, **molybdates**, and **tungstates**—*vide infra*. J. A. Hedvall and N. von Zweigbergk studied the action of **barium dioxide** on vanadium pentoxide. A. Ditte found that **arsenic trioxide** reduces the pentoxide to $V_2O_3 \cdot V_2O_4$.

A. Guyard found that when fused with **boric oxide**, vanadium pentoxide forms a glassy mass; and J. J. Berzelius found that vanadium pentoxide dissolves in molten **borax**, producing a yellow glass in an oxidizing atm., and a green one in a reducing atm. J. J. Berzelius, H. E. Roscoe, and J. F. W. Johnston found that when heated to whiteness with **carbon**, the pentoxide is reduced to the trioxide or to $V_2O_3 \cdot V_2O_4$. R. E. Slade and G. I. Higson found the equilibrium press. of the oxide with carbon is 1.5 mm. at 1340°. B. Mdivani found that the pentoxide is reduced to the trioxide when heated in **carbon monoxide**; and to the dioxide when

heated in **hydrogen cyanide** vapour. A. F. Benton studied the adsorption of carbon monoxide and **carbon dioxide** by vanadium pentoxide. G. Fester and G. Berraz used vanadium pentoxide, and silver and copper vanadates as catalysts in the oxidation of **alcohol**; W. P. Yant and C. O. Hawk, in the oxidation of methane; and K. Chakravarty and J. C. Ghosh, on carbon monoxide and hydrogen. A. Ditte found that **organic salts**—e.g. ammonium oxalate—reduce the pentoxide. The reduction of soln. of vanadic acid with **oxalic acid** or **oxalates** as studied by A. Rosenheim, and W. Halberstadt; and with **tartaric acid** and the **tartrates**, by P. E. Browning. A. Guyard, J. J. Berzelius, and I. Koppel and E. C. Behrendt observed that vanadic acid soln. are reduced by oxalic, tartaric, or **citric acid**; by **sugar, ethyl and methyl alcohol, glucose** and **formaldehyde**. J. J. Berzelius found that the pentoxide is insoluble in absolute alcohol, and sparingly soluble in aq. alcohol. W. Prandtl said that a colourless soln. in absolute alcohol can be obtained in ethyl vanadate by passing the vapour of alcohol into a mixture of alcohol with a fused mixture of vanadic and boric oxides so as to volatilize the boric oxide. A. Ditte found that when the pentoxide is heated with **potassium cyanide**, it is reduced to the trioxide; and W. E. Kay showed that the vapour of **carbon disulphide** reduces it to the trisulphide. P. Jannasch and H. F. Harwood found that when heated in the vapour of **carbon tetrachloride**, vanadium is quantitatively volatilized from vanadium pentoxide and the vanadates. H. D. Gibbs, S. Medsforth, J. M. Weiss and co-workers studied vanadium pentoxide as an oxidation catalyst of benzene, naphthalene, anthracene, and the methylbenzenes. K. Fuwa studied the colouring action of vanadium compounds on glass.

According to J. J. Berzelius, there is a vigorous reaction when vanadium pentoxide is heated with **potassium** and a mixture of the lower oxides is formed. Similar results were obtained by H. E. Roscoe with **sodium**. J. Locke and G. H. Edwards found that **sodium-amalgam** reduces a soln. of quinquevalent vanadium to the trivalent form. According to F. Hundeshagen, vanadic acid and other vanadic compounds do not precipitate **gold** from acidic, neutral, or alkaline soln.; in hydrochloric acid soln. or in presence of chlorides they exert a solvent action on gold, becoming thereby reduced to the vanadous or hypovanadous condition; if the soln. is then made neutral or alkaline, the whole of the gold is at once precipitated as a greyish-violet powder, which redissolves again on acidifying the soln. H. Moissan observed that **calcium** reduces the pentoxide to the lower oxide. The reduction of soln. of vanadic acid to the trioxide stage by **magnesium, zinc, and cadmium** was observed by C. Reichard, C. F. Rammelsberg, H. E. Roscoe, and F. A. Gooch and R. D. Gilbert. B. Glassmann, and A. C. Chapman and H. D. Law found that the pentoxide in sulphuric acid soln is reduced to the dioxide by zinc, and to the trioxide by magnesium. Zinc coated with cadmium acts far more rapidly than zinc coated with platinum. The reaction was also examined by B. Glassmann, and by F. A. Gooch and G. Edgar. K. Someya found that zinc-amalgam, and **bismuth-amalgam** reduce quinquevalent to quadrivalent vanadium salts; the reduction also occurs with **lead-amalgam**. According to L. W. McCay and W. T. Anderson, vanadic acid is reduced to quadrivalent vanadium by **mercury**: $\text{HVO}_3 + \text{Hg} + 3\text{HCl} = \text{VOCl}_2 + \text{HgCl} + 2\text{H}_2\text{O}$; or $2\text{HVO}_3 + 2\text{Hg} + 3\text{H}_2\text{SO}_4 = 2\text{VOSO}_4 + \text{Hg}_2\text{SO}_4 + 4\text{H}_2\text{O}$. K. Someya found that bismuth-amalgam reduces vanadium salts in sulphuric acid soln. to the quadrivalent form. C. W. Ridsdale, O. Lindemann, and D. T. Williams studied the reduction of vanadates by **ferrous salts**. Vanadium pentoxide dissolves in **alkali-lye**, forming **vanadates**.

There is a number of vanadates of higher acidity, for which a satisfactory nomenclature has not been devised. C. F. Rammelsberg had a try. He classed the alkali vanadates :

Basic.	Neutral.	Acidic.
$M_8V_2O_9$		$M_2V_4O_{11}$ (tetra)
M_3VO_4 (ortho)	MVO_3 (meta)	MV_3O_8 (hexa)
$M_4V_2O_7$ (pyro)		

Following the method employed for the silicic acids, the orthopolyvanadic acids may be referred to the general formula $H_{n+2}V_nO_{3n+1}$: the loss of one mol. of water furnishes the protopolyvanadic acid—*i.e.* the *metapolyvanadic acids*—the loss of two mols. of water, deuteroxyvanadic acid ; etc. That is,

Orthopolyvanadic acid	$H_{n+2}V_nO_{3n+1}$
Protopolyvanadic acid	$H_nV_nO_{3n}$
Deuteroxyvanadic acid	$H_{n-2}V_nO_{3n-1}$
Triteroxyvanadic acid	$H_{n-4}V_nO_{3n-2}$
Teteroxyvanadic acid	$H_{n-6}V_nO_{3n-3}$
Penteroxyvanadic acid	$H_{n-8}V_nO_{3n-4}$
Hexeroxyvanadic acid	$H_{n-10}V_{12}O_{3n-6}$

Hence pyrovanadic acid, $H_4V_2O_7$, becomes *orthodivanadic acid* ; P. Düllberg's *tetrabasic hexavanadic acid*, $H_4V_6O_{17}$ —assumed to be present in aq. soln.—becomes *deuterohexavanadic acid* ; and T. Carnelley's salt, $6Tl_2O \cdot 7V_2O_5$, assumed to be a chemical individual, becomes the thallium salt of the imaginary *deuteroheptavanadic acid*, $H_{12}V_{14}O_{41}$.

J. J. Berzelius² observed that when a soln. of vanadic acid is treated with ammonia or an ammonium salt, **ammonium metavanadate**, NH_4VO_3 , is precipitated ; and N. G. Sefström found that it is deposited when solid ammonium chloride, more than sufficient for saturation, is placed in a soln. of a vanadate. B. W. Gerland showed that if the soln. contains a potassium salt the precipitated metavanadate is contaminated with the alkali, but with sodium salts, the precipitate is not affected. M. Lachartre prepared ammonium metavanadate, NH_4VO_3 , by saturating aq. ammonia with moist vanadium pentoxide, and crystallizing the products from dil. aq. ammonia. The sp. gr. is 2.326. One hundred parts of water dissolve 5.18 parts of the salt at 15° and 10.4 parts at 32° ; it is only slightly soluble in hot alcohol and in ether. When heated in a vacuum to 135°–210°, the salt yields anhydrous ammonium triivanadate ; above 210°, lower oxides of vanadium are formed. On boiling in aqueous soln., soluble ammonium divanadate and the insoluble hexavanadate are formed. Ammonium metavanadate forms colourless crystals which, according to J. A. Norblad, are isomorphous with the corresponding potassium salt. J. J. Berzelius obtained a variety with lemon-yellow crystals by digesting vanadium pentoxide in a closed vessel with ammonia, adding an excess of ammonia to the reddish-yellow liquid, and allowing the soln. to evaporate spontaneously. H. E. Roscoe, J. J. Berzelius, and J. A. Norblad found that the colourless crystals lose ammonia when heated and acquire a colour varying from lemon-yellow to reddish-brown. According to J. A. Norblad, when the salt is heated until ammonia is no longer evolved, a dark brown mixture of tetroxide and pentoxide is formed, which when treated with alkali-lye furnishes graphite-like prisms of the tetroxide, and a soln. of the pentoxide ; H. E. Roscoe found that when heated in oxygen, the pentoxide alone remains as a residue, and if heated in a covered crucible, a mixture of vanadium nitride, dioxide, trioxide, and one of the $V_2O_4 \cdot V_2O_5$ oxides is formed. The action of heat on ammonium metavanadate was studied by A. Ditte, C. Matignon, and F. Ephraim and G. Beck—*vide supra*. C. Matignon gave for the heat of formation $V_2O_{5solid} + H_2O_{liquid} + 2NH_{3gas} = 2NH_4VO_{3solid} + 43.6$ Cals. R. Robl observed no fluorescence with the salt in ultra-violet light. J. J. Berzelius said that the salt is only sparingly soluble in cold water, furnishing a colourless soln. ; it is more soluble in boiling

water, forming a yellow soln. The yellow colour is not due to the loss of ammonia because it is formed when the salt is placed in cold water in a closed vessel and the whole immersed in boiling water. C. von Hauer, and J. A. Norblad said that a hot soln. of the salt loses ammonia; while A. Ditte found that after some hours' boiling, the aq. soln. deposits crystals of hexavanadate, and if it is to remain colourless, a large excess of ammonia must be present. A. Guyard said that it dissolves best in water at 70°. A. Ditte said that cold water dissolves 10 grms. per litre, and boiling water 60 grms. per litre. In the latter case, some of the salt is decomposed. C. Matignon found that helianthine is coloured red by the aq. soln. of ammonium metavanadate, but phenolphthalein gives no sharp reaction. J. J. Berzelius obtained a black, inky liquid with tincture of galls; R. Wagner, with gallic acid; and R. Böttger, with pyrogallol. R. Wagner, and J. Bellier observed colorations were produced by a number of organic compounds.

J. J. Berzelius prepared **ammonium deuterotetranavanadate**, $(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5$ with 2 (or 3) mols. of H_2O , that is, $(\text{NH}_4)_2\text{V}_4\text{O}_{11} \cdot 2\text{H}_2\text{O}$; or **ammonium tetrahydrorthotetranavanadate**, $(\text{NH}_4)_2\text{H}_4\text{V}_4\text{O}_{13}$, by evaporating an aq. soln. of ammonia sat. with vanadium pentoxide; A. Guyard evaporated the soln. at 60°–70°. C. von Hauer, A. Ditte, J. J. Berzelius, and A. Guyard added conc. acetic acid to a hot aq. soln. of ammonium metavanadate until the precipitate first formed redissolves, or until the liquid becomes permanently red. The liquid can be evaporated spontaneously while protected from dust, or over conc. sulphuric acid; or it can be cooled for crystallization. The red or garnet-red rhombic prisms or plates have a golden reflex. J. A. Norblad said that the crystals lose water very slowly when exposed to air. A. Ditte, and J. A. Norblad said that the aq. soln. is unstable, and soon deposits plates of the hexavanadate—*vide infra*. According to M. Lachartre, by the action of 4 per cent. acetic acid on boiling soln. of ammonium metavanadate, the tetranavanadate, $2\text{V}_2\text{O}_5 \cdot (\text{NH}_4)_2\text{O} \cdot 3\text{H}_2\text{O}$, is obtained, which on desiccation loses $2\text{H}_2\text{O}$. The use of 10 per cent. acid gives the hexavanadate, $3\text{V}_2\text{O}_5 \cdot (\text{NH}_4)_2\text{O} \cdot 2\text{H}_2\text{O}$, of sp. gr. 2.594, desiccation of which gives an anhydrous, red salt of sp. gr. 2.163. The previously-described, yellow, anhydrous trivanadate has a sp. gr. of 3.029. When the acetic acid is replaced by nitric, hydrochloric, or sulphuric acid, indefinite acid ammonium vanadates are formed, the composition varying with the concentration of the acid added. With a large excess of hydrochloric acid, reduction of the vanadate also takes place.

A. Ditte prepared what he called **ammonium sesquivanadate**, or **ammonium deuterohexavanadate**, $(\text{NH}_4)_4\text{V}_6\text{O}_{17}$, or $(\text{NH}_4)_2\text{O} \cdot 3\text{V}_2\text{O}_5$, with 4 or 6 mols. of H_2O , so that it may be **ammonium tetrahydrorthohexavanadate**, $(\text{NH}_4)_4\text{H}_4\text{V}_6\text{O}_{19}$, in ruby-red crystals, by crystallization from a soln. of vanadium pentoxide in a sat. soln. of ammonium oxalate. Some pale yellow crystals of an oxalatovanadate may be formed at the same time. The salt is easily soluble in cold water. J. A. Norblad prepared golden yellow, rhombic plates of **ammonium triterohexavanadate**, $(\text{NH}_4)_2\text{V}_6\text{O}_{16}$, or $(\text{NH}_4)_2\text{O} \cdot 3\text{V}_2\text{O}_5$, by dissolving ammonium deuterotetranavanadate in luke-warm water, and heating the clear, red liquid on a water-bath. C. F. Rammelsberg made it by adding an excess of acetic acid to a soln. of ammonium metavanadate, and from the mother-liquid obtained in the preparation of the tetreroecavanadate; F. Ephraim and G. Beck, by heating the metavanadate to 202°; and A. Ditte, by boiling an aq. soln. of the metavanadate for a long time, and by keeping at 70° a soln. of vanadium pentoxide in an aq. soln. of the metavanadate. A. Ditte said that the dry salt gives off no ammonia at 125°, a little at 160°, and all is expelled at 350°. It is almost insoluble in cold or hot water; boiling water dissolves 1.5 grms. per litre. This salt is the most stable of all the ammonium vanadates. F. Ephraim and G. Beck observed the formation of no ammonia when this salt is exposed to ammonia gas. A. Ditte's product was *penta-hydrated*; and that of C. von Hauer, *hexahydrated*. Neither J. A. Norblad, nor C. F. Rammelsberg could prepare the hexahydrate.

C. F. Rammelsberg prepared **ammonium tetreroecavanadate**, $(\text{NH}_4)_4\text{V}_{10}\text{O}_{27}$.

$10\text{H}_2\text{O}$, or $2(\text{NH}_4)_2\text{O}\cdot 5\text{V}_2\text{O}_5\cdot 10\text{H}_2\text{O}$, by spontaneously evaporating a red soln. of ammonium metavanadate in acetic acid. The red prisms belong to the quadratic system. C. F. Rammelsberg thought that C. von Hauer's ammonium deuterotetrametavanadate may really be this salt. C. Matignon obtained **ammonium hexerododecavanadate**, $(\text{NH}_4)_2\text{V}_{12}\text{O}_{30}$, as a black, metallic powder, as an intermediate stage in the decomposition of ammonium metavanadate by heat. C. F. Rammelsberg reported what he called $\frac{5}{2}$ -acid ammonium vanadate, that is, **ammonium penterotetradecavanadate**, $(\text{NH}_4)_6\text{V}_{14}\text{O}_{38}\cdot 4\text{H}_2\text{O}$, or $3(\text{NH}_4)_2\text{O}\cdot 7\text{V}_2\text{O}_5\cdot 4\text{H}_2\text{O}$, to be obtained as a yellowish-red powder from an acetic acid soln. of ammonium metavanadate. This salt is possibly C. von Hauer's deuterotetrametavanadate.

The oxidation of hydroxylamine and of hydrazine by vanadium sulphate was examined by K. A. Hofmann and F. Küsspert, and G. von Knorre and K. Arndt. K. A. Hofmann and V. Kohlschütter prepared **ammonium aminodihydroxylaminometavanadate**, $(\text{NH}_4)\text{VO}_3(\text{NH}_2\text{OH})_2(\text{NH}_3)$, by mixing 100 c.c. of aq. ammonia—sat. at 5° —with finely-powdered hydroxylamine hydrochloride (10 grms.); the mixture was cooled to 0° and ammonium metavanadate (3 grms.) gradually added and the mixture allowed to remain at 0° until yellow crystals separated; the lemon-yellow leaflets thus obtained were washed with conc. ammonia and dried in an atm. of ammonia over potassium hydroxide at as low a temp. as possible. The compound is quickly decomposed by water and dilute sodium hydroxide, dissolves in hydrochloric or sulphuric acid with the evolution of nitrous oxide, and when heated decomposes with a slight explosion. They also made **hydroxylamine diamminotrihydroxylaminometavanadate**, $(\text{NH}_4)\text{VO}_3(\text{NH}_2\text{OH})_3(\text{NH}_3)$, in a similar manner to the preceding, but only 1.5 grms. of ammonium metavanadate were employed to 10 grms. of hydroxylamine hydrochloride; it crystallizes in slender yellow needles, is rapidly decomposed by moisture and carbonic anhydride, and contains 1 mol metavanadic acid, 3 mols hydroxylamine, and 2 mols ammonia. They also obtained what they thought to be **ammonium dihydroxylaminometavanadate**, $(\text{NH}_4)\text{VO}_3(\text{NH}_2\text{OH})_2$, as an unstable, impure product.

C. F. Rammelsberg prepared **lithium orthovanadate**, Li_3VO_4 , by heating a mixture of vanadium pentoxide and lithium carbonate, or nitrate, in stoichiometrical proportions. The resulting yellow powder was insoluble in water. A. Ditte obtained the *hexahydrate*, $\text{Li}_3\text{VO}_4\cdot 6\text{H}_2\text{O}$, by crystallization from the mother-liquor obtained in the preparation of the pyrovanadate. A. Rosenheim and W. Reglin obtained the *enneahydrate* in transparent, rhombohedral needles as indicated below, and this is probably the salt obtained by A. Ditte. The solubility coeff. of the ortho-salt is positive, the maximum solubility being 6.25 grms. of Li_3VO_4 per 100 grms. of soln. at 35.2° ; above this temp. the monohydrate is stable and the temp. coeff. is negative. The solubility represented by S grms. of Li_3VO_4 in 100 grms. of soln. is:

	0°	28.0°	28.6°	30.2°	35.2°	38.4°	40°	45°	50°	60°
S	2.40	4.60	5.25	5.91	6.25	5.09	4.20	3.90	2.80	2.60
Solid phase	$\text{Li}_3\text{VO}_4\cdot 9\text{H}_2\text{O}$					$\text{Li}_3\text{VO}_4\cdot \text{H}_2\text{O}$				

A. Ditte found that when a soln. of lithium carbonate in an excess of a hot sat. soln. of lithium hydroxide is sat. with vanadium pentoxide, it furnishes white, microscopical crystals of *monohydrated lithium oxyorthovanadate*, $\text{Li}_2\text{O}\cdot 2\text{Li}_3\text{VO}_4\cdot \text{H}_2\text{O}$; and if this salt is allowed to stand in contact with the mother-liquor for some time, transparent crystals of the *tetradecahydrate*, $\text{Li}_2\text{O}\cdot 2\text{Li}_3\text{VO}_4\cdot 14\text{H}_2\text{O}$, are formed. All the water of crystallization is expelled by heat. A. Rosenheim and W. Reglin obtained the *tetrahydrate* as a precipitate when a soln. of vanadium pentoxide in a large excess of a sat. soln. of lithium hydroxide is heated. It appears to have a negative temp. coeff. of solubility, but at low temp. when stirred with water it changes into the enneahydrated ortho-salt. By melting together stoichiometrical proportions of lithium nitrate and vanadium pentoxide, and crystallizing the aq.

soln. of the cold product, C. F. Rammelsberg obtained *tetrahydrated lithium pyrovanadate*, $\text{Li}_2\text{V}_2\text{O}_7 \cdot 4\text{H}_2\text{O}$, as a mass of white crystals. A. Ditte said that the *hexahydrate*, $\text{Li}_2\text{V}_2\text{O}_7 \cdot 6\text{H}_2\text{O}$, is obtained as a white, crystalline mass from a soln. of the orthovanadate in one of lithium hydroxide. J. J. Berzelius, C. F. Rammelsberg, and A. Ditte warmed a red soln. of lithium tetravanadate with enough lithium carbonate to give a colourless soln. and obtained a yellowish-white, crystalline mass of **lithium metavanadate**, $\text{LiVO}_3 \cdot 2\text{H}_2\text{O}$.

J. J. Berzelius prepared **lithium deuterotetravanadate**, $\text{Li}_2\text{V}_4\text{O}_{11} \cdot 9\text{H}_2\text{O}$, by the method employed for the potassium salt; and J. A. Norblad, by dissolving a fused mixture of lithium carbonate and vanadium pentoxide in hot water, mixing the soln. with acetic acid; evaporating the liquid to a syrup; adding alcohol; dissolving the dried mass in a little water; and crystallizing over conc. sulphuric acid. The orange-red crystals resemble those of potassium dichromate; they effloresce in dry air; they lose 8 mols. of water at 100° ; and almost all the water at 225° . A. Ditte obtained a hydrate with 8 or 12 mols. of water according as the soln. was crystallized hot or cold. C. F. Rammelsberg prepared **lithium orthotetravanadate**, $\text{Li}_6\text{V}_4\text{O}_{13} \cdot 15\text{H}_2\text{O}$, as a white crystalline mass from a soln. of the orthovanadate in the least possible quantity of nitric acid. The salt is sparingly soluble in water. C. F. Rammelsberg evaporated a soln. of lithium vanadate acidified with nitric acid, and obtained red, probably triclinic, crystals of **lithium deuterohexavanadate**, $\text{Li}_4\text{V}_6\text{O}_{17} \cdot 15\text{H}_2\text{O}$. A. Ditte obtained the same salt by boiling a soln. of lithium carbonate with an excess of vanadium pentoxide, acidifying the soln. with a few drops of acetic acid, and concentrating the liquid. The orange-red crystals were hexadecahydrated. C. F. Rammelsberg obtained a trihydrate and an enneahydrate. He also prepared **lithium deuterioctovanadate**, $\text{Li}_8\text{V}_8\text{O}_{18} \cdot 12\text{H}_2\text{O}$, in small, red, probably triclinic, crystals from a soln. of lithium ortho- or metavanadate acidified with acetic acid. By heating the mother-liquor from the octovanadate on a water-bath, orange-red crystals of **lithium triterodecavanadate**, $\text{Li}_6\text{V}_{10}\text{O}_{23} \cdot 14\text{H}_2\text{O}$, were formed. The salt is sparingly soluble in cold water. A soln. of lithium metavanadate in acetic acid furnished red, transparent, prismatic crystals of **lithium deuterododecavanadate**, $\text{Li}_{10}\text{V}_{12}\text{O}_{35} \cdot 30\text{H}_2\text{O}$, which rapidly effloresced in air. The salt is freely soluble in water.

C. Czudnowicz said that when vanadium pentoxide is melted with sodium carbonate each mol. of the former drives out 3 mols. of carbon dioxide, forming **sodium orthovanadate**, Na_3VO_4 . H. E. Roscoe made a similar observation. J. A. Norblad melted stoichiometrical proportions of the two compounds, and obtained a dark green viscid mass which became white. It was soluble in water, not in alcohol. H. Baker, and J. A. Hall obtained 4- or 8-sided plates of the *heptahydrate*, $\text{Na}_3\text{VO}_4 \cdot 7\text{H}_2\text{O}$, by crystallization from a soln. of 10 grms. of the dodecahydrate in 10 c.c. of sodium hydroxide soln. containing 7.5 grms. of NaOH , at 78° ; and H. Baker prepared the *decahydrate*, $\text{Na}_3\text{VO}_4 \cdot 10\text{H}_2\text{O}$, by crystallization by cooling a conc. soln. of the orthovanadate alone or mixed with sodium hydroxide. The solubility is greatly influenced by the temp. The crystals occur in dodecahedral or octahedral cubic crystals, and also in tabular, hexagonal crystals. The *dodecahydrate*, $\text{Na}_3\text{VO}_4 \cdot 12\text{H}_2\text{O}$, was prepared by adding an excess of sodium hydroxide to a soln. of sodium pyrovanadate, or by digesting the cake obtained by heating a mixture of vanadium pentoxide and sodium carbonate, in water or dil. sodium hydroxide, and crystallizing the liquid. The salt is less soluble in soda-lye than in water. The hexagonal crystals develop overgrowths in a soln. of the phosphate. A. Ditte reported that the salt is the *tridecahydrate*, $\text{Na}_3\text{VO}_4 \cdot 13\text{H}_2\text{O}$, but this is probably a mistake. H. E. Roscoe dissolved anhydrous orthovanadate in the smallest quantity of water possible, poured a layer of alcohol over the liquid, and in some hours found that the under layer furnished a mass of colourless needles of the *hexadecahydrate*, $\text{Na}_3\text{VO}_4 \cdot 16\text{H}_2\text{O}$. The salt is readily soluble in water and the soln. has an acidic reaction. H. Baker found that the orthovanadates correspond in composition and crystalline form with the orthophosphates and orthoarsenates;

thus, $\text{Na}_3(\text{P},\text{V},\text{As})\text{O}_4 \cdot 12\text{H}_2\text{O}$ are hexagonal; $\text{Na}_3(\text{P},\text{V},\text{As})\text{O}_4 \cdot 10\text{H}_2\text{O}$ are cubic; $\text{Na}_3(\text{V},\text{P},\text{As})\text{O}_4 \cdot 8\text{H}_2\text{O}$ are rhombic; and $2\text{Na}_3(\text{V},\text{P},\text{As})\text{O}_4 \cdot \text{NaF} \cdot 19\text{H}_2\text{O}$ are cubic. P. Düllberg studied the electrometric titration of soln. of vanadic acid with sodium hydroxide; he also made observations on the f.p. of the soln. He inferred from the results that the so-called orthovanadate is resolved in aq. soln. into pyrovanadate: $2\text{Na}_3\text{VO}_4 + \text{H}_2\text{O} = \text{Na}_4\text{V}_2\text{O}_7 + 2\text{NaOH}$, forming the ions $\text{V}_2\text{O}_7^{4-}$, and not HVO_4^- . A. Rosenheim and K. H. Yang studied the alkalimetric titration of sodium orthovanadate, using phenolphthalein; and α -naphtholphthalein as indicators. The electrometric titration curve of 0.1N-sodium orthovanadate, Na_3VO_4 , with 0.4N-HCl is shown in Fig. 5. A. Lottermoser placed a soln. of sodium vanadate in an inner anode cell, and 0.1N-NaOH in the outer cathode cell, and, using a platinum cylinder as anode, on electrolysis he obtained an acid vanadate in the inner cell. A. Ditte obtained **sodium oxorthovanadate**, $\text{Na}_2\text{O} \cdot 2\text{Na}_3\text{VO}_4 \cdot 26$ (or 30) H_2O , from a soln. of vanadium pentoxide in a great excess of soda-lye. If the soln. is evaporated slowly in vacuo, colourless prisms, with approximately 30 mols. of water of crystallization, are deposited; warm soln. deposit crystals with 26 mols H_2O . The salt melts in its water of crystallization, and the water escapes, leaving a white mass which gives an alkaline soln. with water. H. E. Roscoe melted a mol of vanadic pentoxide with 2 mols of sodium carbonate and obtained **sodium pyrovanadate**, $\text{Na}_2\text{V}_2\text{O}_7$. A. Ditte obtained

FIG. 5.—The Electrometric Titration Curve of Sodium Orthovanadate, Na_3VO_4 .

FIG. 6.—Electrometric Titration Curve of Hexavanadic Acid, $\text{H}_4\text{V}_6\text{O}_{17}$.

acicular crystals of the *octohydrate*, $\text{Na}_2\text{V}_2\text{O}_7 \cdot 8\text{H}_2\text{O}$, by evaporating an aq. soln. of the salt to dryness, extracting the product with aq. alcohol, and cooling the soln. when sat. at 60° . H. E. Roscoe observed that if an aq. soln. be treated with alcohol, the *octodecahydrate*, $\text{Na}_2\text{V}_2\text{O}_7 \cdot 18\text{H}_2\text{O}$, is formed; and the same salt is produced when an aq. soln. of the orthovanadate is allowed to stand, or is boiled: $2\text{Na}_3\text{VO}_4 + \text{H}_2\text{O} = 2\text{NaOH} + \text{Na}_4\text{V}_2\text{O}_7$. The hydrolysis is independent of the effect of any carbon dioxide. Alcohol precipitates an oily liquid from the soln., and this furnishes crystals of the octohydrate; J. A. Norblad obtained the salt by crystallization from a soln. of vanadium pentoxide or sodium vanadate in an excess of soda-lye. The six-sided plates or prisms were said by J. A. Norblad to be monoclinic, but C. F. Rammelsberg regarded them as hexagonal with the axial ratio $a : c = 1 : 0.962$. S. Motylewsky gave 302 mgrms. for the drop-weight of the pyrovanadate when that of water is 100 mgrms. at 0° . The crystals effloresce in air. They are freely soluble in water but not in alcohol. Ammonium chloride precipitates ammonium metavanadate from the aq. soln. J. J. Berzelius prepared **sodium metavanadate**, NaVO_3 , by allowing a soln. of the pentoxide in soda-lye to evaporate spontaneously; H. E. Roscoe, by treating a soln. of the pyrovanadate with carbon dioxide, and separating the sodium carbonate by crystallization; the mother-liquor contains the metavanadate, which is recovered by crystallization. J. A. Norblad used an analogous process, and also by boiling

a soln. of sodium tetravanadate with dil. soda-lye until colourless. On evaporation straw-yellow or colourless, monoclinic, prismatic crystals are formed. The salt readily fuses, and when cold furnishes a white crystalline mass. If the aq. soln. be evaporated over sulphuric acid, it furnishes warty masses of prismatic crystals of the *monohydrate*, $\text{NaVO}_3 \cdot \text{H}_2\text{O}$, and all the water can be removed by keeping the crystals over sulphuric acid. If the mother-liquor from the monohydrate be treated with water and then with alcohol, an oily liquid is precipitated, and this furnishes crystals of the *dihydrate*, $\text{NaVO}_3 \cdot 2\text{H}_2\text{O}$; if crystallized from a mixture of alcohol and water, the salt contains $2\frac{1}{2}$ mols of water; and if crystallized from a soln. of sodium carbonate, 3 or 4 mols of water according to the temp. S. Motylewsky gave 246 mgrms. for the drop weight of the metavanadate, when that of water at 0° is 100 mgrms. P. Düllberg inferred from the f.p. of soln. of the metavanadate, that the salt is really *sodium metatritovanadate*, $\text{Na}_3\text{V}_3\text{O}_9$. According to G. Canneri, the electrical conductivity of soln. of sodium metavanadate, acidified with increasing proportions of acetic acid, varies continuously at 30° , indicating that the condensation of the mols of the metavanadate is a continuous function of the conc. of the acetic acid. At the same time the colour of the soln. changes from yellow to orange-red. P. Pascal gave -30.2×10^{-5} for the mol. magnetic susceptibility of soln. of sodium metavanadate. F. Reichart and R. Wernicke found that soln. of ferric salts and of ferrous sulphate added in small quantities to alkaline soln. of sodium vanadate cause the precipitation of the vanadium as insoluble ferric vanadate, and by adsorption on the ferric hydroxide formed.

J. J. Berzelius prepared *enneahydrated sodium deuterotetravanadate*, $\text{Na}_2\text{V}_4\text{O}_{11} \cdot 9\text{H}_2\text{O}$, by treating a soln. of an excess vanadium pentoxide in one of sodium carbonate at 80° , with an excess of acetic acid, and concentrating the red soln. for crystallization by spontaneous evaporation. C. von Hauer said that an excess of acetic acid is to be avoided or hydrated vanadium pentoxide will be deposited. The transparent, orange-red crystals resemble manganous acetate. The crystals effloresce in dry air and become yellow without changing their form. J. A. Norblad said that the water of crystallization is all expelled at 200° . J. J. Berzelius, and C. von Hauer found the salt to be freely soluble in water, but insoluble in alcohol; one part of the salt will impart a distinct yellow colour to 156,000 parts of water. The anhydrous salt is a little soluble in warm water, and freely soluble in dil. acids. The salt is sensitive to light when in contact with organic matter. A. Ditte prepared the *pentahydrate*, $\text{Na}_2\text{V}_4\text{O}_{11} \cdot 5\text{H}_2\text{O}$, by evaporating in vacuo a soln. of vanadium dioxide in a boiling soln. of sodium carbonate. T. Carnelley reported *sodium orthotetravanadate*, $\text{Na}_6\text{V}_4\text{O}_{13} \cdot 2$ or $6\text{H}_2\text{O}$, analogous to sodium tetraphosphate, by crystallization from a soln. of the cold cake obtained by melting stoichiometrical proportions of sodium carbonate and vanadium pentoxide. The crystals are sparingly soluble in cold water. The aq. soln. furnishes a precipitate of the corresponding silver or thallium salt when treated with a soln. of the corresponding metal salt. J. A. Norblad reported what he called *sodium trivanadate*, that is, *enneahydrated sodium triterohexavanadate*, $\text{Na}_2\text{V}_6\text{O}_{16} \cdot 9\text{H}_2\text{O}$, by heating the red soln. of the tetravanadate on the water-bath: $2\text{Na}_2\text{V}_4\text{O}_{11} = 2\text{NaVO}_3 + \text{Na}_2\text{V}_6\text{O}_{16}$; and A. Ditte obtained orange-red plates of the *trihydrate*, $\text{Na}_2\text{V}_6\text{O}_{16} \cdot 3\text{H}_2\text{O}$, by boiling for a long time soda-lye sat. with vanadium pentoxide. J. A. Norblad simultaneously obtained *sodium deuterohexavanadate*, $\text{Na}_4\text{V}_6\text{O}_{17} \cdot 10\text{H}_2\text{O}$, in orange-red prismatic crystals in the preparation of enneahydrated sodium deuterotetravanadate. The crystals lose 7 mols. of water over conc. sulphuric acid, and melt at a red-heat. C. F. Rammelsberg obtained red, triclinic crystals of the *hexadecahydrate*, $\text{Na}_4\text{V}_6\text{O}_{17} \cdot 16\text{H}_2\text{O}$, which M. Websky found had the axial ratios $\alpha : b : c = 0.9189 : 1 : 1.025$, and $\alpha = 83^\circ 52'$, $\beta = 91^\circ 19'$, and $\gamma = 94^\circ 31'$. The crystals effloresce in air. The water is all expelled when the salt is melted, and it is then brownish-black, and insoluble in water and in acids. S. Motylewsky gave 238 mgrms. for the drop-weight of the hexavanadate when that of water at 0° is 100 mgrms. A. Ditte reported garnet-red needles or six-sided plates of the

octodecahydrate, $\text{Na}_4\text{V}_6\text{O}_{17}\cdot 18\text{H}_2\text{O}$, to be formed by evaporating and cooling a soln. of sodium metavanadate mixed with a little acetic acid. P. Düllberg inferred that the tetravanadate, $\text{Na}_2\text{V}_4\text{O}_{11}$, is really an acid salt of *deuterohexavanadic acid*, $\text{H}_4\text{V}_6\text{O}_{17}$, namely, **sodium hydrodeuterohexavanadate**, $\text{Na}_3\text{HV}_6\text{O}_{17}$; that the salt, $\text{Na}_4\text{V}_6\text{O}_{17}$, is **sodium dihydrodeuterohexavanadate**, $\text{Na}_2\text{H}_2\text{V}_6\text{O}_{17}$; and that the neutral $\text{Na}_4\text{V}_6\text{O}_{17}$ breaks up in aq. soln., forming $\text{Na}_3\text{HV}_6\text{O}_{17}$ and sodium hydroxide. From these hexavanadates, free hexavanadic acid is precipitated by the addition of mineral acids. It decomposes, especially if the soln. is heated or excess of mineral acid added, yielding the pentoxide, which separates as a brown precipitate. If a very large excess of acid has been added, the pentoxide passes into soln. again as a cation. The yellow hexavanadate ions, $\text{HV}_6\text{O}_{17}'''$, are not permanent in the presence either of hydrogen or hydroxyl ions, and the rate of their disappearance corresponds with the velocity of a reaction of the first order. In contrast to the phosphates, the change of metavanadate into pyro- and orthovanadate takes place instantaneously. The electrometric titration curve of the deuterohexavanadic acid with soln. $\text{H}_4=0\cdot 01264N$ -, and $0\cdot 00236N$ - NaOH , is shown in Fig. 6. W. I. Baragiola obtained dark yellow **sodium tetreroctovanadate**, $\text{Na}_2\text{V}_8\text{O}_{21}\cdot 7\frac{1}{2}$ (or $8\frac{1}{2}$) H_2O , by evaporating a boiling soln. of sodium metavanadate with a large excess of ammonium chloride; C. F. Rammelsberg, sparingly soluble **sodium tetrerodecavanadate**, $\text{Na}_4\text{V}_{10}\text{O}_{27}\cdot 3\frac{1}{2}\text{H}_2\text{O}$, from a warm conc. soln. of sodium pyrovanadate with a large excess of acetic acid; C. Friedheim and P. Michaelis, red, rhombic crystals of **sodium tetrerotetradecavanadate**, $\text{Na}_8\text{V}_{14}\text{O}_{39}\cdot 33\text{H}_2\text{O}$, from a soln. of equimolar parts of sodium metavanadate and dihydrophosphate; and C. Friedheim and P. Michaelis, red crystals of **sodium tetrerohexadecavanadate**, $\text{Na}_{10}\text{V}_{16}\text{O}_{45}\cdot 39\text{H}_2\text{O}$, from a soln. of about 1.5 parts of sodium metavanadate, and one part of sodium metaphosphate. C. F. Rammelsberg suggested that J. A. Norblad's trivanadate is really *sodium hexerohexadecavanadate*, $\text{Na}_6\text{V}_{16}\text{O}_{43}\cdot 24\text{H}_2\text{O}$.

J. A. Norblad's experiments on the amount of carbon dioxide displaced from potassium carbonate by potassium vanadate, or triterovanadate, gave no definite results. C. F. Rammelsberg prepared **potassium orthovanadate**, K_3VO_4 , by fusing a mixture of stoichiometrical proportions of potassium carbonate and vanadium pentoxide; the pale yellow, crystalline mass is decomposed by water into the potassium pyrovanadate and hydroxide. E. Jänecke discussed the action of ammonia on this vanadate. A. Ditte found that a soln. of vanadium pentoxide in a soln. of 3 eq. of potassium hydroxide furnishes crystals of the *hexahydrate*, $\text{K}_3\text{VO}_4\cdot 6$ (or $4\frac{1}{2}$) H_2O . A. Ditte reported **potassium oxyorthovanadate**, $\text{K}_2\text{O}\cdot 2\text{K}_3\text{VO}_4\cdot 20\text{H}_2\text{O}$, from a soln. of 4 eq. of potassium hydroxide and one eq. of vanadium pentoxide evaporated to a syrup, and then treated with alcohol. The salt melts in its water of crystallization and becomes anhydrous. J. A. Norblad prepared monoclinic crystals of trihydrated **potassium pyrovanadate**, $\text{K}_4\text{V}_2\text{O}_7\cdot 3\text{H}_2\text{O}$, by boiling a soln. of potassium metavanadate and hydroxide, and evaporating the syrupy liquid over sulphuric acid. C. F. Rammelsberg prepared the same salt. The salt loses one-third its water over sulphuric acid, two-thirds at 100° , and all when melted at 350° . A. Ditte represented the salt as a *tetrahydrate*. J. J. Berzelius prepared **potassium metavanadate**, KVO_3 , from a soln. of vanadium pentoxide in potash-lye by spontaneous evaporation, and extracting the excess of alkali from the product by cold water. J. A. Norblad mixed a soln. of vanadium pentoxide in conc. potash-lye with dil. acetic acid, and boiled the orange liquid until it became colourless, and repeated the treatment until a lemon-yellow liquid was obtained, which, on evaporation, furnished yellowish crystals. When these were recrystallized, colourless crystals of the metavanadate were obtained. The crystals became red, and at 100° , brick-red. They melted at a red-heat. The crystals are sparingly soluble in cold water, freely soluble in hot water, and insoluble in alcohol. J. A. Norblad obtained the *monohydrate*, $\text{KVO}_3\cdot \text{H}_2\text{O}$, by boiling a soln. of ammonium tetravanadate in potash-lye, and evaporating the colourless liquid

over sulphuric acid; or by crystallization from a soln. of the product obtained by fusing vanadium pentoxide with an excess of potassium nitrate. The colourless, needle-like crystals lose all their water at 110° . A. Ditte said that by varying the conditions he could make hydrates with $1\frac{1}{2}$, $1\frac{3}{2}$, 2, and $3\text{H}_2\text{O}$. C. F. Rammelsberg reported a *heptahydrate*, $\text{KVO}_3 \cdot 7\text{H}_2\text{O}$, from a soln. of the product obtained by melting equimolar parts of vanadium dioxide and potassium carbonate.

J. A. Norblad obtained **tetrahydrated potassium deutero-tetranavanadate**, $\text{K}_2\text{V}_4\text{O}_{11} \cdot 4\text{H}_2\text{O}$, by mixing a hot soln. of potassium metavanadate in an excess of potash-lye with acetic acid so as to produce a dark red liquid. C. F. Rammelsberg used nitric acid. On cooling the boiling liquid, orange-yellow crystals are formed. J. J. Berzelius, C. Radau, and F. Ephraim also prepared this salt. A better yield is obtained if alcohol be added after the acid. The orange-yellow, rhombic crystals are stable in air, and they are freely soluble in water; they lose no water over conc. sulphuric acid; a part is lost at 100° ; and all at 200° . The salt melts below redness. J. J. Berzelius, and J. A. Norblad also prepared a *hemiheptahydrate*, $\text{K}_2\text{V}_4\text{O}_{11} \cdot 3\frac{1}{2}\text{H}_2\text{O}$, by adding alcohol to a dil. soln. of the tetrahydrate; F. Ephraim, the *hexahydrate*, $\text{K}_2\text{V}_4\text{O}_{11} \cdot 6\text{H}_2\text{O}$, by evaporating the aq. extract of a fused mixture of a mol of vanadium pentoxide with 4 mols of potassium chloride; and A. Ditte, the *decahydrate*, by cooling the garnet-red liquid obtained by sat. a soln. of potassium carbonate at 80° with vanadium pentoxide. If the crystallization occurs at a high temp. the *trihydrate* is formed, if at a lower temp., the *octohydrate*; and if at a lower temp. still, the *decahydrate*. C. F. Rammelsberg, and J. A. Norblad prepared tabular crystals of **potassium triterohexavanadate**, $\text{K}_2\text{V}_6\text{O}_{16}$, by heating a soln. of the tetranavanadate on a water-bath until the yellow liquid becomes red: $2\text{K}_2\text{V}_4\text{O}_{11} = 2\text{KVO}_3 + \text{K}_2\text{V}_6\text{O}_{16}$. The salt is almost insoluble in water, and it is similar to the ammonium salt. J. A. Norblad obtained the *hexahydrate* $\text{K}_2\text{V}_6\text{O}_{16} \cdot 6\text{H}_2\text{O}$, from a soln. of the tetranavanadate and acetic acid; and A. Ditte reported the *monohydrate*, $\text{K}_2\text{V}_6\text{O}_{16} \cdot \text{H}_2\text{O}$, in orange-yellow crystals from a soln. of vanadium pentoxide in potassium carbonate, mixed with acetic acid, and heated to about 70° . The cold mother-liquor afterwards deposits garnet-red crystals of the *pentahydrate*, $\text{K}_2\text{V}_6\text{O}_{16} \cdot 5\text{H}_2\text{O}$. C. F. Rammelsberg made **potassium deutero-hexavanadate**, $\text{K}_4\text{V}_2\text{O}_{17} \cdot 2\text{H}_2\text{O}$, in brownish crystals, by adding acetic acid to a soln. of potassium metavanadate. A. Ditte obtained it as a *hexahydrate*. F. Ephraim melted vanadium pentoxide with an excess of potassium chloride, and washed out the soluble salts. S. Motylewsky gave 168 mgrms. for the drop-weight of the hexavanadate when that of water at 0° is 100 mgrms. The greyish-brown, tabular crystals of **potassium tetreroctovanadate**, $\text{K}_2\text{V}_8\text{O}_{21} \cdot 1\frac{1}{2}\text{H}_2\text{O}$, are sparingly soluble in water. O. Manasse obtained **potassium tetrero-decavanadate**, $\text{K}_4\text{V}_{10}\text{O}_{27} \cdot 12\text{H}_2\text{O}$, by evaporating on a water-bath the mother-liquor employed in the preparation of potassium strontium vanadate (*q.v.*). C. F. Rammelsberg obtained a crystalline mass of **potassium ortho-octovanadate**, $\text{K}_{10}\text{V}_8\text{O}_{25} \cdot 7\text{H}_2\text{O}$, by adding acetic acid to the mother-liquor obtained in preparing potassium pyrovanadate until colour disappears. C. Radau obtained **potassium triterodecavanadate**, $\text{K}_6\text{V}_{10}\text{O}_{28} \cdot 10\text{H}_2\text{O}$, by evaporating a hot soln. of 20 grms. potassium metavanadate with 22–23 c.c. of 30 per cent. acetic acid. The acid is diluted to prevent the separation of hydrated vanadium pentoxide. The dark red, monoclinic crystals have, according to A. Fock, the axial ratios $a : b : c = 0.5902 : 1 : 0.6040$, and $\beta = 117^{\circ} 40'$; 100 parts of water dissolve 19.20 parts of salt at 17.5° . F. Ephraim reported that violet crystals of **potassium hepteroctodecavanadate**, $\text{K}_4\text{V}_{18}\text{O}_{47}$, are produced by washing the soluble salts from a fused mixture of a mol of vanadium pentoxide and 2 mols of potassium fluoride; and he obtained **potassium deutero-tetracosivanadate**, $\text{K}_{22}\text{V}_{24}\text{O}_{71} \cdot 3\frac{1}{2}\text{H}_2\text{O}$, from a fused mixture of vanadium pentoxide and potassium chloride.

W. I. Baragiola prepared **ammonium sodium tetrerotetradecavanadate**, $\{(\text{NH}_4)_{0.545}\text{Na}_{0.455}\}_8\text{V}_{14}\text{O}_{39} \cdot 17\frac{1}{2}\text{H}_2\text{O}$, by crystallization from a conc. soln. of a mol of sodium metavanadate and 2 mols of ammonium chloride; A. Ditte, **ammonium**

sodium triterodecavanadate, $(\text{NH}_4)_{0.66}\text{Na}_{0.346}\text{V}_{10}\text{O}_{28}\cdot 15\text{H}_2\text{O}$, in orange plates, from a soln. of sodium silicate, ammonium metavanadate, and acetic acid; W. I. Baragiola, **ammonium potassium metatetravanadate** $(\text{NH}_4)_{0.5}\text{K}_{0.54}\text{V}_4\text{O}_{12}\cdot 1\frac{1}{2}\text{H}_2\text{O}$, by fractional crystallization from a boiling soln. of a mol of potassium metavanadate and ammonium chloride; and **ammonium potassium triterodecavanadate**, $(\text{NH}_4)_{0.25}\text{K}_{0.756}\text{V}_{10}\text{O}_{28}\cdot 13\text{H}_2\text{O}$, if the ammonium chloride be present in great excess. C. Friedheim and P. Michaelis reported **potassium sodium deuterohexavanadate**, $(\text{K}_{0.2}\text{Na}_{0.8})_4\text{V}_6\text{O}_{17}\cdot 7\text{H}_2\text{O}$, to be obtained in red, prismatic crystals from a mixture of the mother-liquor of sodium tetrohexadecavanadate, mixed with potassium chloride; and red crystals of $(\text{K}_{0.4}\text{Na}_{0.6})_4\text{V}_6\text{O}_{17}\cdot 6\text{H}_2\text{O}$, from the mother-liquor of sodium tetrerotetradecavanadate mixed with an excess of potassium chloride.

G. Chabrie prepared **cæsium metavanadate**, CsVO_3 , by boiling a mixture of 3.65 grms. of vanadium pentoxide, 6.5 grms. of cæsium carbonate, and 25 c.c. of water; and cooling the filtered liquid.

§ 10. The Vanadates of the Copper Family

C. Radau¹ found that when copper is precipitated in the presence of vanadic acid, it is always vanadiferous. B. W. Gerland said that **copper orthovanadate**, $\text{Cu}_2(\text{VO}_4)_2$, is precipitated when a soln. of copper sulphate is treated with ammonium

metavanadate, or sodium deuterotetavanadate. The product contains a small excess of vanadium pentoxide. G. Tammann gave 450° for its temp. of formation from its component oxides. I. Kurbatoff obtained a dark green mineral which he called **usbekite**, from Karatschagir, Fergana, and its analysis approximated the *trihydrate*, $\text{Cu}_3(\text{VO}_4)_2 \cdot 3\text{H}_2\text{O}$. A. E. Fersman gave the formula $4\text{CuO} \cdot \text{V}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$. K. A. Nenadkewitsch found an olive-green mineral which he called *turanite* in the limestone of Tyuya-Muyun, Alai Mt., Turkestan. Its composition approximated **copper dihydroxyorthovanadate**, $\text{Cu}(\text{OH})_2 \cdot 3\text{Cu}_3(\text{VO}_4)_2$, or $5\text{CuO} \cdot \text{V}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$. A. Carnot said that a warm soln. of vanadic acid gives a yellowish-brown precipitate of **copper pyrovanadate**, $\text{Cu}_2\text{V}_2\text{O}_7$, when poured into a soln. of cupric salt sat. with ammonia. A. Ditte found that a dil. soln. of copper sulphate gives a precipitate with ammonium vanadate which, on raising the temp., dissolves; if the copper salt be in excess, the precipitate remains, and when the mother-liquor is boiled, it furnishes greenish-yellow plates of the *trihydrate*, $\text{Cu}_2\text{V}_2\text{O}_7 \cdot 3\text{H}_2\text{O}$. C. Radau said that the precipitate is a mixture of the ortho- and pyrovanadates. J. J. Berzelius said that the yellow precipitate obtained by adding alcohol to a mixture of a copper salt with an alkali vanadate is **copper metavanadate**, $\text{Cu}(\text{VO}_3)_2$. C. Radau obtained it from a boiling soln. of 10 grms. of potassium metavanadate in 250 c.c. of water, and of 17.5 grms. of hydrated copper sulphate in 250 c.c. of water, and allowed the mixture to stand for some time. The precipitate is contaminated with much alkali. A. Carnot also prepared this salt. G. Fester and G. Berraz used copper vanadate deposited on silica as a catalyst for oxidizing alcohol. C. Radau obtained **copper dioxyorthotetavanadate**, $8\text{CuO} \cdot 2\text{V}_2\text{O}_5$, or $\text{CuO} \cdot \text{Cu}_3\text{V}_4\text{O}_{13}$, as an apple-green precipitate by adding copper sulphate to an acid vanadate; and J. J. Berzelius, **copper deuterotetavanadate**, $\text{CuV}_4\text{O}_{11}$, from a mixture of copper sulphate and potassium deuterotetavanadate.

C. Radau prepared **potassium copper triterohexavanadate**, $\text{K}_{0.66}\text{Cu}_{0.66}\text{V}_6\text{O}_{16} \cdot 1\frac{1}{2}\text{H}_2\text{O}$, from a mixture of a boiling soln. of 10 grms. of potassium triterodecavanadate in 250 c.c. of water, and 15 grms. of hydrated copper sulphate in 250 c.c. of water, and allowing the clear liquid to evaporate spontaneously. A. Fock showed that the crystals are triclinic pinacoids with the axial ratios $a:b:c = 0.9382:1:1.1059$, and $\alpha = 98^\circ 45'$; $\beta = 99^\circ 38'$; and $\gamma = 85^\circ 33'$. C. Radau found that 100 c.c. of water at 18° dissolve 11.1 parts of the salt. In 1838, H. Hess described a mineral which he called **volborthite**—after A. Volborth. It is brown-yellow or olive-green, and occurs at Siserek and Nizhni Tagilsk, Ural, and several parts of Perm. Analyses by F. A. Genth correspond with **copper calcium hydroxyorthovanadate**, $(\text{Cu,Ca,Ba})_3(\text{OH})_3\text{VO}_4 \cdot 6\text{H}_2\text{O}$. A variety from Friedrichsrode, Thuringia, analyzed by H. Credner, was represented by C. F. Rammelsberg by $(\text{Cu,Ca})_4\text{V}_2\text{O}_9 \cdot \text{H}_2\text{O}$, where $\text{Cu}:\text{Ca} = 3:2$, or **copper calcium pyrovanadate**, $2(\text{Cu,Ca})\text{O} \cdot (\text{Cu,Ca})_2\text{V}_2\text{O}_7 \cdot \text{H}_2\text{O}$; and A. d'Achiardi called it *calciovorborthite*, and M. Adam, *calciovorborthite*. J. Antipoff represented a variety from Turkestan by **copper calcium orthovanadate**, $\text{Cu}_3\text{Ca}_3(\text{VO}_4)_4 \cdot 2\text{H}_2\text{O}$, or $(\text{Cu,Ca})_3(\text{VO}_4)_2 \cdot \text{H}_2\text{O}$; and W. F. Hillebrand and H. E. Merwin gave for a variety from Utah, $5\text{RO} \cdot \text{V}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$. Some arsenic and phosphoric oxides are present. Volborthite occurs in small six-sided plates often aggregated into globular forms. W. F. Hillebrand and H. E. Merwin said that the plates are probably monoclinic. The optic axial angle is $2V = 68$ for Li-light; 83° for Na-light; and 19° for Tl-light. The optical character is positive for red-light, and negative for violet-light. The sp. gr. given by H. Credner is 3.495 for a green sample, and 3.860 for a grey one. The hardness is 3.0–3.5. W. F. Hillebrand said that the mineral has the indices of refraction $\mu = 2.01$, $\beta = 2.05$, and $\gamma = 2.10$ for the Na-light. B. W. Gerland said the mineral dissolves if sulphur dioxide be passed through water with the mineral in suspension. F. Ephraim and G. Beck obtained **copper triterodecavanadate**, $3\text{CuO} \cdot 5\text{V}_2\text{O}_5 \cdot 22\text{H}_2\text{O}$, by treating a soln. of the barium deuterohexavanadate with cupric sulphate. The salt, dehydrated at 220° , absorbs ammonia, forming the blue *dodecammine* at 245° ,

which forms a green *hexammine* between 190° and 210° , and the brown *diammine* between 120° and 145° .

H. E. Roscoe prepared **silver orthovanadate**, Ag_3VO_4 , by mixing a freshly prepared soln. of the sodium salt with a neutral soln. of silver nitrate. If any free acid be present some pyrovanadate is formed. A. Ditte obtained the yellow precipitate from a soln. of ammonium vanadate and silver nitrate. The precipitate slowly dissolves in molten silver nitrate, and when the cold mass is leached with water, golden-yellow rhombohedral plates or six-sided prisms are formed. H. E. Roscoe found that the orthovanadate is freely soluble in aq. ammonia and nitric acid. E. C. Franklin and C. A. Kraus said that the orthovanadate is insoluble in liquid ammonia. A pale yellow precipitate of **silver pyrovanadate**, $\text{Ag}_4\text{V}_2\text{O}_7$, is formed when a soln. of sodium pyrovanadate is added to one of silver nitrate. W. Prandtl and L. Hess, and J. A. Hall also prepared this salt, and found that it furnishes ethyl orthovanadate when treated with ethyl bromide in ethereal soln. J. J. Berzelius said that a pale yellow or white precipitate of **silver metavanadate**, AgVO_3 , is produced when a soln. of ammonium metavanadate is added to one of silver nitrate. It is not completely decomposed by hydrochloric acid. A. Ditte obtained acicular crystals of **silver dicitramminometavanadate**, $3\text{AgVO}_3 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$ in yellow needles, by evaporating a soln. of silver pyrovanadate in aq. ammonia, over sulphuric acid. T. Carnelley prepared silver orthotetranvanadate, $\text{Ag}_6\text{V}_4\text{O}_{13}$, by adding silver nitrate to a soln. of the sodium salt. The sp. gr. is 5.67 at 18° ; and 100 parts of water at 14° dissolve 0.00467 part of the salt, and 0.00735 part at 100° . G. Fester and G. Berraz used silver vanadate deposited on fuller's earth as a catalyst in the oxidation of alcohol.

§ 11. The Vanadates of the Alkaline Earths

A. Ditte¹ prepared pale yellow plates of **strontium orthovanadate**, $\text{Sr}_3(\text{VO}_4)_2$, by heating vanadium pentoxide with potassium and strontium iodides, and washing away the soluble salts. O. Manasse could not obtain **barium orthovanadate**, $\text{Ba}_3(\text{VO}_4)_2$, because it immediately decomposed into the pyrovanadate and hydroxide. G. Tammann gave 300° for its temp. of formation from its component oxides. H. E. Roscoe made a similar observation with respect to **calcium orthovanadate**, $\text{Ca}_3(\text{VO}_4)_2$, precipitated by sodium orthovanadate from a soln. of calcium

chloride. G. Tammann gave 375° for the temp. of formation from its component oxides. D. Balareff discussed the reaction. F. de Carli found that the reaction with barium oxide and vanadium pentoxide begins at 270°, and with calcium oxide, at 630°.

H. E. Roscoe obtained **calcium pyrovanadate**, $\text{Ca}_2\text{V}_2\text{O}_7 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, as a white amorphous precipitate by adding sodium pyrovanadate or orthovanadate to a soln. of calcium chloride. A. Ditte said that an excess of calcium chloride gives no precipitation with a soln. of ammonium metavanadate, but on adding ammonia, there is a white precipitate formed which, when boiled with the mother-liquor, forms needle-like crystals of the *dihydrate*, $\text{Ca}_2\text{V}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$. When heated, it loses its water without melting, and becomes yellow. It is freely soluble in dil. acids. F. Ephraim and G. Beck found that the pyrovanadate absorbs a little gaseous ammonia, but does not form a definite ammine. F. L. Hess and W. T. Schaller found that the *enneahydrate* occurs as a green efflorescence on the sandstone cliffs of Canon Pintado, Utah. It was called **pintadoite**. The analysis corresponds with $\text{Ca}_2\text{V}_2\text{O}_7 \cdot 9\text{H}_2\text{O}$. The mineral is slightly pleochroic, and has a moderately high birefringence. It slowly dissolves in cold water. R. Robl observed a marked fluorescence when calcium pyrovanadate, or **strontium pyrovanadate**, SrV_2O_7 , is exposed to ultra-violet light. H. E. Roscoe obtained **barium pyrovanadate**, $\text{Ba}_2\text{V}_2\text{O}_7$, in a similar manner; and the precipitate obtained by J. J. Berzelius with baryta-water is thought to be the same thing. A. Carnot also prepared it by adding barium chloride to a boiling mixture, neutral or feebly ammoniacal soln. of a vanadate. The white precipitate becomes yellow when heated. R. Robl found that the salt fluoresces in the ultra-violet light of a quartz mercury lamp with light of wave-length 440μ to 280μ .

A. Scheuer obtained pale yellow needles of trihydrated **calcium metavanadate**, $\text{CaVO}_3 \cdot 3\text{H}_2\text{O}$, by adding alcohol to a soln. of calcium chloride and ammonium metavanadate. J. J. Berzelius, and J. A. Norblad found that the hot soln. just indicated gradually yields a yellowish-white mass of the *tetrahydrate*. O. Manasse found that the precipitate is mixed with some calcium chloride. J. A. Norblad said that the precipitate is stable in air but loses 2 mols. of water over conc. sulphuric acid; and at 180°, all the water is expelled. The salt melts at a red-heat. It is more soluble in water than the strontium salt, and is not precipitated by alcohol from the dil. aq. soln. F. L. Hess and W. F. Foshag observed a yellow, triclinic mineral occurring in Utah; they called it **rossite**, and considered it to be calcium metavanadate, $\text{Ca}(\text{VO}_3)_2 \cdot 4\text{H}_2\text{O}$. The indices of refraction are $\alpha=1.710$, $\beta=1.710$, and $\gamma=1.840$; the dispersion is strong; the optic axial angle $2V$ is large; the sp. gr. is 2.45; and the hardness 2 to 3. It is soluble in water. The so-called **metarossite** is partially dehydrated rossite, having the composition $\text{Ca}(\text{VO}_3)_2 \cdot 2\text{H}_2\text{O}$. It is yellow, soft, and fibrous. It is biaxial; $2V$ is large; the dispersion is strong; the indices of refraction $\alpha=1.840$, and β and γ exceed 1.85. J. J. Berzelius, J. A. Norblad, and O. Manasse obtained *tetrahydrated strontium metavanadate*, $\text{SrVO}_3 \cdot 4\text{H}_2\text{O}$, in a similar way. Its properties are similar; and it is sparingly soluble in water. A. Ditte obtained crystals of **barium metavanadate**, BaVO_3 , by heating a mixture of vanadium pentoxide, sodium bromide, and a little barium bromide. A. Ditte obtained it by pouring an excess soln. of barium nitrate into a boiling soln. of ammonium metavanadate; and on standing the whole precipitate crystallizes. The yellowish, prismatic crystals are sparingly soluble in water. J. J. Berzelius, and J. A. Norblad obtained a yellow, gelatinous precipitate by adding a soln. of ammonium metavanadate to one of barium chloride, and allowing the mixture to stand for some hours. A white, crystalline powder of the *monohydrate*, $\text{BaVO}_3 \cdot \text{H}_2\text{O}$, is formed. The aq. soln. on spontaneous evaporation yields small white crystals resembling the strontium salt. O. Manasse also obtained the barium salt. It is soluble in water.

F. Ephraim and G. Beck made crystals of **strontium orthotetrvanadate**,

$3\text{SrO} \cdot 2\text{V}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, by adding a soln. of strontium nitrate to a soln. of the potassium salt. O. Manasse prepared red crystals of **hexahydrated calcium deutero-tetranavanadate**, $\text{CaV}_4\text{O}_{11} \cdot 6\text{H}_2\text{O}$, by the spontaneous evaporation of equimolar parts of a soln. of calcium chloride and potassium deutero-tetranavanadate. J. J. Berzelius and C. von Hauer obtained the **enneahydrate**, $\text{CaV}_4\text{O}_{11} \cdot 9\text{H}_2\text{O}$, from soln. of calcium chloride and ammonium deutero-tetranavanadate. The orange-red crystals do not effloresce in air, and they are freely soluble in water. The salt melts easily, and after fusion it does not dissolve readily in water. J. A. Norblad reported a number of other hydrated forms. J. J. Berzelius, and C. von Hauer obtained **enneahydrated strontium deutero-tetranavanadate**, $\text{SrV}_4\text{O}_{11} \cdot 9\text{H}_2\text{O}$, from a soln. of the sodium salt and strontium chloride; and A. Scheuer, by adding alcohol to the mother-liquor from the preparation of the pervanadate. J. Grailich said that the orange plates are monoclinic with the axial ratios $a:b:c=0.842:1:1.045$, and $\beta=98^\circ 14'$. It is decomposed by the prolonged action of cold or hot water. J. J. Berzelius' **barium deutero-tetranavanadate** was shown by C. von Hauer to be the triterodecavanadate.

A. Ditte mixed an excess of ammonium metavanadate with calcium nitrate and a little nitric acid, and slowly evaporated the red soln. when golden-yellow crystals of **calcium triterohexavanadate**, $\text{CaV}_6\text{O}_{18} \cdot 12\text{H}_2\text{O}$, were obtained. They are freely soluble in water, and are transformed by boiling water into a yellow powder. According to W. F. Hillebrand and co-workers, a mineral which they called **hewettite**—after D. F. Hewett—occurs as an alteration product of patronite at Minarragen, Peru. It is mahogany-red and consists of minute rhombic needles of sp. gr. 2.554. The analysis corresponds with $\text{CaO} \cdot 3\text{V}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$, or **calcium dihydrodeutero-hexavanadate**, $\text{Ca}_2\text{H}_2\text{V}_6\text{O}_{17} \cdot 8\text{H}_2\text{O}$. The indices of refraction for Li-light are $\alpha=1.77$; $\beta=2.18$; and $\gamma=2.35-2.40$. The pleochroism is strong— α is light cadmium yellow; β , cadmium yellow; and γ , orange. The mineral readily fuses to a dark red liquid, and is slightly soluble in water. Another dark red, earthy mineral of the same composition, occurring in Paradox Valley, Colorado, and in Eastern Utah, is similar to hewettite in composition. It occurs in minute rhombic plates. This dimorphous form of hewettite is called **metahewettite**. Its sp. gr. is 2.511, and for material with $3\text{H}_2\text{O}$, 2.942. The optical axial angle $2V=52^\circ$. The indices of refraction for Li-light are $\alpha=1.70$; $\beta=2.10$; and γ could not be determined. The pleochroism is intense: α and β are light orange-yellow, and γ is dark red. Both minerals are very sensitive to atm. humidity, and nearly all the water can be expelled without breaking the structure. The dehydration curves show a difference in the behaviour of the two minerals. A third mineral occurs as an orange-red or orange-yellow powdery efflorescence on the walls of the mine workings at Minasragna, Cerro de Pasco, Peru, and it is called **pascoite**. The analyses agrees with **calcium deutero-hexavanadate**, $\text{Ca}_2\text{V}_6\text{O}_{17} \cdot 11\text{H}_2\text{O}$. The optical characters agree with the monoclinic symmetry. The optic axial angles are $2V=50.5^\circ$ for the Na-light, and $2V=56^\circ$ for Li-light; the indices of refraction are $\alpha=1.775$, $\beta=1.815$, and $\gamma=1.825$; the optical character is negative; the dispersion is strong; and the sp. gr. is 2.457. The mineral melts readily to a dark red liquid; and it is freely soluble in water. W. Lindgren and co-workers described black needles of a mineral from the shale of Minasragna, Cerro de Pasco, and they called it **melanovanadite**. Its composition agrees with **calcium hypovanadatovanadate**, $2\text{CaO} \cdot 3\text{V}_2\text{O}_5 \cdot 2\text{V}_2\text{O}$. The monoclinic crystals have the axial ratios $a:b:c=0.4737:1:0.5815$, and $\beta=88^\circ 37'1''$. The sp. gr. is 3.477 at 15° , and the hardness 2.5. It is readily soluble in acids, forming a green soln. C. von Hauer made **strontium triterohexavanadate**, $\text{SrV}_6\text{O}_{18} \cdot 13\frac{1}{2}\text{H}_2\text{O}$, analogous to the corresponding calcium salt by boiling a dil. acetic acid soln. of strontium tetranavanadate with strontium chloride, and evaporating the filtrate at a gentle heat, or over sulphuric acid. The salt can be recrystallized from acetic acid. The red crystals are stable in air; and the four-sided plates belong to the triclinic system. Some measurements were made by A. Handl. The salt loses $8\frac{1}{2}$ mols. of water at

100°, and melts to a dark red liquid at dull redness. The aq. soln. suffers a little decomposition when heated. J. A. Norblad verified C. von Hauer's observations, but O. Manasse could not do so. A. Ditte obtained orange-red, rhombic crystals of the *tetradecahydrate* of **barium deuterohexavanadate**, $\text{Ba}_2\text{V}_6\text{O}_{17}\cdot 14\text{H}_2\text{O}$, by treating with barium nitrate a boiling soln. of ammonium vanadate in dil. acetic acid. F. Ephraim and G. Beck prepared the *dodecahydrate* of barium deuterohexavanadate, $2\text{BaO}\cdot 3\text{V}_2\text{O}_5\cdot 12\text{H}_2\text{O}$, by boiling a mixture of 30 grms. of ammonium metavanadate, 15 grms. of calcium oxide, and 200 c.c. of water until the smell of ammonia has gone; adding enough conc. hydrochloric acid to give the liquid a permanent yellow colour, and making the liquid up to 500 c.c. with 2*N*-acetic acid. The liquid was then treated with a soln. of 30 grms. of barium chloride in 300 c.c. of water and 100 c.c. of 2*N*-acetic acid, and allowed to stand for 2–3 hrs., when the salt appears as a crystalline precipitate the colour of dichromates. It does not form an ammine with ammonia.

O. Manasse prepared **calcium deuterioctovanadate**, $\text{Ca}_3\text{V}_8\text{O}_{23}\cdot 15\text{H}_2\text{O}$, from a soln. of eq. proportions of potassium tetravanadate, and calcium chloride in an excess of acetic acid; the filtrate furnishes red, tabular crystals of the salt. He likewise obtained **strontium deuterioctovanadate**, $\text{Sr}_3\text{V}_8\text{O}_{23}\cdot 4\text{H}_2\text{O}$, which lost 17.6 per cent. of water at 100°; 17.9 per cent. at 200°; and the rest at dull redness. O. Manasse obtained **strontium tetreroctovanadate**, $\text{SrV}_8\text{O}_{21}\cdot 11\text{H}_2\text{O}$, by adding alcohol to a soln. of the tetradecavanadate in hot water. The yellow powder loses 16.42 per cent. of water at 100°, and nearly all at 200°.

F. Ephraim and G. Beck made **calcium tetreroctecavanadate**, $2\text{CaO}\cdot 5\text{V}_2\text{O}_5\cdot 5\text{H}_2\text{O}$, by boiling a soln. of ammonium metavanadate with lime, and then acidifying the liquid with 2*N*-acetic acid. On cooling the conc. soln. dichromate-yellow prisms were obtained. It does not form an ammine with ammonia. J. A. Norblad treated a soln. of potassium tetravanadate with barium chloride and allowed the filtrate to evaporate spontaneously when orange-red, prismatic crystals of **barium deuterodecavanadate**, $\text{Ba}_4\text{V}_{10}\text{O}_{29}\cdot 24\text{H}_2\text{O}$, were produced. O. Manasse could not confirm this. C. von Hauer, J. J. Berzelius, J. A. Norblad, and O. Manasse obtained **barium triterodecavanadate**, $\text{Ba}_3\text{V}_{10}\text{O}_{28}\cdot 19\text{H}_2\text{O}$, as a precipitate, by mixing hot soln. of potassium tetravanadate and barium chloride. The precipitate forms in a few hours small, yellow prisms. According to A. Fock, the triclinic crystals have the axial ratios $a : b : c = 0.7805 : 1 : 0.9528$, and $\alpha = 106^\circ 53'$, $\beta = 122^\circ 13'$, and $\gamma = 71^\circ 9'$. After the crystals had stood 12 days over conc. sulphuric acid, O. Manasse found that they had lost 11 per cent. of water; 15.07 per cent. in vacuo; and 16.74 per cent. after heating for a week at 100°. All is expelled at a dull red-heat when the salt fuses. C. von Hauer said that 100 parts of water at 20°–25° dissolve about 0.02 part of the salt, and dissolves more at a higher temp. The salt is decomposed by boiling water with the separation of the metavanadate. The salt can be recrystallized from acetic acid.

O. Manasse reported the formation of **calcium penterotetradecavanadate**, $\text{Ca}_3\text{V}_{14}\text{O}_{38}\cdot 7\text{H}_2\text{O}$, to be formed by crystallization from a soln. of the hexadecavanadate in hot water. The scarlet powder may not be a chemical individual. He also prepared **strontium tetreroctecavanadate**, $\text{Sr}_4\text{V}_{14}\text{O}_{39}\cdot 30\text{H}_2\text{O}$, by adding alcohol to a dil. soln. of eq. proportions of potassium tetravanadate and strontium chloride. J. A. Norblad regarded the orange-red plates as monoclinic. They lose 16.0–16.5 per cent. of water at 100°. O. Manasse reported **calcium hexerohexadecavanadate**, $\text{Ca}_6\text{V}_{16}\text{O}_{43}\cdot 26\text{H}_2\text{O}$, to be formed by adding acetic acid to a warm soln. of potassium tetravanadate and calcium chloride, and evaporating the liquid on the water-bath. The red crystals can be recrystallized from hot water, washed with alcohol, and ether, and dried in a current of dry air. The crystals lose 17.77 per cent. of water at 100°, and all at 180°. The crystals are decomposed by absolute alcohol.

O. Manasse prepared **potassium calcium deuterotettravanadate**, $(\text{K}_{0.8}\text{Ca}_{0.4})\text{V}_4\text{O}_{11}\cdot 4.4\text{H}_2\text{O}$, in yellowish-brown scales, by evaporating the mother-liquor from

the preparation of calcium hexerohexadecavanadate. He also found that when eq. proportions of potassium tetravanadate and strontium chloride are allowed to crystallize together from 200 c.c. of hot water, reddish-yellow crystals of **potassium strontium tetreretradecavanadate**, $(K_{0.25}Sr_{0.375})_8V_{14}O_{39} \cdot 20H_2O$, which A. Fock said were triclinic, are formed. At 100° , 14.38 per cent. of water is given off, and at 200° , 17.74 per cent. Working with more dil. soln., the triacontahydrate is formed in monoclinic prisms which, according to A. Fock, have the axial ratios $a : b : c = 1 : 4729 : 1 : 1.3744$, and $\beta = 96^\circ 15'$. The salt can be recrystallized from water or acetic acid. If equimolar proportions of potassium tetravanadate and strontium chloride, and 180 c.c. of water be mixed with acetic acid, and allowed to crystallize, dark red crystals aggregates of $(K_{1.0}Sr_{0.5})_4V_{14}O_{37} \cdot 18H_2O$ are formed. A. E. Fersman described a mineral from Tyuya-Muyun, Fergana, which he called **tangeite**. K. A. Nenadkewitsch and P. A. Volkoff found that the analysis corresponds with **copper calcium vanadate**, $2CuO \cdot 2CaO \cdot V_2O_5 \cdot H_2O$. The term tangeite is used for the crystalline form and Turkestan volborthite for the colloidal variety.

§ 12. Vanadates of the Magnesium Family

J. J. Berzelius¹ reported **beryllium metavanadate** to be formed as a yellow powder sparingly soluble in water, by the action of ammonium metavanadate on a soln. of a beryllium salt; and with potassium tetravanadate and a beryllium salt soln., **beryllium tetravanadate** is formed as a yellow powder sparingly soluble in water. S. M. Tanatar and E. K. Kurowsky prepared a yellow amorphous precipitate by the action of sodium vanadate on a soln. of beryllium chloride; it contained $mBeCl_2 \cdot nBe_3(VO_4)_2 \cdot pBeO$; and with a soln. of beryllium nitrate, $mBe(NO_3)_2 \cdot nBe_3(VO_4)_2 \cdot pBeO$. P. H. M. P. Brinton found that the products obtained by the addition of soln. of soluble vanadates to soln. of beryllium salts are mixtures of variable composition, and not definite salts. The compound **beryllium metavanadate**, $Be(VO_3)_2 \cdot 4H_2O$, has been obtained by boiling eq. quantities of beryllium hydroxide and vanadium pentoxide with water for about an hour; the soln. was filtered and concentrated to about 40 c.c., which usually yielded an orange-red syrup. This, while hot, was poured into a large volume of 95 per cent. alcohol, when a copious deposit of yellow particles was produced, which in twenty-four hours had settled to a thick layer of yellow crystals, which, microscopically, are yellow, waxy plates. The crystals are cubic, being cubes modified by the octahedron. Beryllium metavanadate is sparingly soluble in cold water, 1 per

1000, but readily so in hot water, and has a strong tendency to supersaturate. It is practically insoluble in chloroform, ether, or absolute alcohol, but is soluble in pyridine to about the same extent as in water. The crystals have a sp. gr. of 2.273, and lose the whole of their water of crystallization over sulphuric acid. F. Ephraim and G. Beck obtained **beryllium deuterohexavanadate**, $2\text{BeO} \cdot 3\text{V}_2\text{O}_5 \cdot 11\text{H}_2\text{O}$, by treating the barium salt with beryllium sulphate. The dehydrated salt absorbs ammonia gas very slowly, forming the *dodecammine*, which forms the *hexammine* between 160° and 220° , and the *diammine* between 280° and 295° .

J. J. Berzelius prepared **magnesium metavanadate**, $\text{Mg}(\text{VO}_3)_2 \cdot 6\text{H}_2\text{O}$, by boiling magnesia with vanadium pentoxide and water, and evaporating the filtrate. R. Sugiura and H. Baker could not obtain a definite salt by evaporating the aq. soln. F. de Carli found that the reaction between magnesium oxide and vanadium pentoxide begins at 455° . O. Manasse treated a conc. soln. of the filtrate with alcohol, and allowed the yellow, syrupy liquid to stand some days when aggregates of colourless, prismatic crystals were formed. The salt is freely soluble in water. A. Ditte found that when heated to redness the water of crystallization is driven off, and at a higher temp., fusion takes place. J. J. Berzelius reported **octohydrated magnesium deuterotetrvanadate**, $\text{Mg}_2\text{V}_4\text{O}_{11} \cdot 8\text{H}_2\text{O}$, to be formed in yellow plates by the spontaneous evaporation of an aq. soln. of potassium tetravanadate and magnesium sulphate; if the salt be precipitated by alcohol, it appears as a yellow powder. C. von Hauer obtained it by mixing soln. of ammonium metavanadate with magnesium sulphate, and recrystallizing the precipitate from hot water. The salt is sparingly soluble in water. A. Ditte obtained the *enneahydrate*, $\text{MgV}_4\text{O}_{11} \cdot 9\text{H}_2\text{O}$, in red crystals, by treating a hot sat. soln. of ammonium metavanadate with an excess of magnesium chloride and acetic acid. O. Manasse reported **magnesium deuterohexavanadate**, $\text{Mg}_2\text{V}_6\text{O}_{17} \cdot 9\frac{1}{2}\text{H}_2\text{O}$, by treating a hot soln. of potassium tetravanadate with a small excess of magnesium sulphate. V. Cuttica and co-workers obtained the same compound as an *enneadecahydrate*, by the action of water on magnesium chlorovanadate. The yellowish-red crystals of O. Manasse's salt were found by A. Fock to be triclinic with the axial ratios $a : b : c = 0.7928 : 1 : 0.9506$, and $\alpha = 114^\circ 28'$, $\beta = 108^\circ 18'$, and $\gamma = 74^\circ 17'$. The salt is said to be isomorphous with the corresponding salts of barium, zinc, manganese, and cobalt. The salt loses all its water at 100° . R. Sugiura and H. Baker, and O. Manasse prepared **magnesium triterodecavanadate**, $\text{Mg}_3\text{V}_{10}\text{O}_{28} \cdot 28\text{H}_2\text{O}$, by boiling magnesia with vanadium pentoxide and water, and mixing the soln. with an excess of acetic acid. When the liquid is allowed to evaporate spontaneously, it furnishes two kinds of crystals: (i) brown, triclinic prisms with the axial ratios $a : b : c = 0.997 : 1 : 1.009$, and $\alpha = 89^\circ 24'$, $\beta = 104^\circ 20'$, and $\gamma = 82^\circ 22'$; the sp. gr. is 2.199 at 18° . (ii) Red, triclinic prisms with the axial ratios $a : b : c = 0.788 : 1 : 0.676$, and $\alpha = 93^\circ 35'$, $\beta = 101^\circ 30'$, and $\gamma = 166^\circ 55'$. The sp. gr. is 2.167 at 18° . A. Ditte could not prepare *ammonium magnesium vanadate*.

According to A. Ditte,² **zinc pyrovanadate**, $\text{Zn}_2\text{V}_2\text{O}_7$, is produced by melting vanadium pentoxide with a mixture of 5 parts of sodium bromide and one part of zinc bromide, and treating the product with water. The evaporation of the liquid gives orange-red prisms, freely soluble in water. C. Radau believed that the product is an acid vanadate. G. Tammann made some observations on the action of zinc oxide on vanadium pentoxide; and F. de Carli found that the reaction begins at 260° . J. J. Berzelius obtained **zinc metavanadate**, $\text{Zn}(\text{VO}_3)_2 \cdot 2\text{H}_2\text{O}$, by double decomposition; and A. Ditte, by warming a mixture of soln. of ammonium metavanadate with an excess of zinc nitrate. The yellowish-white precipitate when kept warm in contact with its mother-liquor furnishes pale-yellow crystals. C. Radau said that the product is a mixture of an acid vanadate and pyrovanadate. J. J. Berzelius obtained an acid vanadate. F. Ephraim and G. Beck prepared **zinc deuterohexavanadate**, $2\text{ZnO} \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{H}_2\text{O}$, as in the case of the beryllium salt. It forms a *dodecammine* when the dehydrated salt is exposed to ammonia gas: this becomes the *hexammine* at 170° , and the *diammine* at 235° . C. Radau

reported **potassium zinc triterodecavanadate**, $K_2Zn_2V_{10}O_{28} \cdot 16H_2O$, to be formed by mixing boiling soln. of 20 grms. of potassium metavanadate in 400 c.c. of water, and 18 grms. of hydrated zinc sulphate in 250 c.c. of water. The evaporation of the filtrate furnishes pale red crystals which, according to A. Fock, are triclinic prisms with the axial ratios $a : b : c = 0.8025 : 1 : 0.9675$, and $\alpha = 115^\circ 2'$, $\beta = 109^\circ 35'$, and $\gamma = 74^\circ 57'$. They are isomorphous with the corresponding magnesium salt (*q.v.*). The salt is sparingly soluble in water, and freely soluble in acids. C. Radau found that a mixture of soln. of 20 grms. of potassium metavanadate in 200 c.c. of water and 17 grms. of hydrated zinc sulphate in 200 c.c. of water and 20 c.c. of 25 per cent. acetic acid gives a liquid which furnishes red crystals of **potassium zinc tetretrotetradecavanadate**, $(K_{0.56}Zn_{0.22})_4V_{14}O_{39} \cdot 22\frac{2}{3}H_2O$.

J. J. Berzelius prepared **cadmium metavanadate**, $Cd(VO_3)_2$, by mixing a conc. soln. of an alkali vanadate and a cadmium salt; the yellow precipitate gradually becomes white and crystalline. A. Ditte made it by melting vanadium pentoxide with a mixture of 5 parts of sodium bromide and one part of cadmium bromide, and washing the product with water. The fine needles melt at a red-heat. F. de Carli found that the reaction between vanadium pentoxide and cadmium oxide begins at 480° . By boiling a soln. of ammonium metavanadate, cadmium nitrate and acetic acid, A. Ditte prepared red crystals of **cadmium triterohexavanadate**, $CdV_6O_{16} \cdot 2H_2O$. F. Ephraim and G. Beck found that **cadmium deuterohexavanadate**, $2CdO \cdot 3V_2O_5 \cdot 15H_2O$, is formed as in the case of the zinc salt. It yields a *dodecammine*, which forms the *triammine* at about 200° , and the *diammine* at about 235° . C. Radau prepared red crystals of **potassium cadmium deuterohexavanadate**, $K_2CdV_6O_{17} \cdot 9H_2O$, by crystallization from a filtered soln. of 12 grms. of potassium triterodecavanadate and 17 grms. of cadmium sulphate in 400 c.c. of water. He also obtained **potassium cadmium triterodecavanadate**, $(KCd_{0.5})_3V_{10}O_{28} \cdot 10\frac{1}{2}H_2O$, from a soln. of 10 grms. potassium metavanadate in 200 c.c. of water, 17 grms. of cadmium sulphate in 250 c.c. of water, and 25 c.c. of 30 per cent. acetic acid. The spontaneous evaporation of the red soln. furnishes orange-red crystals; 100 parts of water at 18° dissolve 0.54 part of salt.

A. Carnot obtained **mercurous metavanadate** by treating a soln. of mercurous nitrate with ammonium metavanadate, and by almost neutralizing a soln. of vanadium pentoxide with ammonia and adding mercurous nitrate. The orange yellow precipitate is decomposed by ammonia, and hydrogen sulphide. J. J. Berzelius also obtained **mercurous tetravanadate**, as an orange-yellow precipitate, by treating a soln. of ammonium tetravanadate with mercurous nitrate. By using soln. of mercuric salts, J. J. Berzelius obtained by double decomposition, **mercuric metavanadate**, as a lemon-yellow precipitate sparingly soluble in water; and also yellow **mercuric tetravanadate**.

§ 13. The Vanadates of the Aluminium and Lead Families

J. J. Berzelius¹ obtained **aluminium metavanadate**, and aluminium tetra-**vanadate** by the method employed for the beryllium salts. The two aluminium salts are less soluble than those of beryllium. C. Renz obtained **indium metavanadate**, $\text{In}(\text{VO}_3)_3 \cdot 2\text{H}_2\text{O}$, as a pale yellow precipitate, from a mixed soln. of indium chloride and sodium metavanadate.

T. Carnelley made a series of thallium vanadates. By melting together eq. proportions of sodium carbonate and vanadium pentoxide, at a dull red-heat, a red mass of **thallium orthovanadate**, Tl_3VO_4 , is formed. There is a slight loss of thallium by volatilization. The sp. gr. is 8.6 at 17°; the salt is only slightly soluble since 100 parts of water at 15° dissolve 0.1 part of salt, and at 100°, 0.17 part. By mixing aq. soln. of thallous sulphate and sodium orthovanadate, **thallium pyrovanadate**, $\text{Tl}_4\text{V}_2\text{O}_7$, is precipitated; and the same salt is obtained by fusing eq. proportions of sodium carbonate and thallium orthovanadate. The sp. gr. of the salt is 8.21 at 18.5°; 100 parts of water at 14° dissolve 0.02 part of salt, and 0.026 part at 100°. By melting together eq. proportions of thalious carbonate and vanadium pentoxide, **thallium metavanadate**, TlVO_3 , is formed in dark grey scaly crystals of sp. gr. 6.019 at 17°, 100 parts of water at 11° dissolve 0.0087 part of salt, and at 100°, 0.021 part. By mixing a boiling soln. of sodium pyrovanadate with a cold soln. of thalious sulphate, a white precipitate of **thallium orthotetравanadate**, $\text{Tl}_6\text{V}_4\text{O}_{13}$, is formed. The same salt is obtained by the action of sodium orthotetравanadate on a soln. of thalious sulphate. The sp. gr. of the yellow powder is 8.59 at 17.5°; 100 parts of water dissolve 0.0293 part of salt at 14° and 0.0285 part at 100°. If thalious sulphate be added to a boiling soln. of sodium pyrovanadate in the presence of an excess of vanadium pentoxide, a white precipitate of **thallium orthodecavanadate**, $\text{Tl}_{12}\text{V}_{10}\text{O}_{31}$, is formed. 100 c.c. of water dissolve 0.0107 part of the pale yellow salt at 11°, and 0.0297 part at 100°. If a soln. of ammonium metavanadate be treated with an excess of thalious sulphate, and the precipitate be allowed to stand in contact with the mother-liquor, a reddish-white **thallium deuterotetradecavanadate**, $\text{Tl}_{12}\text{V}_{14}\text{O}_{41}$, is formed. V. Cuttica and co-workers made **thalious triterohexavanadate**, $\text{Tl}_2\text{O} \cdot 3\text{V}_2\text{O}_5$, by the action of water on the chlorovanadate.

J. J. Berzelius found that **yttrium metavanadate** is precipitated as a yellow powder when a yttrium salt soln. is treated with a metavanadate; but with tetra-**vanadates** no precipitation occurs. A. Cleve treated a soln. of ytterbium nitrate with ammonium metavanadate and obtained a precipitate of **ytterbium oxyorthodecavanadate**, $\text{Yb}_2\text{O}_3 \cdot \text{Yb}_4\text{V}_{10}\text{O}_3$; and the mother-liquor deposits brown $\text{Yb}_2\text{O}_3 \cdot 15\text{V}_2\text{O}_5$. P. T. Cleve prepared **didymium vanadate**, DiVO_4 , by double decomposition; and also **didymium metavanadate**, $\text{Di}(\text{VO}_3)_3$, he also found that neutral soln. of samarium salts and alkali metavanadate give pale yellow amorphous precipitates mainly samarium orthovanadate, but with sodium vanadate and samarium nitrate, a yellow precipitate of variable composition is obtained. The soln. on spontaneous evaporation at ordinary temp. gave red crystals of **samarium triterodecavanadate**, $\text{Sa}_2\text{V}_{10}\text{O}_{28} \cdot 20\text{H}_2\text{O}$, of sp. gr. 2.524 at 17.5°, and yellow crystals of $\text{Sa}_2\text{V}_{10}\text{V}_{28} \cdot 24\text{H}_2\text{O}$, of sp. gr. 2.624 at 17.5°. C. Benedicks obtained **gadolinium vanadate**, $\text{Gd}_2\text{O}_3 \cdot 5\text{V}_2\text{O}_5 \cdot 26\text{H}_3\text{O}$, in triclinic crystals with $a : b : c = 1.7083 : 1 : 0.9894$, and $\alpha = 84^\circ 51'$, $\beta = 94^\circ 51'$, and $\gamma = 82^\circ 13.5'$. Dark red dichroic crystals of **cerous orthovanadate**, CeVO_4 , are produced when sodium orthovanadate is fused with cerous chloride; and **cerous triterodecavanadate**, $\text{Ce}_2\text{V}_{10}\text{O}_{28} \cdot 27\text{H}_2\text{O}$, has been prepared. G. Tammann gave 350° for the temp. of formation of cerous orthovanadate from its component oxides. G. Carobbi and

S. Restaino prepared cerium orthovanadate from soln. of cerium nitrate and sodium orthovanadate, and he found that cerium, lanthanum, didymium, and samarium can replace lead isomorphously in vanadates.

J. J. Berzelius² observed no precipitation of a *zirconium vanadate* occurs when a soln. of a zirconium salt is treated with an alkali metavanadate or tetravanadate; and S. M. Tanatar and E. K. Kurowsky obtained mixed precipitates—e.g., alkali vanadate and zirconium chloride gave **zirconium oxychlorovanadate** of the composition $m\text{ZrCl}_4 \cdot n\text{Zr}_3(\text{VO}_4) \cdot p\text{ZrO}_2$. J. J. Berzelius found that with thorium salts, a yellow precipitate is formed. C. Volek prepared **thorium pyrovanadate**, $\text{Th}_2\text{V}_2\text{O}_7 \cdot 6\text{H}_2\text{O}$, otherwise represented as **thorium hydrovanadate**, $\text{Th}(\text{HVO}_4)_2 \cdot 5\text{H}_2\text{O}$, by treating a dil. soln. of thorium chloride with an 8 per cent. aq. soln. of ammonium metavanadate. The yellow precipitate is soluble in dil. acids. J. J. Berzelius said that **thorium metavanadate**, $\text{Th}(\text{VO}_3)_4 \cdot n\text{H}_2\text{O}$, is soluble in water. P. T. Cleve mixed a feebly acid soln. of thorium nitrate with sodium tetravanadate, evaporated the soln. on a water-bath, and obtained a brown powder of **thorium triterohevanadate**, $\text{Th}(\text{V}_6\text{O}_{16})_2 \cdot 8\text{H}_2\text{O}$.

J. J. Berzelius said that neither *stannous vanadate* nor *stannic vanadate* is precipitated when ammonium vanadate is added to a soln. of the corresponding salt of tin. F. de Carli found that the reaction between stannous oxide and vanadium pentoxide begins at 250°. According to W. Prandtl and O. Rosenthal, a series of **sodium stannovanadates** are produced when a soln. of sodium orthovanadate and stannic chloride or sodium stannate is carefully neutralized. By cooling or diluting a soln. of stannic vanadate in hot conc. soda-lye, substances crystallizing in white needles are obtained; similar products are formed when a soln. of sodium stannate and orthovanadate is crystallized; and by cooling a fused mixture of stannic oxide, vanadium pentoxide, and sodium hydroxide. The compounds: **sodium stannatotriivanadate**, $\text{Na}_2\text{SnO}_3 \cdot 3\text{Na}_3\text{VO}_4 \cdot 32\text{H}_2\text{O}$; **sodium stannotettravanadate**, $\text{Na}_2\text{SnO}_3 \cdot 4\text{Na}_3\text{VO}_4 \cdot 48\text{H}_2\text{O}$; **sodium stannatopentavanadate**, $\text{Na}_2\text{SnO}_3 \cdot 5\text{Na}_3\text{VO}_4 \cdot 64\text{H}_2\text{O}$; and **sodium stannatohexavanadate**, $\text{Na}_2\text{SnO}_3 \cdot 6\text{Na}_3\text{VO}_4 \cdot 80\text{H}_2\text{O}$, were obtained by varying the conc. and temp. of the reacting constituents. The salts all furnish transparent, doubly refracting, rhombic crystals of the aragonite habit.

H. E. Roscoe³ prepared **lead orthovanadate**, $\text{Pb}_3(\text{VO}_4)_2$, by adding lead acetate to a soln. of sodium orthovanadate. The white precipitate is insoluble in water.

FIG. 7.—Freezing-point Curves of Lead Oxide and Orthovanadate.

G. Tammann gave 325° for the temp. of formation; and F. de Carli said that the reaction between vanadium pentoxide and lead oxide begins at 560°. D. Balareff discussed the reaction. M. Amadori measured the f.p. of mixture of lead orthovanadate and lead oxide, and the results, summarized in Fig. 7, show the existence of only one basic salt—**lead pentoxyorthovanadate**, $5\text{PbO} \cdot \text{Pb}_3(\text{VO}_4)_2$, melting at 794°. M. Amadori gave 1042° for the m.p. of lead orthoarsenate, and 952° for that of lead orthovanadate, and for mixtures with 25, 50, 75, and 90 per cent. of lead orthovanadate he found the f.p. to be 1018°, 994°, 968°, and 960° respectively.

R. Robl observed no fluorescence with the salt in ultra-violet light. There is no evidence on the f.p. curves of the formation of **lead oxyorthovanadate**, $\text{PbO} \cdot \text{Pb}_3(\text{VO}_4)_2$. A. Ditte prepared **lead pyrovanadate**, $\text{Pb}_2\text{V}_2\text{O}_7$, by pouring ammonium metavanadate into an acetic acid soln. of lead nitrate, and boiling the mixture. The sulphur-yellow, prismatic crystals are soluble in hot dil. nitric acid. F. Ephraim and G. Beck made **lead orthohexavanadate**, $3\text{PbO} \cdot 2\text{V}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, by treating manganese hexavanadate with lead nitrate. The dehydrated salt absorbs ammonia. H. E. Roscoe prepared what has been regarded as **lead oxypyrovanadate**, $\text{PbO} \cdot 2\text{Pb}_2\text{V}_2\text{O}_7$ —possibly a mixture: $\text{Pb}_3(\text{VO}_4)_2 \cdot \text{Pb}_2\text{V}_2\text{O}_7$ —by precipitation on mixing soln. of sodium

pyrovanadate and lead acetate. The pale-yellow salt was found by T. Carnelley to melt at 731°. It is neither soluble in nor decomposed by water; it is insoluble in acetic acid; and decomposed by nitric acid. R. D. Thomson also described a lead vanadate.

C. Bergmann described a mineral from Lauterthal, Bavaria, which he named **dechenite**—after H. von Dechen. Analyses reported by C. Bergmann, H. Fischer and J. Nessler, and C. F. Rammelsberg agree with the formula for **lead metavanadate**, $\text{Pb}(\text{VO}_3)_2$. According to G. J. Brush, dechenite belongs to the same mineral species as eusynchite and aræoxene—*vide infra*. Lead metavanadate was made by J. J. Berzelius, H. E. Roscoe, and A. Carnot by treating ammonium or an alkali metavanadate with lead nitrate or acetate. The yellow precipitate becomes less voluminous when allowed to stand in contact with its mother-liquor for 24 hrs. Dechenite occurs botryoidal, nodular, in stalactitic masses sometimes with a columnar structure. The colour is deep red, yellowish-red or brownish-red. According to J. Grailich, the rhombic crystals of dechenite have the axial ratios $a : b : c = 0.8354 : 1 : 0.6538$. The artificial compound is white. The sp. gr. of dechenite is 5.60–5.81, and the hardness 3.5–4.0. T. Carnelley gave 849° for the m.p. of the salt. R. Robl observed no fluorescence with the salt in ultra-violet light. J. J. Berzelius found that the compound is sparingly soluble in water; freely soluble in warm dil. nitric acid; the soln. in conc. nitric acid, when warm, deposits a brown powder of vanadium pentoxide mixed with some lead. Conc. sulphuric acid decomposes the salt incompletely; it is decomposed by molten potassium hydrosulphate but not by a soln. of potassium carbonate. A. Terreil noticed that a boiling 10 per cent. soln. of sodium sulphide decomposed dechenite and dissolved the vanadium pentoxide.

J. J. Berzelius treated a soln. of lead nitrate with potassium tetravanadate, and obtained a yellow precipitate of **lead deuterotetravanadate**, $\text{PbV}_4\text{O}_{11}$; and A. Ditte obtained it by fusing vanadium pentoxide with a mixture of lead and sodium iodides. It is somewhat soluble in water; freely soluble in dil. nitric acid; and a boiling soln. of potassium carbonate extracts half the vanadium.

A. Damour⁴ described a mineral from Sierra de Cordoba, Argentina, and he called it **descloizite**—after A. des Cloizeaux; F. X. M. Zippe, G. Tschermak, and A. Schrauf, called it rhombic *vanadite*; A. Frenzel, *tritochorite*—*τρίτος*, third; and *χαρπεϊν*, to follow—in allusion to the assumption that the mineral formed a third member of a series with eusynchite and aræoxene; M. V. de Leon, *ramarite*; and F. Pisani, *schaffnerite*. The mineral *vesbine*, found by A. Scacchi as yellow crusts in the crevices of the massive lava flows of 1631 at Vesuvius, was at first thought to be aluminium vesbate—a salt of a new element, vesbium. F. Zambonini, and L. de Luise showed that it is probably a vanadate; and F. Zambonini and G. Carobbi, that it is a hydrated cupro-descloizite approximating $(\text{Pb,Cu})_3(\text{VO}_4)_2 \cdot (\text{Pb,Cu})(\text{OH})_2 \cdot 5\text{H}_2\text{O}$, and was formed through the agency of water during the solidification of the lava. Analyses of descloizite were reported by A. Damour, C. F. Rammelsberg, P. A. Wagner, W. F. Hillebrand, A. Döring, F. A. Genth, F. Pisani, M. V. de Leon, S. L. Penfield, O. Pufahl, A. Brunlechner, D. Lovisato, F. N. Guild, R. C. Wells, and A. Frenzel. The results in general agree with the formula $(\text{Pb,Zn})_3(\text{VO}_4)_2 \cdot (\text{Pb,Zn})(\text{OH})_2$ —*i.e.* **zinc lead hydroxyorthovanadate**, $(\text{Pb,Zn})_2(\text{OH})\text{VO}_4$; while C. F. Rammelsberg's *cuprodescloizite* agrees with $(\text{Pb,Cu})_5(\text{VO}_4)_{22} \cdot (\text{Pb,Cu})(\text{OH})_2$ —*i.e.* **copper lead hydroxyorthovanadate**, $(\text{Pb,Zn})_2(\text{OH})\text{VO}_4$. Some arsenic may replace vanadium. The colour of descloizite may be red, reddish-brown, brown, dark brown, and black; cuprodescloizite is green, greenish-black, or yellowish brown. The mineral occurs massive, and with radiating fibres; in stalactitic aggregates of crystals, or in short prismatic crystals belonging to the rhombic system. M. Websky thought the crystals were monoclinic, but A. des Cloizeaux showed that they are rhombic. According to G. vom Rath, the axial ratios $a : b : c = 0.6368 : 1 : 0.8045$. The (130)-face may be striated vertically. There is no cleavage. C. F. Rammelsberg gave 5.856–6.080 for the sp. gr.;

A. Döring, 5-93-6-14; S. L. Penfield, 6-202; F. A. Genth, 6-203; F. Pisani, 6-06; W. F. Hillebrand, 5-88; D. Lovisato, 5-72; and M. V. de Leon, 6-01-6-10. The hardness is 3-5. The optical character is negative. R. C. Wells gave 1-74 for the index of refraction of cupro-descloizite, and 0-03-0-04 for the birefringence. T. W. Case observed that descloizite is a poor conductor and is not appreciably affected by light. E. E. Fairbanks gave 7-7 to 8-6 for the dielectric constant (water 81). The mineral is soluble in cold dil. nitric acid.

H. E. Roscoe⁵ described a mineral which he called **mottramite** and which occurred as thin, crystalline incrustations in the keuper sandstones of Mottram St. Andrews, and Alderley Edge, Cheshire; he represented his analysis by $(\text{Pb,Cu})_3(\text{VO}_4)_5 \cdot 2(\text{Pb,Cu})(\text{HO})_2$, **copper lead tetrahydroxyorthovanadate**; and C. F. Rammelsberg represented its composition by $\text{R}_3(\text{VO}_4)_2 \cdot 3\text{R}(\text{OH})_2$. It was also analyzed by O. Pufahl. F. A. Genth found a mineral which he called **psittacinite**—from *psittacinus*, siskin or parrot-green—occurring in the Silver Star District, Montana, and elsewhere. Analyses reported by F. A. Genth, A. Döring, C. F. Rammelsberg, and F. Pisani agree with formula $\text{R}_3(\text{VO}_4)_2 \cdot \text{R}(\text{OH})_2 \cdot \text{H}_2\text{O}$, or **copper dihydroxyorthovanadate**.

G. A. Kenngott,⁶ and I. Domeyko described a lead copper vanadate occurring in the Mina de la Marqueza, Chile. M. Adam called it *cuprovanadite*, and I. Domeyko, *chileite*. Its existence as a definite mineral species has not been confirmed. Likewise also with the *vanadinite* of R. Hermann, found in small green crystals in the Slindianka River near Lake Baikal, Siberia. C. F. Rammelsberg supposes it to be a mixture of augite and a vanadate. T. Thomson described a lead vanadate occurring in Wicklow, Ireland, and called it *wicklowite*—A. d'Achiardi called it *vichlovite*. F. Pisani described zinc lead vanadate a mineral from Laurium, Greece; W. P. Blake has also described a lead vanadate from Castle Dome, Arizona. V. Dürrfeld described a hydrated zinc lead vanadate mineral from Lahr, Baden; he called it *hügelite*—after F. Hügel. The monoclinic crystals have the axial ratios $a : b : c = 0.48954 : 1 : 0.38372$, and $\beta = 60^\circ 12' 6''$; it usually occurs in microscopic needles irregularly arranged. The colour is orange-yellow or yellowish-brown. The pleochroism is yellowish-green and greenish-yellow. The sp. gr. is 5.

H. Fischer and J. Nessler⁷ found a massive or nodular mineral in Hofgrund, Baden, and they called it **eusynchite**. Its colour is yellowish-red, reddish-brown, or green. Analyses, reported by C. F. Rammelsberg, C. Czudnowicz, C. Bergmann, and J. Lang, agree with the formula for **zinc lead orthovanadate**, $(\text{Pb,Zn})_3(\text{VO}_4)_2$. The sp. gr. is 5-6-5-8; and the hardness, 3-4. The related mineral *aræoxene* from Dahn, Rhenish, Bavaria, was described by F. von Kobell; it is similar to eusynchite, but contains some arsenic in place of vanadium. F. Sandberger, and F. Schumacher regard aræoxene as a variety of descloizite. The mineral **brackebuschite**—named after D. L. Brackebusch by A. Döring⁸—occurs in several localities in Cordoba, Argentine. Analyses reported by A. Döring, and C. F. Rammelsberg gave a formula close to that of descloizite, and the mineral is regarded as a **lead ferrous manganese orthovanadate**, $(\text{Pb,Mn,Fe})_3(\text{VO}_4)_2 \cdot \text{H}_2\text{O}$. The mineral occurs in small, black, prismatic crystals—possibly monoclinic. A. Damour considers that the manganese, iron, and copper present are only impurities.

§ 14. Vanadates of the Bismuth and Chromium Families

The arsenic vanadates are treated in connection with vanadium arsenates. O. W. Gibbs¹ believed that a series of antimony vanadates corresponding with the arsenic vanadates are capable of existence. A soln. of potassium antimonal tartrate gives a yellowish-brown precipitate when treated with ammonium metavanadate, and this dissolves when the mixture is shaken. A. Frenzel found a mineral at the Pacher Mine, Schnerberg, Saxony, and he called it **pacherite**. Analyses by A. Frenzel and W. T. Schaller agree with **bismuth orthovanadate**, BiVO₄. A. Frenzel obtained it by evaporating over sulphuric acid, a soln. containing bismuth

nitrate and vanadium chloride. Pacherite occurs in reddish-brown tabular, or acicular crystals which M. Websky found to be rhombic with the axial ratios $a : b : c = 0.5317 : 1 : 2.5357$. The (001)-cleavage is perfect. E. V. Shannon examined the crystals of a sample from Brazil. G. Cesaro studied the optical properties. The sp. gr. is 6.249 at 24.5° , and the hardness 4. The mineral is soluble in hydrochloric acid with the evolution of chlorine. W. T. Schaller's analyses of bismuth ochres (*q.v.*) from California show that they are probably **bismuth trihydroxyvanadate**, $\text{BiVO}_4 \cdot \text{Bi}(\text{OH})_3$, or $\text{HO} \cdot \text{Bi} : \text{VO}_4 \cdot \text{Bi}(\text{OH})_2$. E. Zintl and L. Vanino prepared bismuth vanadate for therapeutic use by the addition of vanadates, at the ordinary or at raised temp., to soln. containing bismuth salts and substances which prevent the separation of basic bismuth compounds, such as acetic acid, mixtures of acetic acid and acetates, small quantities of mineral acids, polyhydric alcohols, or ketones. The product is subsequently heated in the air in case any reduction has taken place during the precipitation.

A. Carnot² found that chromium salts give a precipitate of **chromium vanadate**, CrVO_4 , when treated with an alkali vanadate. A. Ditte prepared **ammonium vanadatochromate**, $2(\text{NH}_4)_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot 2\text{CrO}_3 \cdot 7\text{H}_2\text{O}$, or *chromatovanadate*, by dissolving vanadium pentoxide in a soln. of ammonium chromate at 60° , and evaporating the red liquid in vacuo; if the liquid be evaporated on a water-bath, crystals of ammonium hexavanadate are formed. B. Glasmann evaporated an aq. soln. of 2 mols each of chromic anhydride, ammonium metavanadate and ammonia at 60° , until a conc. soln. was obtained, and then evaporated it in vacuo. Red prismatic crystals of ammonium vanadatochromate mixed with crystals of ammonium hexavanadate were formed. B. Glasmann was unable to prepare any other vanadatochromate.

J. J. Berzelius³ found that when vanadyl sulphate is treated with ammonium molybdate, a dark purple soln. is formed which, on exposure to air, becomes blue, and then yellow, without precipitation; and that molybdenum salt soln. give a yellow liquid when treated with ammonium metavanadate. O. W. Gibbs observed that when molybdic acid is added to a boiling soln. of ammonium metavanadate, complex **vanadatomoxybdates** or **molybdatoxovanadates** are formed. A number of these complexes have been reported by L. Milch, C. Friedheim and co-workers, H. von Euler-Chelpin, F. Toggenburg, H. Stamm, A. Isenburg, etc. The tests for chemical individuality are not sufficient to decide the question. Consequently, we are unable to distinguish between chemical individuals and mixtures. The salts are prepared by adding molybdic acid to a soln. of a vanadate; by adding vanadic acid to a soln. of molybdate or by mixing soln. of a vanadate and a molybdate. There is an extraordinarily wide variation in the composition of the salts—thus, there are nearly twenty ammonium vanadatomoxybdates. Their constitution has not yet been elucidated. One series can be represented by $3\text{R}_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 4\text{MoO}_3 \cdot n\text{H}_2\text{O}$, where R denotes NH_4 or K. This is one of the most stable of the series, and on the co-ordination theory they can be regarded as salts of the heteropolyacid, $\text{H}_{10}[(\text{V}_2\text{O}_6)_3\text{H}_2(\text{Mo}_2\text{O}_7)_3] \cdot n\text{H}_2\text{O}$, where the ammonium salt becomes $(\text{NH}_4)_9\text{H}[(\text{V}_2\text{O}_6)_3\text{H}_2(\text{Mo}_2\text{O}_7)_3] \cdot 9\text{H}_2\text{O}$. The three series, $2\frac{1}{2}\text{R}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot 6\text{MoO}_3 \cdot n\text{H}_2\text{O}$, where R_2 denotes K_2 , $(\text{NH}_4)_2$, or Ba; $2\text{R}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot 6\text{MoO}_3 \cdot n\text{H}_2\text{O}$, where R denotes Na or K; and $3\text{R}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot 6\text{MoO}_3 \cdot n\text{H}_2\text{O}$, where R denotes NH_4 or K, may be derived from either of the heteropolyacids:

None of these acids has been isolated, but A. Ditte reported that if ammonium vanadatomoxybdate is boiled with aqua regia containing an excess of nitric acid, a reddish, non-crystalline deposit is obtained, and if this is boiled with a large excess of nitric acid, it gradually changes into small, slender, transparent, orange-red needles of **vanadatomoxybdic acid**, $\text{V}_2\text{O}_5 \cdot 8\text{MoO}_3 \cdot 5\text{H}_2\text{O}$. Vanadatomoxybdic acid

is only slightly soluble in boiling nitric acid, and is still less soluble in water. In this respect, it differs from phosphatomolybdic and arsenatomolybdic acids, which are readily soluble in water.

G. Canneri showed that within the limits imposed by the solubility of molybdic anhydride in soln. of the metavanadates of sodium, potassium, and ammonium, compounds of two types, differing in their physical properties, are formed. These crystallize respectively in large, orange-red prisms and in yellow, silky needles, or, sometimes, in pulverulent form. One and the same soln. may give both red and yellow crystals, either together or successively in either order. The value of the ratio $V_2O_5 : MoO_3$ varies gradually in the red crystals from 3 : 1 to values corresponding with the maximum percentage of vanadium, this approaching the proportion occurring in polyvanadates. The ratio changes suddenly in value for the yellow crystals, which are poorer in vanadium. The various red crystals appear to consist of isomorphous mixtures, but the isomorphogenous terms cannot yet be defined, neither can their chemical natures be established; it is, however, possible that they consist of polyvanadates and polymolybdates. Along with these isomorphous mixtures there exist certain well-defined compounds which are obtained under definite conditions. With these compounds difficulty is encountered in distinguishing between combined water and water of crystallization, but the salts are regarded as heteropolyaques and are supposed to have formulæ based on the hypothesis of A. Rosenheim. According to W. Prandtl, molybdovanadates are double salts, and should hence be completely dissociated in soln.; in sufficiently dil. soln., therefore, fractional precipitation of the different constituents should be possible, but this is not found to be the case.

G. Canneri found that the crystals formed by the system $NH_4VO_3 : MoO_3$ have the same pale-yellow colour and crystal habit in all cases, and consist of **ammonium hexavanadatopentamolybdate**, $4(NH_4)_2O \cdot 3V_2O_5 \cdot 5MoO_3 \cdot 10H_2O$. C. Friedheim and C. Castendyck obtained reddish-brown crystals of **ammonium tetravanadatodimolybdate**, $(NH_4)_2O \cdot 2V_2O_5 \cdot 2MoO_3 \cdot 8H_2O$, along with four other salts—*vide infra*—by fractional crystallization from a soln. of 800 grms. of ammonium silicomolybdate and 180 grms. of ammonium metavanadate; also yellowish-green crystals of **ammonium divanadatodimolybdate**, $(NH_4)_2O \cdot V_2O_5 \cdot 2MoO_3 \cdot 4H_2O$, almost insoluble in water. H. von Euler-Chelpin obtained **ammonium divanadatotrimolybdate**, $(NH_4)_2O \cdot V_2O_5 \cdot 3MoO_3 \cdot 17H_2O$, as a yellow crystalline powder, from a hot soln. of equimolar parts of molybdic acid and ammonium metavanadate; and white needles of $2(NH_4)_2O \cdot V_2O_5 \cdot 3MoO_3 \cdot 6H_2O$, from the mother-liquor in the preparation of the divanadatotetramolybdate, and also from a soln. of 4 mols of ammonium metavanadate and a soln. of ammonium paramolybdate. A. Isenburg also made this salt; and W. Prandtl represented it by $(NH_4)_6V_6O_{18} \cdot 3(NH_4)_2H_4Mo_3O_{12} \cdot 12H_2O$. C. Friedheim and C. Castendyck obtained pale brown **ammonium hexavanadatotetramolybdate**, $2(NH_4)_2O \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 11H_2O$, by the fractional crystallization of the soln. employed for the tetravanadatodimolybdate; L. Milch, and M. Liebert obtained **ammonium tetravanadatotetramolybdate**, $3(NH_4)_2O \cdot 2V_2O_5 \cdot 4MoO_3 \cdot 7\frac{1}{2}(9, \text{ or } 11)H_2O$, by the action of a soln. of molybdic acid on an aq. soln. of ammonium metavanadate at about 70° ; and cooling the hot soln. or evaporating it over sulphuric acid. H. von Euler-Chelpin obtained it by the action of 4 mols of ammonium metavanadate on 3 mols of molybdic acid; and A. Ditte from a hot soln. of vanadium pentoxide and ammonium molybdate. W. Prandtl represented this salt by the formula $(NH_4)_3HV_6O_{17} \cdot 6NH_4HM_4O_4 \cdot 7, 10, \text{ or } 13H_2O$. The salt is readily soluble in water, from which soln. it can be recrystallized unchanged. It is decomposed by acids and alkali-lye, and the soln. gives a precipitate with salts of the alkaline earths, silver, mercury, lead, etc., but not by salts of the alkalis, copper, zinc, manganese, cobalt, and nickel. H. von Euler-Chelpin obtained **ammonium divanadatotetramolybdate**, $2(NH_4)_2O \cdot V_2O_5 \cdot 4MoO_3 \cdot 7 \text{ or } 8H_2O$, from hot soln. of a mol of ammonium paramolybdate and 2 mols of ammonium metavanadate, by allowing it to stand

over sulphuric acid. M. Liebert obtained the same salt from the mother-liquor in the preparation of divanadatohexamolybdate. C. Friedheim and C. Castendyck obtained brownish-red needles of **ammonium tetracosivanadatopentamolybdate**, $4(\text{NH}_4)_2\text{O}\cdot 12\text{V}_2\text{O}_5\cdot 5\text{MoO}_3\cdot 24\text{H}_2\text{O}$, by fractional crystallization of the soln. employed for the tetravanadatodimolybdate; at the same time there is formed a yellow crystalline crust of **ammonium tetravanadatopentamolybdate**, $2(\text{NH}_4)_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 5\text{MoO}_3\cdot 8\text{H}_2\text{O}$. H. von Euler-Chelpin produced yellow crystals of the anhydrous salt from a soln. of 3 mols of molybdic acid and one mol of ammonium metavanadate; and M. Liebert, $3(\text{NH}_4)_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 5\text{MoO}_3\cdot 8\frac{1}{2}\text{H}_2\text{O}$, from a boiling soln. of vanadium pentoxide in normal ammonium molybdate, and afterwards evaporated over conc. sulphuric acid. This salt was also obtained as a heptahydrate by A. Isenburg. H. von Euler-Chelpin prepared white needles of **ammonium octovanadatohexamolybdate**, $5(\text{NH}_4)_2\text{O}\cdot 4\text{V}_2\text{O}_5\cdot 6\text{MoO}_3\cdot 12$ or $14\text{H}_2\text{O}$, from a soln. of a mol of molybdic acid and 2 or 4 mols of ammonium metavanadate. W. Prandtl also prepared this salt, and he considered its composition is better expressed by $(\text{NH}_4)_3\text{HV}_6\text{O}_{17}\cdot 5\text{NH}_4\text{HMoO}_4\cdot 7\text{H}_2\text{O}$. O. W. Gibbs prepared *pentahydrated ammonium divanadatohexamolybdate*, $2(\text{NH}_4)_2\text{O}\cdot \text{V}_2\text{O}_5\cdot 6\text{MoO}_3\cdot 5\text{H}_2\text{O}$, from a soln. of molybdic acid in a boiling soln. of ammonium metavanadate, and allowing the soln. to evaporate spontaneously. M. Liebert prepared the *hexahydrate* from a boiling soln. of ammonium paramolybdate and vanadium pentoxide. W. Prandtl represented it by the formula $(\text{NH}_4)_3\text{HV}_6\text{O}_{17}\cdot 6(\text{NH}_4)_2\text{H}_4\text{Mo}_3\text{O}_{12}\cdot \text{H}_2\text{O}$; and O. W. Gibbs by $5(\text{NH}_4)_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 12\text{MoO}_3\cdot 10\text{H}_2\text{O}$. A. Isenburg made $3(\text{NH}_4)_2\text{O}\cdot \text{V}_2\text{O}_5\cdot 6\text{MoO}_3\cdot 7\text{H}_2\text{O}$, by evaporating a soln. of 145 grms. of ammonium metavanadate and 765 grms. of ammonium paramolybdate in 2.5 litres of water. W. Prandtl represented it by $(\text{NH}_4)_6\text{V}_6\text{O}_{18}\cdot 6(\text{NH}_4)_2\text{H}_4\text{Mo}_3\text{O}_{12}\cdot 9\text{H}_2\text{O}$. F. Toggenburg prepared **ammonium hexavanadatoheptamolybdate**, $5(\text{NH}_4)_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 7\text{MoO}_3\cdot 13$ or $16\text{H}_2\text{O}$, by dissolving 35.1 grms. of ammonium metavanadate and 50.4 grms. of molybdic acid in as little warm water as possible, mixing the liquid with 32.1 c.c. of aq. ammonia of sp. gr. 0.956, concentrating and cooling the hot, filtered liquid. It was also made by treating the dil. soln. of ammonium diphosphatododecavanadatododecamolybdate with aq. ammonia. The yellow needles can be recrystallized from water without decomposition. The aq. soln. gives no precipitate with potassium chloride, but a white one with barium chloride. W. Prandtl represented it $(\text{NH}_4)_4\text{V}_6\text{O}_{17}\cdot (\text{NH}_4)_2\text{H}_4\text{Mo}_3\text{O}_{12}\cdot 4\text{NH}_4\text{HMoO}_4\cdot 9$ or $12\text{H}_2\text{O}$. H. Stamm made **ammonium hexavanadatoctomolybdate**, $5(\text{NH}_4)_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 8\text{MoO}_3\cdot 14\text{H}_2\text{O}$, in rhombic crystals, from the mother-liquid after the preparation of ammonium diphosphatoctovanadatotetradecamolybdate. W. Prandtl represented it $(\text{NH}_4)_4\text{V}_6\text{O}_{17}\cdot 2\text{NH}_4\text{HMoO}_4\cdot 2(\text{NH}_4)_2\text{H}_4\text{Mo}_3\text{O}_{12}\cdot 8\text{H}_2\text{O}$. O. W. Gibbs made **ammonium divanadatoctodecamolybdate**, $8(\text{NH}_4)_2\text{O}\cdot \text{V}_2\text{O}_5\cdot 12\text{MoO}_3\cdot 15\text{H}_2\text{O}$, by saturating a boiling soln. of ammonium metavanadate with molybdic acid, and cooling the liquid slowly. The yellowish-green tabular crystals are decomposed by boiling water. A. Isenburg made **ammonium octovanadatotridecamolybdate**, $8(\text{NH}_4)_2\text{O}\cdot 4\text{V}_2\text{O}_5\cdot 13\text{MoO}_3\cdot 21\text{H}_2\text{O}$, by the spontaneous evaporation of a soln. of 2 mols of ammonium metavanadate and a mol of ammonium paramolybdate in 4 litres of hot water. W. Prandtl represented it $(\text{NH}_4)_3\text{HV}_6\text{O}_{17}\cdot 2(\text{NH}_4)_2\text{H}_4\text{Mo}_3\text{O}_{12}\cdot 4\text{NH}_4\text{HMoO}_4\cdot 6\text{H}_2\text{O}$. L. Milch reported **ammonium hexavanadatotetracosimolybdate**, $10(\text{NH}_4)_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 24\text{MoO}_3\cdot 10\text{H}_2\text{O}$, by concentrating on the water-bath a hot soln. of ammonium molybdate sat. with hydrated vanadium pentoxide. The salt can be purified by recrystallization. W. Prandtl represented it by $(\text{NH}_4)_4\text{V}_6\text{O}_{17}\cdot 8(\text{NH}_4)_2\text{H}_2\text{Mo}_3\text{O}_{11}\cdot 2\text{H}_2\text{O}$.

G. Canneri found that the pale yellow crystals, formed in the system $\text{KVO}_3 : \text{MoO}_3$ at 30° , vary in composition with the conc. of the soln., forming compounds **potassium hexavanadatotetramolybdate**, $4\text{K}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 4\text{MoO}_3\cdot 7\text{H}_2\text{O}$, and **potassium tetravanadatohexamolybdate**, $3\text{K}_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 6\text{MoO}_3\cdot 7\text{H}_2\text{O}$. While with the system $\text{NaVO}_3 : \text{MoO}_3$, **sodium hexavanadatoctomolybdate**, $4\text{Na}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 8\text{MoO}_3\cdot 10\text{H}_2\text{O}$, occurs in equilibrium with the red mixed crystals until the molybdenum has attained

the ratio $V_2O_5 : MoO_3 = 112$, and it separates as a single phase when the proportion of molybdenum is still further increased. The red salt is **sodium hexavanadato-molybdate**, $2Na_2O \cdot 3V_2O_5 \cdot MoO_3 \cdot 9H_2O$. It yields **barium octovanadatodimolybdate**, $3BaO \cdot 4V_2O_5 \cdot MoO_3 \cdot 12H_2O$, and **sodium hexavanadatodimolybdate**, $3Na_2O \cdot 3V_2O_5 \cdot 2MoO_3 \cdot 12H_2O$. H. von Euler-Chelpin prepared yellow crystals of **potassium divanadatotrimolybdate**, $K_2O \cdot V_2O_5 \cdot 3MoO_3 \cdot 15H_2O$, from aq. soln. of potassium metavanadate and molybdic acid in equimolar proportions. He also obtained **potassium tetravanadatotetramolybdate**, $3K_2O \cdot 2V_2O_5 \cdot 4MoO_3 \cdot 7(8 \text{ or } 9)H_2O$, from a soln. of a mol of potassium metavanadate and 0.5 mol of molybdic acid; by treating with potassium chloride, a cold sat. soln. of ammonium tetravanadatotetramolybdate, or octovanadatohexamolybdate, or from a soln. of potassium hydroxide and ammonium tetravanadatotetramolybdate. M. Liebert obtained it from the mother-liquor in the preparation of potassium tetravanadatododecamolybdate. W. Prandtl represented it by the formula $K_3HV_6O_{17} \cdot 6KHM_oO_4 \cdot 7, 8, \text{ or } 10H_2O$. H. von Euler-Chelpin obtained olive-green crystals of **potassium tetravanadato-pentamolybdate**, $2K_2O \cdot 2V_2O_5 \cdot 5MoO_3 \cdot 10H_2O$, mixed with yellow monoclinic crystals of potassium tetravanadatododecamolybdate, from a soln. of a mol of potassium metavanadate and 1.5 mols of molybdic acid in hot water. M. Liebert prepared lemon-yellow crystals of **potassium divanadatohexamolybdate**, $2K_2O \cdot V_2O_5 \cdot 6MoO_3 \cdot 6H_2O$, from a hot, sat. soln. of potassium paramolybdate and hydrated vanadium pentoxide; H. von Euler-Chelpin also made it by mixing a soln. of equimolar parts of ammonium metavanadate and molybdic acid with a cold, sat. soln. of potassium chloride. H. Jacoby also prepared this salt. It is sparingly soluble in cold water, freely soluble in hot water, from which it crystallizes without decomposition. H. von Euler-Chelpin made $3K_2O \cdot V_2O_5 \cdot 6MoO_3 \cdot 5H_2O$, from a hot soln. of a mol of potassium paramolybdate and 2 mols of potassium metavanadate; W. Prandtl represented it by $K_6V_6O_{18} \cdot 6K_2H_4Mo_3O_{12} \cdot 3H_2O$. H. von Euler-Chelpin also prepared **sodium divanadatohexamolybdate**, $2Na_2O \cdot V_2O_5 \cdot 6MoO_3 \cdot 16H_2O$, from a soln. of equimolar parts of sodium metavanadate and molybdic acid; W. Prandtl represented it by $Na_2H_2V_6O_{17} \cdot 6Na_2H_4Mo_3O_{13} \cdot 26H_2O$. M. Liebert reported **potassium tetravanadatododecamolybdate**, $5K_2O \cdot 2V_2O_5 \cdot 12MoO_3 \cdot 12H_2O$, from a sat. soln. of normal potassium molybdate and hydrated vanadium pentoxide; and H. von Euler-Chelpin, from a soln. of two mols of sodium metavanadate and a mol of sodium paramolybdate mixed with potassium chloride. W. Prandtl represented it by $K_3HV_6O_{17} \cdot 6K_2H_4Mo_3O_{12} \cdot 6H_2O$, and he also obtained the anhydrous salt $K_3HV_6O_{17} \cdot 6K_2H_4Mo_3O_{12}$, as well as the mixed salt $(K, Na)_3HV_6O_{17} \cdot 6(Na, K)_2H_4Mo_3O_{12} \cdot 14H_2O$. M. Liebert reported **potassium divanadatododecamolybdate**, $3K_2O \cdot V_2O_5 \cdot 12MoO_3 \cdot 15H_2O$, from a soln. of 3 mols of potassium carbonate, one mol of vanadium pentoxide, and 24 mols of molybdic acid. W. Prandtl prepared red pulverulent **potassium hexavanadatoicosimolybdate**, $10K_2O \cdot 3V_2O_5 \cdot 21MoO_3 \cdot 17H_2O$, or, as he writes it, $K_6V_6O_{18} \cdot 7K_2H_4Mo_3O_{12} \cdot 3H_2O$, from a soln. of 3 mols of vanadium pentoxide, and 18 mols of molybdic anhydride in potash-lye at ordinary temp., and then adding an excess of dil. acetic acid; he also reported $23K_2O \cdot 6V_2O_5 \cdot 60MoO_3 \cdot 57H_2O$, or, as he wrote it, $K_3HV_6O_{17} \cdot 10K_2H_4Mo_3O_{12} \cdot 8H_2O$, to be formed if a boiling soln. is used. A warm soln. of 3 mols of vanadium pentoxide and 6-8 mols of molybdic anhydride in potash-lye when treated with dil. acetic acid, furnishes yellowish-white needles of **potassium dodecavanadatohexadecamolybdate**, $9K_2O \cdot 6V_2O_5 \cdot 16MoO_3 \cdot 34H_2O$, or $K_3HV_6O_{17} \cdot 2KHM_oO_4 \cdot 2K_2H_4Mo_3O_{12} \cdot 6H_2O$. A soln. of 5 grms. each of vanadium pentoxide, and molybdic anhydride in potash-lye, feebly acidified with acetic acid, was found by W. Prandtl to furnish **potassium divanadato-dimolybdate**, $3K_2O \cdot V_2O_5 \cdot 2MoO_3 \cdot 8H_2O$, or $KVO_3 \cdot K_2MoO_4 \cdot 4H_2O$, or $K_3V_3O_9 \cdot 3K_2MoO_4 \cdot 12H_2O$; if soda-lye be used instead of potash-lye, **sodium hexavanadatohexamolybdate**, $5Na_2O \cdot 3V_2O_5 \cdot 6MoO_3 \cdot 15H_2O$, or $Na_4V_6O_{17} \cdot 6NaHM_oO_4 \cdot 12H_2O$, was obtained. If the ratio $V_2O_5 : MoO_3$ be between the limits 3 : 6 and 3 : 18, **sodium hexavanadatoheptamolybdate**, $4Na_2O \cdot 3V_2O_5 \cdot 7MoO_3 \cdot 21H_2O$, or $Na_2H_2V_6O_{17}$.

$\text{Na}_2\text{H}_4\text{Mo}_3\text{O}_{12}\cdot 4\text{NaHMoO}_4\cdot 16\text{H}_2\text{O}$, is formed; with the ratio 3:8, **sodium hexavanadatoctodecamolybdate**, $9\text{Na}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 18\text{MoO}_3\cdot 48\text{H}_2\text{O}$, or $\text{Na}_6\text{V}_6\text{O}_{18}\cdot 6\text{Na}_2\text{H}_4\text{Mo}_3\text{O}_{12}\cdot 36\text{H}_2\text{O}$ is formed.

H. von Euler-Chelpin reported **ammonium potassium tetravanadatotetramolybdate**, $2\text{K}_2\text{O}\cdot (\text{NH}_4)_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 4\text{MoO}_3\cdot 5\text{H}_2\text{O}$, in yellow prisms, from a soln. of 2 mols of ammonium metavanadate and a mol of molybdic acid with potassium chloride; on recrystallization, potassium tetravanadatotetramolybdate is formed. W. Prandtl represented its composition by $(\text{K}\cdot\text{NH}_4)_3\text{HV}_6\text{O}_{17}\cdot 5(\text{K}\cdot\text{NH}_4)\text{HMoO}_3\cdot 6$ or $13\text{H}_2\text{O}$. H. Jacoby made a similar salt. H. von Euler-Chelpin also made in yellow prismatic crystals **ammonium potassium hexavanadatopentamolybdate**, $3\text{K}_2\text{O}\cdot (\text{NH}_4)_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 5\text{MoO}_3\cdot 9\text{H}_2\text{O}$, from the mother-liquor in the preparation of the preceding salt. H. Jacoby also obtained white needles of $3\cdot 5\text{K}_2\text{O}\cdot 0\cdot 5(\text{NH}_4)_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 5\text{MoO}_3\cdot 16\text{H}_2\text{O}$, by treating the mother-liquor in the preparation of ammonium diphosphatododecavanadatododecamolybdate, with potassium chloride. H. von Euler-Chelpin obtained **ammonium sodium tetravanadatohexamolybdate**, $\text{Na}_2\text{O}\cdot (\text{NH}_4)_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 6\text{MoO}_3\cdot 12\text{H}_2\text{O}$, from a soln. of a mol of molybdic acid and a mol of ammonium metavanadate mixed with sodium chloride and evaporated over a desiccating agent. The mother-liquor employed in the preparation of potassium tetravanadatododecamolybdate furnished pale yellow crystals of **sodium potassium tetravanadatododecamolybdate**, $4\text{Na}_2\text{O}\cdot \text{K}_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 12\text{MoO}_3\cdot 18\text{H}_2\text{O}$.

O. W. Gibbs found that a soln. of ammonium divanadatohexamolybdate gives no precipitate with copper sulphate. H. von Euler-Chelpin obtained an egg-yellow crystalline powder, **barium vanadatomolybdate**, $\text{BaO}\cdot \text{V}_2\text{O}_5\cdot \text{MoO}_3\cdot 7\text{H}_2\text{O}$, from the mother-liquor employed in the preparation of **barium octovanadatohexamolybdate**, $5\text{BaO}\cdot 4\text{V}_2\text{O}_5\cdot 6\text{MoO}_3\cdot 28\text{H}_2\text{O}$, by adding a 10 per cent. soln. of barium chloride to a soln. of 2 mols of ammonium metavanadate and a mol of molybdic acid. The pale yellow crystalline powder is soluble in hot water. H. von Euler-Chelpin obtained **barium tetravanadatohexamolybdate**, $3\text{BaO}\cdot 2\text{V}_2\text{O}_5\cdot 6\text{MoO}_3\cdot 8\text{H}_2\text{O}$, by crystallization from a soln. of ammonium barium divanadatotrimolybdate. O. W. Gibbs obtained **barium tetravanadatohexadecamolybdate**, $5\text{BaO}\cdot 2\text{V}_2\text{O}_5\cdot 16\text{MoO}_3\cdot 29\text{H}_2\text{O}$, by adding barium chloride to a dil. boiling soln. of vanadium pentoxide and an acid ammonium molybdate. W. Prandtl represented it by $\text{Ba}_2\text{V}_6\text{O}_{17}\cdot 6\text{BaH}_2\text{Mo}_4\text{O}_{14}\cdot 41\text{H}_2\text{O}$. M. Liebert prepared **barium hexavanadatoctodecamolybdate**, $7\text{BaO}\cdot 3\text{V}_2\text{O}_5\cdot 18\text{MoO}_3\cdot 36$ or $48\text{H}_2\text{O}$, by mixing with barium chloride a cold soln. of potassium tetravanadatododecamolybdate, or divanadatohexamolybdate. W. Prandtl represented it by $\text{BaH}_2\text{V}_6\text{O}_{17}\cdot 6\text{BaH}_4\text{Mo}_3\text{O}_{12}\cdot 24$ or $36\text{H}_2\text{O}$; and H. von Euler-Chelpin obtained it from the mother-liquor employed in the preparation of **ammonium barium divanadatotrimolybdate**, $(\text{NH}_4)_2\text{O}\cdot \text{BaO}\cdot \text{V}_2\text{O}_5\cdot 3\text{MoO}_3\cdot 6\text{H}_2\text{O}$, which was obtained in yellow crystals, by treating a soln. of ammonium metavanadate and molybdic acid with barium chloride; or evaporating a soln. of 2 mols of ammonium metavanadate and one mol of molybdic acid over sulphuric acid. W. Prandtl represented it by the formula $(\text{Ba}\cdot\text{NH}_4)\text{HV}_6\text{O}_{17}\cdot 5\text{NH}_4\text{HMoO}_4\cdot 6\text{H}_2\text{O}$. W. Prandtl prepared **barium hexavanadatoctodecamolybdate**, $9\text{BaO}\cdot 3\text{V}_2\text{O}_5\cdot 18\text{MoO}_3\cdot 32$ or $86\text{H}_2\text{O}$, or $\text{Ba}_3\text{V}_6\text{O}_{18}\cdot 6\text{BaH}_4\text{Mo}_3\text{O}_{12}\cdot 20$ or $74\text{H}_2\text{O}$, by adding barium chloride to a boiling soln. of 3 mols of vanadium pentoxide and 18 mols of molybdic anhydride in soda-lye treated with an excess of dil. acetic acid. L. Milch found that by dropping a soln. of barium chloride into a hot soln. of ammonium vanadatomolybdate, crystals of **ammonium barium dodecavanadatohexatricontamolybdate**, $5(\text{NH}_4)_2\text{O}\cdot 15\text{BaO}\cdot 6\text{V}_2\text{O}_6\cdot 36\text{MoO}_3$, are formed. O. W. Gibbs made **mercurous vanadatomolybdate** by adding mercurous nitrate to a soln. of ammonium divanadatohexamolybdate.

According to J. J. Berzelius,⁴ a yellowish-brown precipitate of **vanadyl tungstate** is formed when a soln. of a vanadyl salt and an alkali tungstate are mixed; the product is slightly soluble in water, and when kept under water, oxidation to the pentoxide occurs and the soln. acquires a yellow colour. Mixed soln. of tungstates and vanadates, or soln. of vanadium pentoxide in a soln. of a paratungstate,

or a mixture of soln. of paratungstates and metavanadates, furnish a series of salts of heteropoly acids—the **vanadatotungstates** or **tungstovanadates**. The salts have been studied by C. F. Rammelsberg, A. Ditte, O. W. Gibbs, A. Rosenheim and co-workers, and C. Friedheim and co-workers, but as in the case of the heteropolymolybdates, the subject is yet in rather an empirical stage. There are three fairly well-defined series: (i) The orange-red series, $5R_2O \cdot 3V_2O_5 \cdot 6WO_3 \cdot nH_2O$, with NH_4 , K, or Na in place of R. On the co-ordination theory, the formula is $R_5H_2[(WO_4)_3H_2(WO_3)_3] \cdot nH_2O$; (ii) The yellowish-red series $2R_2O \cdot V_2O_5 \cdot 4WO_3 \cdot nH_2O$, with $R = NH_4$, K, Na, CN_3H_6 , Ag, $\frac{1}{2}Ba$, $\frac{1}{2}Ca$, and $\frac{1}{2}Sr$. The co-ordination formula is

(iii) The purple-red series, $5R_2O \cdot 3V_2O_5 \cdot 14WO_3 \cdot nH_2O$, with $R = NH_4$, K, Cs, CN_3H_6 , and $\frac{1}{2}Ba$, has the co-ordination formula:

It is doubtful if a **vanadatotungstic acid** has been prepared. O. W. Gibbs boiled a mixture of soln. of ammonium metavanadate and sodium paratungstate with nitric acid, and found that the orange-red liquid deposited a sulphur-yellow crystalline precipitate of a **divanadatotungstic acid**, $V_2O_5 \cdot 10WO_3 \cdot 22H_2O$, sparingly soluble in cold water. The mother-liquor furnished on evaporation needle-like crystals of **divanadatoctodecatungstic acid**, $V_2O_5 \cdot 18WO_3 \cdot 36H_2O$. A. Rosenheim could not confirm these statements, but he said that **octovanadatohexadecatungstic acid**, $4V_2O_5 \cdot 16WO_3 \cdot 41H_2O$, is obtained by suspending in water barium tungstate and vanadate in the proportions $V_2O_5 : 4WO_3$; precipitating the barium with sulphuric acid; and concentrating the filtered liquid in vacuo over phosphoric pentoxide. The violet plates are sparingly soluble in cold water and freely soluble in hot water. 24 mols of water are lost at 100° – 120° , and only one mol remains at 250° . C. Friedheim suggested that A. Rosenheim's product is a mixture of metatungstic acid and hydrated vanadium pentoxide.

C. F. Rammelsberg said that he obtained **ammonium hexavanadatotungstate**, $(NH_4)_2O \cdot 3V_2O_5 \cdot WO_3 \cdot 6H_2O$, by treating commercial sodium vanadate (contaminated with tungstate) with acetic acid, and evaporating the red liquid spontaneously. The dark brown octahedra are decomposed by heat. F. Rothenbach evaporated a soln. of equimolar proportions of ammonium nitrate and sodium hexavanadatododecatungstate, over calcium chloride, and obtained octahedral crystals with the composition $34(NH_4)_2O \cdot 21V_2O_5 \cdot 60WO_3 \cdot 58H_2O$; the analysis would agree equally well with simpler proportions.

A. Rosenheim obtained garnet-red crystals of **hemipentahydrated ammonium divanadatotetratungstate**, $2(NH_4)_2O \cdot V_2O_5 \cdot 4WO_3 \cdot 3\frac{1}{2}H_2O$, by boiling hydrated vanadium pentoxide with acid ammonium tungstate; and C. Friedheim and E. Löwy obtained the **tetrahydrate** by evaporating a boiling soln. of a mol of ammonium paratungstate with 14 mols of ammonium metavanadate. A crop of orange-red, rhombohedral crystals appears after the deposition of a little ammonium metavanadate. C. Friedheim regarded both hydrates as ammonium hexavanadatododecatungstate, $6(NH_4)_2O \cdot 3V_2O_5 \cdot 12WO_3 \cdot nH_2O$; and he obtained garnet-red octahedra of $4(NH_4)_2O \cdot 3V_2O_5 \cdot 12WO_3 \cdot 30H_2O$, by the action of vanadium pentoxide on a boiling soln. of ammonium paratungstate; or from a mixture of acetic acid, ammonium metatungstate, and acid ammonium vanadate. A. Ditte obtained dark red octahedra of **ammonium divanadato pentatungstate**, $2(NH_4)_2O \cdot V_2O_5 \cdot 5WO_3 \cdot 10H_2O$, from a soln. of vanadium pentoxide in ammonium tungstate. C. Friedheim said that this product is identical with the one described immediately preceding this. O. W. Gibbs assigned the formula $4(NH_4)_2O \cdot V_2O_5 \cdot 5WO_3 \cdot 13H_2O$, to a salt obtained by boiling a soln. of ammonium metavanadate with ammonium paratungstate, and evaporating the orange-yellow liquid. The salt is sparingly

soluble in cold water, and freely soluble in hot water; the soln. gives precipitates with silver nitrate, mercurous nitrate, and potassium bromide. A. Rosenheim believed that this salt is really **ammonium octovanadatotetradecatungstate**, $7(\text{NH}_4)_2\text{O}\cdot 4\text{V}_2\text{O}_5\cdot 14\text{WO}_3\cdot 16\text{H}_2\text{O}$. Hydrochloric and nitric acids precipitate tungstic acid from the aq. soln.

A. Rosenheim reported **sodium divanadatotetratungstate**, $2\text{Na}_2\text{O}\cdot \text{V}_2\text{O}_5\cdot 4\text{WO}_3\cdot 14\frac{1}{2}\text{H}_2\text{O}$, to be formed by boiling an excess of hydrated vanadium pentoxide with an aq. soln. of sodium paratungstate; evaporating the deep orange liquid on a water-bath; and allowing the syrupy liquid to crystallize over sulphuric acid. The deep red, triclinic crystals have the axial ratios $a : b : c = 0.5184 : 1 : 1.0812$, and $\alpha = 106^\circ 41'$, $\beta = 90^\circ 44'$, and $\gamma = 85^\circ 27'$. The crystals rapidly effloresce, and they are freely soluble in water. The aq. soln. precipitates tungstic acid when treated with mineral acids, it gives amorphous precipitates with mercurous and ferrous salts, and a deep red, crystalline precipitate with silver nitrate. C. Friedheim alleged that the correct formula for this compound is **sodium hexavanadododecatungstate**, $6\text{Na}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 12\text{WO}_3\cdot 42\text{H}_2\text{O}$, and he represented the formation of the salt by the equation: $3\text{Na}_{10}\text{W}_{12}\text{O}_{41} + 6\text{V}_2\text{O}_5 = 3\text{Na}_2\text{W}_4\text{O}_{13} + 2\text{Na}_{12}\text{V}_6\text{W}_{12}\text{O}_{57}$. He added that it can be synthesized from sodium paratungstate and trivanadate. F. Rothenbach obtained a salt with the composition $4\text{Na}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 12\text{WO}_3\cdot 38\text{H}_2\text{O}$, in dark red octahedral crystals along with the triclinic divanadatotetratungstate. It can also be obtained by evaporating sodium metatungstate with an acetic acid soln. of sodium hexavanadate, and crystallizing. C. Friedheim and E. Löwy prepared **sodium hexavanadohexatungstate**, $5\text{Na}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 6\text{WO}_3\cdot 38\text{H}_2\text{O}$, from a hot water soln. of 135 grms. of sodium paratungstate and 83 grms. of the metavanadate, by evaporation on a water-bath to a syrupy liquid, and fractional crystallization over sulphuric acid. The rhombohedral orange-brown crystals can be recrystallized from aq. soln. The salt retains 4 mols. of water at 120° ; and 100 parts of water at 13.8° dissolve 80 parts of the salt. The aq. soln. does not give a precipitate with potassium chloride, but silver nitrate, and barium chloride give precipitates quickly, and calcium chloride slowly. The salt fuses at a red heat, forming a glassy mass. C. Friedheim and E. Löwy reported that **sodium divanadododecatungstate**, $7\text{Na}_2\text{O}\cdot \text{V}_2\text{O}_5\cdot 12\text{WO}_3\cdot 29\text{H}_2\text{O}$, can be obtained from the mother-liquid from the preceding salt. It is decomposed by recrystallization forming **sodium divanadatotetradecatungstate**, $8\text{Na}_2\text{O}\cdot \text{V}_2\text{O}_5\cdot 14\text{WO}_3\cdot 60$ (or 66) H_2O .

A. Rosenheim obtained **potassium divanadatotetratungstate**, $2\text{K}_2\text{O}\cdot \text{V}_2\text{O}_5\cdot 4\text{WO}_3\cdot 8\text{H}_2\text{O}$, by boiling a soln. of potassium paratungstate with hydrated vanadium pentoxide, and evaporating the deep red liquid to a syrupy consistency. It is freely soluble in water and the soln. behaves like the corresponding sodium salt. The yellowish-red or reddish-brown crystals are tabular, and rarely prismatic; they belong to the triclinic system, and have the axial ratios $a : b : c = 0.6993 : 1 : 0.6696$, and $\alpha = 95^\circ 38'$; $\beta = 93^\circ 58'$; and $\gamma = 90^\circ 4'$. At 120° , 24 mols. of water are given off; between 120° and 300° , 8 mols. are expelled; and one mol. is retained very tenaciously. He therefore wrote the formula $8\text{K}_2\text{O}\cdot 4\text{V}_2\text{O}_5\cdot 16\text{WO}_3\cdot 9\text{H}_2\text{O}\cdot 24\text{Aq}$. A. Rosenheim found that along with the crystals of potassium metatungstate, and the preceding salt, there are present garnet-red, sparingly soluble, octahedral crystals of **potassium hexavanadododecatungstate**, $4\text{K}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 12\text{WO}_3\cdot 30\text{H}_2\text{O}$. C. Friedheim and E. Löwy obtained a series of **sodium potassium hexavanadohexatungstates** which are presumably solid soln. of $5\text{Na}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 6\text{WO}_3\cdot n\text{H}_2\text{O}$ and $5\text{K}_2\text{O}\cdot 3\text{V}_2\text{O}_5\cdot 6\text{WO}_3\cdot n\text{H}_2\text{O}$, in the proportions 5 : 1, 1 : 4, and 4 : 3 by concentrating mixed soln. of the component salts over sulphuric acid. A. Rosenheim prepared **silver octovanadohexadecatungstate**, $8\text{Ag}_2\text{O}\cdot 4\text{V}_2\text{O}_5\cdot 16\text{WO}_3\cdot 9\text{H}_2\text{O}$, by boiling a soln. of 3 : 7 sodium vanadate with hydrated vanadium pentoxide, and mixed with silver nitrate. The purple-red precipitate is soluble in cold water, but is decomposed by hot water. The mother-liquor, when evaporated in vacuo, gives red triclinic crystals of **silver tetravanadohexatungstate**, $3\text{Ag}_2\text{O}\cdot 2\text{V}_2\text{O}_5\cdot 6\text{WO}_3\cdot 3\text{H}_2\text{O}$, almost insoluble in cold water, and decomposed by

hot water. O. W. Gibbs reported **mercurous vanadatotungstate** as a dark green precipitate from mercurous nitrate and octoammoniumdivanadatopentatungstate.

According to A. Rosenheim, **barium divanadatotetratungstate**, $2\text{BaO} \cdot \text{V}_2\text{O}_5 \cdot 4\text{WO}_3 \cdot 11\frac{1}{2}$ (or 13) H_2O , is obtained by boiling hydrated vanadium pentoxide with a soln. of acid sodium tungstate, and adding the calculated quantity of barium chloride. The pale yellow liquid furnishes orange-red crystals when evaporated over sulphuric acid. C. Friedheim prepared it by boiling vanadium pentoxide and barium paratungstate with water, and by boiling with water a mol of barium carbonate, 3 mols of vanadium pentoxide, and 10 mols of the 5:12 barium tungstate, or 6 mols of barium carbonate, 3 of vanadium pentoxide, and 12 of tungstic acid. C. Friedheim and E. Löwy obtained the salt by adding barium chloride to a soln. of sodium hexavanadatohexatungstate. The yellowish-red, rhombic crystals were reported by A. Rosenheim to have the axial ratios $a : b : c = 0.8332 : 1 : 1.4264$. The aq. soln. reacts like the alkali salts. It retains 9 mols. of water at $100^\circ\text{--}120^\circ$; and at $250^\circ\text{--}300^\circ$, one mol. of water is retained, and accordingly A. Rosenheim gave the formula $8\text{BaO} \cdot 4\text{V}_2\text{O}_5 \cdot 16\text{WO}_3 \cdot 9\text{H}_2\text{O} \cdot 44\text{Aq}$. C. Friedheim and E. Löwy said that the salt is $6\text{BaO} \cdot 3\text{V}_2\text{O}_5 \cdot 12\text{H}_2\text{O} \cdot 34$ (or 39) H_2O . A. Rosenheim obtained garnet-red octahedral crystals of **barium hexavanadododecatungstate**, $4\text{BaO} \cdot 3\text{V}_2\text{O}_5 \cdot 12\text{WO}_3 \cdot 30\text{H}_2\text{O}$, in the preparation of the preceding salt from vanadium pentoxide and a boiling soln. of barium paratungstate. C. Friedheim obtained it by treating barium metatungstate with an acetic acid soln. of acid potassium vanadate. C. Friedheim obtained a purple-red barium salt of the same composition by adding insufficient dil. sulphuric acid to precipitate all the barium from a mixture of 4 mols of barium metatungstate and a mol of barium metavanadate suspended in water. A. Rosenheim reported that the crystals obtained by evaporating the clear liquor correspond with a mixture of barium vanadate $\text{BaV}_8\text{O}_{21}$, and tungstate, $\text{BaW}_4\text{O}_{18}$. A. Rosenheim also obtained a mixture from the liquid obtained by boiling barium paratungstate and ammonium metavanadate. O. W. Gibbs boiled a mixture of barium metatungstate and metavanadate and obtained deep red, quadratic plates mixed with crystals of ammonium metavanadate and tungstic acid.

C. Friedheim and E. Löwy treated sodium hexavanadatohexatungstate with calcium chloride and obtained yellow **calcium vanadatotungstate**, $2\text{CaO} \cdot \text{V}_2\text{O}_5 \cdot 2\text{WO}_3 \cdot 12\text{H}_2\text{O}$. F. Rothenbach reported orange-yellow **barium vanadatotungstate**, $2\text{Ba}_2\text{V}_{10}\text{O}_{27} \cdot 3\text{Ba}_5\text{W}_{12}\text{O}_{41} \cdot 94\text{H}_2\text{O}$, to be formed from eq. soln. of sodium hexavanadododecatungstate and barium chloride; orange-red cubes of **strontium vanadatotungstate**, $2\text{Sr}_2\text{V}_{10}\text{O}_{27} \cdot 3\text{Sr}_5\text{W}_{12}\text{O}_{41} \cdot 122\text{H}_2\text{O}$, were made in a similar way with strontium chloride; with magnesium sulphate, pale orange-yellow prismatic crystals of **sodium magnesium vanadatotungstate**, $\text{Na}_2\text{MgV}_6\text{O}_{17} \cdot \text{Na}_{10}\text{W}_{12}\text{O}_{41}$; and with aluminium sulphate, dark garnet-red crystals of **sodium aluminiumvanadatotungstate**, $4\text{Al}_2\text{V}_{18}\text{O}_{48} \cdot 3\text{Na}_{15}\text{Al}_2\text{W}_{48}\text{O}_{156} \cdot 504\text{H}_2\text{O}$, were reported to be formed.

According to J. J. Berzelius,⁵ uranium salts give a lemon-yellow precipitate of **uranium metavanadate** with alkali metavanadates, and of **uranium tetravanadate** with alkali tetravanadates. J. Antipoff reported a mineral from Ferghana, Turkestan, which was called **ferghanite**. Its analysis corresponded with **uranyl metavanadate**, $\text{UO}_2(\text{VO}_3)_2 \cdot 6\text{H}_2\text{O}$. The mineral is biaxial with large optic axial angles; there is no pleochroism. The sp. gr. is 3.31; the hardness 2; the double refraction and index of refraction are small; and the radioactivity is 8 when that of uranium oxide is unity. F. L. Hess and W. T. Schaller found a brownish-yellow powder disseminated in the sandstone of Temple Rock, Utah. The mineral resembles carnotite and it was called **uranite**. The analysis agrees with $2\text{UO}_2 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{H}_2\text{O}$, or **uranyl deuterohexavanadate**, $(\text{UO}_2)_2\text{V}_6\text{O}_{17} \cdot 15\text{H}_2\text{O}$. The minute crystalline particles have a high birefringence. The mineral is not soluble in water, but it dissolves quickly in a soln. of ammonium carbonate.

C. Friedel and E. Cumenge⁶ reported a mineral from Montrose Co., Colorado, which they called **carnotite**—after A. Carnot. Analyses by W. F. Hillebrand and

F. L. Ransome are indicated in Table II; other analyses were reported by C. Friedel and E. Cumenge, T. Crook and G. S. Blake, E. F. Wherry, W. F. Hillebrand, F. L. Hess, A. Schoep and E. Richet, A. Schoep, G. Canneri and V. Pestelli,

P. Jannasch and H. F. Harwood, and E. Gleditsch. C. Friedel and E. Cumenge represented the analyses by the formula $K_2O \cdot 2UO_3 \cdot V_2O_5 \cdot 3H_2O$, that is, **potassium diuranil orthovanadate**, $K(UO_2)VO_4 \cdot 1\frac{1}{2}H_2O$; and G. Canneri and V. Pestelli regarded it as a salt of **uranylvanadic acid** :

E. Gleditsch found 0.03 per cent. of lithium and 0.15 per cent. of copper. W. F. Hillebrand believed that no definite representative formula can be assigned to carnotite, because it is a mixture of minerals. T. Crook and G. S. Blake, however, regard it as a definite mineral species. Some regarded the crystals of the lemon-yellow mineral as hexagonal. T. Crook and G. S. Blake suppose it to be rhombic. The optical character is negative; the optical axial angle $2E=c. 90^\circ$. Pleochroism can be observed. E. S. Larsen gave for the indices of refraction $\alpha=1.750$, $\beta=1.925$, and $\gamma=1.950^\circ$. R. J. Strutt observed in the carnotite from Montrose 5.27×10^{-7} per cent. of radium bromide, 2.98 per cent. U_3O_8 , and 0.01 c.c. of helium per gram. Observations on the radioactivity were made by B. B. Boltwood, E. Gleditsch, W. Marckwald and A. S. Russell, E. P. Adams, S. C. Lind and C. F. Whittemore, H. M. Plum, H. Schlundt, and A. G. Loomis and H. Schlundt. E. E. Fairbanks found the dielectric constant to be 9.3. The mineral is soluble in nitric acid. G. Canneri and V. Pestelli prepared **potassium uranylvanadate**, or *potassium-carnotite*, $K[V(UO_3)O_3]$, by adding uranic anhydride in the form of ammonium pyrouanate, to fused potassium metavanadate. The microscopic, rectangular, fluorescent plates belong to the rhombic system. The salts resemble the corresponding uranylphosphates. Unlike the vanadates, these artificial carnotites do not alter in colour when treated with acids. The analogous **sodium uranylvanadate**, $Na[V(UO_3)O_3]$, or *sodium-carnotite*, was similarly prepared.

K. A. Nenadkewitsch reported a *calcium-carnotite* from Tyuya-Muyun, Fergana, Turkestan, and he called it **tyuyamunite** or *tjuiamunite*. The analysis was (Ca,Sr)O, 5.99 per cent.; UO_3 , 63.09; V_2O_5 , 21.00; and H_2O , 7.04. E. Y. Rode also analyzed the mineral. A trace of thallium was also present. W. F. Hillebrand observed a similar mineral from Paradox Valley, Colorado. It is a hydrated **calcium diuranyl orthovanadate**—a kind of calcium carnotite. When treated with potassium mercuric iodide, as a separating liquid, the calcium is displaced by potassium and ordinary carnotite is formed; and F. L. Hess represented it by the formula $\text{CaO} \cdot 2\text{UO}_3 \cdot \text{V}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$. V. V. Dolivo-Dobrovolsky gave $a:b:c=1.303:1:2.337$ for the axial ratios of the rhombic crystals; the optical axial angle $2V=48^\circ$; the optical character is negative. F. L. Hess gave for the optical axial angle $2V=48^\circ$; and W. F. Hillebrand, $2V=45^\circ-51^\circ$, and the indices of refraction $\alpha=1.965-1.968$; $\beta=1.927-1.932$; while F. L. Hess gave $\alpha=1.72$, $\beta=1.868$, and $\gamma=1.953$, and E. S. Larsen, $\alpha=1.670$, $\beta=1.870$, and $\gamma=1.895$. The optical character is negative, and the pleochroism α , nearly colourless; β , canary-yellow; and γ , dark canary-yellow. P. Tschirwinsky found the hardness=4, and the sp. gr. 4.46. The mineral is radioactive. E. Y. Rode showed that the water makes the mineral of a zeolitic character. It is easily soluble in acids. The purple-red mineral **rauvite** was found by F. L. Hess and W. T. Schaller to have the composition $\text{CaO} \cdot 2\text{UO}_3 \cdot 6\text{V}_2\text{O}_5 \cdot 20\text{H}_2\text{O}$. The index of refraction is 1.88.

§ 15. The Vanadates of the Manganese and Iron Families

A. Ditte¹ prepared brown needles of **manganese pyrovanadate**, $Mn_2V_2O_7$, by melting vanadium pentoxide with a mixture of equal parts of sodium and manganous bromides, and washing the cold product with water. It is decomposed by nitric acid with the separation of manganic oxide. A. Scheuer obtained reddish-brown six-sided plates of **manganese metavanadate**, $Mn(VO_3)_2$, by adding manganese sulphate to a soln. of ammonium metavanadate, and boiling the mixture for a long time. J. J. Berzelius obtained a hydrated form—presumably the *tetrahydrate*—by treating a mixed soln. of ammonium metavanadate and manganous chloride with alcohol, washing the precipitate in alcohol, dissolving it in water, and allowing the soln. to evaporate spontaneously. C. Radau obtained a reddish-brown precipitate of the tetrahydrate by mixing a soln. of potassium metavanadate in 250 c.c. of water with 20 grms. of manganese sulphate in 250 c.c. of water. The washed and dried product consists of microscopic needles. It loses 15.59 per cent. of water at 120°; 20.71 per cent. at 200°; and all is lost by fusing the salt. The tetrahydrate is sparingly soluble in cold water, but feebly soluble in hot water and in acids. F. Ephraim and G. Beck made **manganese deuterohexavanadate**, $2MnO \cdot 3V_2O_5 \cdot 11H_2O$, by the action of the barium salt on manganese sulphate. The dehydrated salt forms a *dodecammine* with ammonia, and this passes to the *hexammine* at 130°, and the *diammine* at 240°. A series of **potassium manganese metavanadates** was prepared by C. Radau. Thus, $K_2Mn_7(VO_3)_{16} \cdot 25H_2O$, is produced when a soln. of 20 grms. of potassium metavanadate in 100 c.c. of water is mixed with 20 grms. of manganese sulphate in the same quantity of water; and when the aq. soln. of the precipitate is evaporated spontaneously, dark brown crystals with the composition $K_2Mn_{11}(VO_3)_{14} \cdot 48H_2O$ are formed. By evaporating the mother-liquor obtained in the preparation of manganese tetrahydrated metavanadate, C. Radau obtained crystals with the composition $2K_3VO_4 \cdot 3Mn_3V_5O_{23} \cdot 27H_2O$. A mixture of potassium triterodecavanadate and manganese sulphate gives a salt $6K_2O \cdot 0.15MnO \cdot 0.35V_2O_5 \cdot 98H_2O$. Ochre-yellow crystals of *pentadecahydrated* **potassium manganese triterodecavanadate**, $K_2Mn_2V_{10}O_{28} \cdot 15H_2O$, were obtained by mixing a soln. of 11.5 grms. of potassium triterodecavanadate in 100 c.c. of water with 5 grms. of manganese sulphate in the same amount of water. The *hexadecahydrate* was produced by mixing boiling soln. of 20 grms. of potassium metavanadate and 10 grms. of manganese sulphate each in 100 c.c. of water, and gradually adding 58 c.c. of 30 per cent. acetic acid. On crystallizing the filtered soln.,

red, triclinic crystals were obtained with the axial ratios $a : b : c = 0.7952 : 1 : 0.9678$, and $\alpha = 114^\circ 22'$; $\beta = 109^\circ 35'$; and $\gamma = 74^\circ 54'$. 100 c.c. of cold water at 18° dissolve only 1.7 grms. of the salt; more is dissolved by hot water; and the salt is freely soluble in acids. A mixture of potassium tetravanadate and manganese sulphate yields **potassium manganese penterotetradecavanadate**, $K_2Mn_3V_{14}O_{39} \cdot 21\frac{1}{2}H_2O$. G. Flink found a mineral at Langban, Sweden, which he called **pyrobelonite**— $\pi\upsilon\rho$, fire, and $\beta\epsilon\lambda\acute{o}\nu\eta$, a needle—in allusion to the red, acicular crystals, which are really rhombic prisms with the axial ratios $a : b : c = 0.80402 : 1 : 0.65091$. The analysis corresponds with **lead manganese tetravanadate**, $Mn_7Pb_4V_4O_{21} \cdot 3H_2O$. The sp. gr. is 5.377; and the hardness 3.5.

J. J. Berzelius obtained a dark greenish-brown precipitate of **ferrous metavanadate**, by treating ferrous salts with potassium metavanadate; it is soluble in hydrochloric acid, forming a green soln. Potassium tetravanadate under similar conditions furnishes green **ferrous tetravanadate**, which in 24 hrs. becomes yellow and crystalline. J. J. Berzelius also obtained **ferric metavanadate** as a straw-yellow precipitate slightly soluble in water by treating ferric sulphate with potassium metavanadate; and straw-yellow **ferric tetravanadate** from potassium tetravanadate and ferric sulphate. J. J. Berzelius obtained straw-yellow, insoluble **cobalt metavanadate** from a soln. of cobalt nitrate and ammonium metavanadate. A. Carnot, and C. Radau also made a similar observation. J. A. Hedvall prepared green cobalt metavanadate, by heating mixtures of vanadium pentoxide and cobalt oxide. A. Ditte warmed a mixture of ammonium metavanadate with an excess of cobalt nitrate feebly acidified with nitric acid, and obtained garnet-red, rhombic prisms of the *hydrate* $Co(VO_3)_2 \cdot H_2O$. A. Carnot obtained this salt, $Co(VO_3)_2$, by treating an ammoniacal soln. of a cobalt salt with ammonium metavanadate. It absorbs oxygen from air and becomes brownish-red. J. J. Berzelius found that a soln. of a cobalt salt and an alkali tetravanadate gives a yellow precipitate of **cobalt tetravanadate** when treated with alcohol. The product is soluble in water. F. Ephraim and G. Beck obtained **cobalt deuterohexavanadate**, $2CoO \cdot 3V_2O_5 \cdot 15H_2O$, by the action of cobalt sulphate on the barium salt. The compound dehydrated at 220° absorbs a small proportion of ammonia. A. Carnot obtained orange-yellow **cobaltic pentamminotriferodecavanadate**, $Co_2V_{10}O_{28} \cdot 5NH_3 \cdot 9H_2O$, from a dil. acetic acid soln. of the cobaltamine and ammonium metavanadate; when heated, it forms **cobalt teterodecavanadate**, $Co_2V_{10}O_{27}$. C. Radau prepared **potassium cobalt triferodecavanadate**, $K_2O \cdot 2CoO \cdot 5V_2O_5 \cdot 16$ (or $16\frac{1}{2}$) H_2O , from a soln. of potassium metavanadate and cobalt sulphate; from a soln. of potassium triferodecavanadate and cobalt sulphate; and from a soln. of potassium tetravanadate and cobalt sulphate. The reddish-yellow crystals belong to the triclinic system and have the axial ratios $a : b : c = 0.7861 : 1 : 0.9679$; and $\alpha = 114^\circ 49'$; $\beta = 109^\circ 20'$; and $\gamma = 75^\circ 5'$. 100 parts of water at 17.5° dissolve 0.48 part of the salt. C. Radau also prepared yellowish-brown acicular crystals of **potassium cobalt tetrotetradecavanadate**, $K_2O \cdot 3CoO \cdot 7V_2O_5 \cdot 21H_2O$, from a soln. of 20 grms. of potassium metavanadate in 400 c.c. of water and 18 grms. of cobalt sulphate in 250 c.c. of water by evaporation over a water-bath.

W. Vernadsky obtained a green or brown radioactive mineral from the Tyuya-Muyun mine, Fergana, which he called **kolovratite**—after L. C. Kolovrat. Analyses show 6.5–12.22 per cent. NiO; and 6.20–11.55 per cent. V_2O_5 . It was also mentioned by D. I. Shcherbakoff, S. P. Aleksandroff, and I. Kurbatoff. A. Ditte fused a mixture of vanadium pentoxide and nickel bromide with a large excess of potassium bromide, and obtained green, prismatic crystals of **nickel orthovanadate**, $Ni_3(VO_4)_2$. G. Tammann gave 515° for the temp. of formation. A. Ditte said that the salt does not melt at a red-heat, and is insoluble in nitric acid. J. J. Berzelius evaporated an aq. soln. of a nickel salt and alkali metavanadate and obtained a yellow, crystalline mass of **nickel metavanadate**, soluble in water and precipitated by alcohol from its aq. soln. A. Ditte obtained the metavanadate, $Ni(VO_3)_2$, in small, greenish-yellow prisms, by heating for a long time a soln. of

ammonium metavanadate and nickel nitrate feebly acidified with nitric acid. J. J. Berzelius obtained yellow crystals of **nickel tetravanadate** by evaporating a soln. of alkali tetravanadate and a nickel salt. The salt is soluble in water, and is precipitated from its aq. soln. by alcohol. A. Ditte prepared the greenish-brown crystals of **nickel deuterotettravanadate**, $\text{Ni}_4\text{O}_{11}\cdot 3\text{H}_2\text{O}$, by evaporating the mother-liquor obtained in preparing the metavanadate. F. Ephraim and G. Beck prepared **nickel triterodecavanadate**, $3\text{Ni}\cdot 0.5\text{V}_2\text{O}_5\cdot 24\text{H}_2\text{O}$, by treating barium deuterohexavanadate with nickel sulphate. The dehydrated salt forms a **dodecammine** at 108° ; a **hexammine** at 160° ; a **tetrammine** at 198° ; and a **decammine** at 214° . C. Radau prepared greenish-yellow crystals of potassium **nickel dodecametavanadate**, $\text{K}_2\text{Ni}_5(\text{VO}_3)_{12}\cdot 27\text{H}_2\text{O}$, by mixing, at ordinary temp., soln. of 20 grms. of potassium metavanadate in 100 c.c. of water with 19 grms. of nickel sulphate; straw-yellow, acicular crystals of **potassium nickel deuterodecavanadate**, $\text{K}_2\text{Ni}_3\text{V}_{10}\text{O}_{29}\cdot 17\text{H}_2\text{O}$, from a soln. of 20 grms. of potassium metavanadate in 100 c.c. of water mixed with 20 grms. of nickel sulphate in 150 c.c. of water; greenish-yellow crystals of **potassium nickel triterodecavanadate**, $\text{K}_2\text{Ni}_2\text{V}_{10}\text{O}_{28}\cdot 16\frac{1}{2}\text{H}_2\text{O}$, from a boiling soln. of 920 grms. each of potassium metavanadate and nickel sulphate in 400 c.c. of water, and mixed with 80 c.c. of 25 per cent. acetic acid; and **potassium nickel penteroheptadecavanadate**, $\text{K}_2\text{O}\cdot \text{N}_2\text{O}\cdot 7\text{V}_2\text{O}_5\cdot 23\text{H}_2\text{O}$, from a soln. of the preceding salt mixed with a nickel salt soln.; 100 parts of water at $17\cdot 5^\circ$ dissolve 0.17 part of salt.

§ 16. The Hypovanadatovanadates

A series of mixed hypovanadates and vanadates have been reported and they have been called **vanadylvanadates**, **vanadicovanadates**, and **hypovanadatovanadates**. J. J. Berzelius¹ noticed that when a soln. of hydrated vanadium tetroxide and ammonium carbonate is exposed to air in a tall narrow cylinder, dark green crystals collect at the bottom of the vessel. J. T. Brierley prepared **ammonium dihypovanadatotettravanadate**, $(\text{NH}_4)_2\text{O}\cdot 2\text{V}_2\text{O}_4\cdot 2\text{V}_2\text{O}_5\cdot 14\text{H}_2\text{O}$, by dissolving vanadium pentoxide in aq. ammonia, reducing two-thirds of the soln. with sulphur dioxide; mixing both fractions; making the liquid slightly alkaline with ammonia; acidifying with acetic acid, and adding alcohol. The dark green, crystalline precipitate is unstable. If ammonium chloride be added instead of acetic acid, and the liquid boiled for a long time, dark violet crystals of **ammonium dihypovanadatoctovanadate**, $3(\text{NH}_4)_2\text{O}\cdot 2\text{V}_2\text{O}_4\cdot 4\text{V}_2\text{O}_5\cdot 6\text{H}_2\text{O}$, are formed. O. W. Gibbs reported a green, crystalline powder of **ammonium hypovanadatoctovanadate**, $(\text{NH}_4)_2\text{O}\cdot \text{V}_2\text{O}_4\cdot 4\text{V}_2\text{O}_5\cdot 8\text{H}_2\text{O}$, from a soln. of a vanadyl salt and ammonium metavanadate.

W. Prandtl melted 50 grms. of vanadium pentoxide, 6 grms. of sodium carbonate, and about one c.c. of syrupy phosphoric acid in a platinum crucible. Spitting occurs as the mass cools, and oxygen is given off; when the product is boiled with ammoniacal water, dark steel-blue, rhombic, pleochroic needles of **sodium hypovanadatoctodecavanadate**, $\text{Na}_2\text{O}\cdot \text{V}_2\text{O}_4\cdot 5\text{V}_2\text{O}_5$, appear. The salt is insoluble in water; is

not changed by hot or cold nitric acid; ammoniacal hydrogen dioxide slowly oxidizes it to a vanadate; and conc. sulphuric acid forms a yellowish-brown soln. which is green when diluted. The salt melts at about 800° and absorbs oxygen from the air. With potassium carbonate under similar conditions, W. Prandtl prepared potassium hypovanadatodecavanadate, $K_2O.V_2O_4.8V_2O_5$. J. T. Brierley prepared **sodium dihypovanadato-divanadate**, $2Na_2O.2V_2O_4.V_2O_5.13H_2O$, in aggregates of microscopic, hexagonal prisms, by treating 12 grms. of vanadium pentoxide with an excess of a sat. soln. of sulphur dioxide, and, after adding a little sulphuric acid and boiling the liquid to drive off the excess of sulphur dioxide, mixing the hot blue liquid with a soln. of 6 grms. of vanadium pentoxide in soda-lye, and adding enough alkali to make the liquid alkaline. After standing a few days the soln. is acidified with acetic acid, mixed with a cold sat. soln. of sodium acetate, and the crystals washed first with a soln. of sodium acetate and then with alcohol. The salt is freely soluble in water, but not in a conc. soln. of alkali acetate. G. Canneri also obtained the sodium salts: $Na_2O:V_2O_4:V_2O_5=1:1:5$; $1:1:4$; $2:1:4$; $3:1:5$; and $1:1:1$. J. T. Brierley obtained **potassium dihypovanadato-vanadate**, $2K_2O.2V_2O_4.V_2O_5.6H_2O$, by working with potash-lye under similar conditions. The potassium salt is accompanied by dark violet octahedra of **potassium dihypovanadatoctovanadate**, $5K_2O.2V_2O_4.V_2O_5.H_2O$, and the same salt is obtained by boiling the mother-liquor from the sodium salt with potassium acetate. G. Canneri also prepared the potassium salts: $K_2O:V_2O_4:V_2O_5=1:1:5$; $2:1:4$; and $1:1:1$.

O. W. Gibbs reported dark green crystals of **copper hypovanadato-vanadate** to be formed by mixing a hydrochloric acid soln. of vanadyl chloride with a soln. of copper sulphate and sodium tetravanadate; and **silver hypovanadato-vanadate**, $6Ag_2O.3VO_2.2V_2O_5.12WO_3.8H_2O$, by treating the corresponding ammonium salt with silver nitrate. W. T. Schaller described a dull green, massive, cryptocrystalline mineral from Minasraga, Peru, which he called **fernandinite**—after E. E. Fernandini. It rarely occurs in rectangular plates. The analysis corresponds with **calcium hypovanadatodecavanadate**, $CaO.V_2O_4.5V_2O_5.14H_2O$, or it can be regarded as a metavanadate, $H_4Ca(VO)_2(VO_3)_{10}.12H_2O$. W. T. Schaller described it as cryptocrystalline. The mineral is non-pleochroic, and the birefringence is medium. E. S. Larsen gave 2.05 for the index of refraction. It is sufficiently soluble in cold water to give a yellow soln., and it forms a green soln. with acids. W. Lindgren and co-workers described **melanovanadite** as a black mineral from Mina Ragra, Pasco, Peru. The analysis corresponds with $2CaO.2V_2O_4.3V_2O_5.nH_2O$. The monoclinic crystals have the axial ratios $a:b:c=0.4737:1:0.5815$, and $\beta=83^\circ 37\frac{1}{2}'$. The sp. gr. is 3.477 at 20°; the hardness 2.5; the index of refraction $\alpha=1.74$; and the birefringence is strong. The pleochroism α =dark yellowish-brown, β and γ =dark reddish-brown.

O. W. Gibbs reported **ammonium dihypovanadato-divanadatoctocosimolybdate**, $11(NH_4)_2O.2V_2O_4.V_2O_5.28MoO_3.20H_2O$, to be formed in greenish-yellow crystals by heating ammonium tetravanadate with an excess of a soln. of ammonium paramolybdate, and evaporating the soln. The salt can be purified by recrystallization. When the soln. is treated with barium chloride, a precipitate of **barium hypovanadato-vanadatomolybdate**—to which the formula $4BaO.3VO_2.2V_2O_5.30MoO_3.48H_2O$ has been assigned—is formed as a sparingly soluble, crystalline powder. An orange-yellow, crystalline precipitate is produced when the salt is boiled with silver nitrate; and with mercurous nitrate a crystalline precipitate of **mercurous hypovanadato-vanadatotungstate** is produced. O. W. Gibbs also obtained **ammonium hypovanadato-vanadatotungstate**—possibly $6(NH_4)_2O.3VO_2.2V_2O_5.12WO_3.12H_2O$ was assigned; **potassium hypovanadato-vanadatotungstate**, $6K_2O.3VO_2.2V_2O_5.12WO_3.nH_2O$; and **sodium hypovanadato-vanadatotungstate**, $6Na_2O.3VO_2.2V_2O_5.12WO_3.43H_2O$; when the soln. is treated with mercurous nitrate, **mercurous hypovanadato-vanadatotungstate** is formed.

§ 17. Pervanadic Acid and the Pervanadates

L. C. A. Barreswil¹ observed that an acid soln. of ammonium metavanadate is coloured deep red by hydrogen dioxide, and the coloration is more stable than that produced with chromic acid. According to G. Werther, in the presence of ether, 0.000225 part of vanadium pentoxide produces a red colour, and 0.000012 part a pale rose-pink. The ethereal layer remains uncoloured. An excess of hydrogen dioxide decolorizes the red soln. produced when an acid is added to a mixture of hydrogen dioxide and an alkali vanadate. A. Scheuer evaporated a soln. of vanadium pentoxide in hydrogen dioxide in vacuo, and obtained a yellow crust of a **pervanadic acid**, which was not analyzed. It forms a red soln. with water; and when treated with hydrochloric acid, it forms oxygen and chlorine. V. Auger said that pervanadic acid, like perchromic acid, catalytically decomposes hydrogen dioxide, at the same time, the pervanadic acid is reduced to a vanadyl salt, and this reaction becomes more rapid and more complete in the presence of an acid. Vanadyl salts, however, unlike chromium salts, are immediately oxidized to pervanadic acid in the presence of hydrogen dioxide, so that in the course of time the whole of the hydrogen dioxide introduced into an acid soln. of vanadic acid is completely destroyed and the reduction of the vanadic acid is more or less marked, according to the H⁻ion content of the soln. As shown by J. B. Cammerer, L. Pissarjewsky, and P. Düllberg, vanadium pentoxide dissolves in hydrogen dioxide, and after the catalytic decomposition of the latter there remains a yellow soln. in which L. Pissarjewsky assumed vanadic acid was present, and P. Düllberg, hexavanadic acid, H₄V₆O₁₇. J. Meyer and A. Pawletta called it **isopolyvanadic acid**. J. Meyer showed that the yellow soln. of vanadium pentoxide in hydrogen dioxide gradually decomposes liberating oxygen and depositing vanadium pentoxide. The rate of dissolution depends on the nature of pentoxide, the conc. of the soln. of hydrogen dioxide, and on the temp. The stability of the yellow soln. is small and is a function of the temp., and of the vanadium concentration; a 0.1*N*-soln. becomes turbid in 8 hrs., while a 0.01*N*-soln. becomes turbid in some months—all at room temp. The mol. conductivity, μ , of soln. with *m* mols per litre is :

<i>m</i>	:	:	:	:	0.0002	0.002	0.02	0.025	0.05
μ	:	:	:	:	368.9	365.8	340.8	333.8	306.8

It is assumed that the vanadium goes into soln. as a peroxo-orthovanadic acid, H₃[V(O₂)O₃, which gives off oxygen more rapidly than hydrogen dioxide. Hence the catalytic action of vanadic acid on hydrogen dioxide. J. Meyer and A. Pawletta represented the reaction with hydrogen dioxide and soln. containing vanadium pentoxide and sulphuric acid by $[\text{VO}_2]_2(\text{SO}_4)_3 + 6\text{H}_2\text{O} \xrightleftharpoons[\text{H}_2\text{SO}_4]{\text{H}_2\text{SO}_4} 2\text{VO}_2(\text{OH})_3 + \text{H}_2\text{SO}_4$.

The vanadium compound indicated on the left is reddish-brown, and that on the right, bright-yellow. In agreement with this hypothesis, the vanadium radicle travels to the cathode on electrolysis. The product is not pervanadic acid, HVO₄, but a peroxidized vanadium sulphate [V(O₂)₂(SO₄)₃, with quinquevalent vanadium as cation. They said that there is no satisfactory evidence of the existence of pervanadic acid, and J. Meyer denied the existence of the hexavanadic acid of P. Düllberg.

A. Scheuer obtained salts of the type RVO₄, **pervanadate**, or **permetavanadate** by the action of hydrogen dioxide on the alkali metavanadates. These compounds are regarded as salts of monobasic **pervanadic acid**, or **permetavanadic acid** HVO₄. The **permetavanadate** derivatives of the hypothetical acid :

are yellow and amorphous or microcrystalline ; they are insoluble in alcohol ; give off oxygen when treated with dil. sulphuric acid ; and behave towards hydrochloric acid as indicated above. A. Scheuer reported **ammonium pervanadate**, NH_4VO_4 , to be produced as a yellow flocculent precipitate when a sat. soln. of ammonium metavanadate in a dil. sulphuric acid soln. of hydrogen dioxide is treated with alcohol ; **lithium pervanadate**, LiVO_4 , was obtained by treating a soln. of lithium carbonate and ammonium metavanadate with hydrogen dioxide ; **sodium pervanadate**, NaVO_4 from a soln. of the alkali vanadate ; and similarly with **potassium pervanadate**, KVO_4 . The heats of the reaction between a mol of potassium metavanadate and 1, 2, $3\frac{1}{2}$, and 4 mols of hydrogen dioxide are respectively 9.024, 17.772, 17.731, and 17.521 Cals. ; thus showing that increasing the proportion of hydrogen dioxide beyond 2 mols has no influence on the heat of reaction. Allowing for the heat of formation of hydrogen dioxide from water and oxygen, the heat of formation of the pervanadate is $\text{KVO}_3 + \text{O} = \text{KVO}_4 - 14.076$ Cals. In aq. soln., a more highly oxidized compound exists. This is either a salt KVO_5 , or a complex $\text{KVO}_4 \cdot \text{H}_2\text{O}_2$. The heat of soln. is -4.155 Cals. The electrical conductivity of soln. of the pervanadate shows that it is a salt of a monobasic acid. A mol of the salt KVO_4 in v litres has a conductivity of 134.8 for $v=128$; 138.0 for $v=256$; 139.2 for $v=512$; and 140.36 for $v=1024$; so that $\lambda\text{H}_{1024} - \lambda\text{H}_{128} = 5.56$. A soln. of ammonium pervanadate, free from hydrochloric acid, gives with silver nitrate a yellowish-brown precipitate of **silver pervanadate**, AgVO_4 . Yellow, microcrystalline **calcium pervanadate**, $\text{Ca}(\text{VO}_4)_2$, was precipitated by adding alcohol to a sat. soln. of ammonium metavanadate in an acid soln. of hydrogen dioxide and calcium chloride. The precipitate is washed with a soln. of hydrogen dioxide free from sulphuric acid, and dried over calcium chloride. Similarly also with **strontium pervanadate**, $\text{Sr}(\text{VO}_4)_2$; **barium pervanadate**, $\text{Ba}(\text{VO}_4)_2$; **cadmium pervanadate**, $\text{Cd}(\text{VO}_4)_2$; and **lead pervanadate**, $\text{Pb}(\text{VO}_4)_2$.

When the alkali pervanadates are treated with alkali peroxides, P. Melikoff and L. Pissarjewsky obtained products which they regarded as salts—**perpyrovanadates**—of the hypothetical **perpyrovanadic acid**, $\text{H}_4\text{V}_2\text{O}_{11}$, which contains 4 atoms of active oxygen per molecule : $\text{H}_4\text{V}_2\text{O}_{11} = \text{H}_4\text{V}_2\text{O}_7 + 4\text{O}$. By passing ammonia into a soln. of ammonium vanadate in hydrogen dioxide until the liquid smells strongly of that gas, and adding alcohol, yellow, rhombic prisms of **ammonium perpyrovanadate**, $(\text{NH}_4)_4\text{V}_2\text{O}_{11}$, are formed :

The dry powder and the aq. soln. smell of ammonia ; the dry salt decomposes with the evolution of oxygen after it has stood a short time. Conc. sulphuric acid gives ozonized oxygen, dil. sulphuric acid, hydrogen dioxide. An insoluble precipitate is produced when the aq. soln. is treated with barium chloride or silver nitrate. By treating an aq. soln. of a mol of potassium pervanadate and an aq. soln. of hydrogen dioxide and 3 mols of potassium hydroxide, yellow crystals with the composition $3\text{K}_4\text{V}_2\text{O}_{12} \cdot 4\text{KVO}_4 \cdot 4\text{H}_2\text{O}$, are obtained ; and the electrical conductivity of the soln. shows that it contains a salt of a tetrabasic acid. If this compound be treated with an excess of hydrogen dioxide and 4 to 5 mols of potassium hydroxide at 0° , the addition of two vols. of alcohol precipitates a dirty green compound which is washed with cold alcohol, and ether, and dried on a porous tile. The salt is **potassium perpyrovanadate**, $\text{K}_4\text{V}_2\text{O}_{13} \cdot 7\text{H}_2\text{O}$, or $\text{K}_8\text{V}_5\text{O}_{13} \cdot 14\text{H}_2\text{O}$. When heated it detonates. It slowly decomposes in aq. soln., giving off oxygen ; and if allowed to stand some time it deposits crystals of a product with a lower proportion of available oxygen, approximating $\text{K}_4\text{V}_2\text{O}_{12} \cdot 4\text{H}_2\text{O}$, or to $3\text{K}_4\text{V}_2\text{O}_{12} \cdot 4\text{KVO}_4 \cdot 4\text{H}_2\text{O}$. L. Pissarjewsky found the conductivity of one-eighth of the mol $\text{K}_8\text{V}_5\text{O}_{26}$ in v litres to be in accord

with $\lambda_{1024} - \lambda_{32} = 24.16$, that is, with the assumption that it is a salt of a tetrabasic and of a monobasic acid. The data are :

ν	32	64	128	256	512	1024
λ	92.06	103.25	107.45	114.42	115.44	116.22

§ 18. The Vanadium Fluorides and Oxyfluorides

According to E. Petersen,¹ when vanadium trioxide is dissolved in hydrofluoric acid, and the dark green liquid concentrated on the water-bath, the soln., when cooled, furnishes dark green, rhombohedral crystals of **vanadium trifluoride**, $\text{VF}_3 \cdot 3\text{H}_2\text{O}$. O. Ruff and H. Lickfett found that mixtures of different vanadium fluorides, difficult to separate, are obtained by the action of fluorine on vanadium, or vanadium chlorides; better results are obtained by the action of anhydrous hydrogen fluoride on the anhydrous bromides or chlorides. When hydrogen fluoride is passed over heated vanadium trichloride, a brown intermediate product is obtained at $120^\circ - 130^\circ$; at 340° , the brown powder becomes green, but to remove all chlorine it is necessary to pass the gas for 6 to 8 hrs. with the temp. raised to a dark red-heat. Vanadium trifluoride remains as a greenish-yellow powder of sp. gr. 3.3628 at 19° ; its m.p. lies above 800° , and it sublimes at a bright red-heat. It is almost insoluble in water and the usual organic solvents; but E. Petersen said that the salt is freely soluble in water, particularly hot water, and the soln. has an acid reaction; showing that hydrolysis probably occurs. If the aq. soln. be crystallized, a greyish-green product thought to be a basic salt is obtained. The salt can, however, be recrystallized from hydrofluoric acid. When exposed to air, the salt quickly effloresces; and at 100° about one-third the water is lost, and the remainder at 130° . Some oxygen is at the same time absorbed from the atm.; when heated in air, vanadium pentoxide is formed; and probably a little fluoride is lost by volatilization. The salt is insoluble in alcohol. The aq. soln. acts as a reducing agent—silver salts furnish silver, and mercuric and cupric salts form respectively mercurous and cuprous salts. Many of the metal fluorides furnish complex salts. Soln. of alkali hydroxides and carbonates precipitate greyish-green vanadium trihydroxides. The analysis of the salt agrees with the formula $\text{VF}_3 \cdot 3\text{H}_2\text{O}$, which was written $\text{V}_2\text{F}_6 \cdot 6\text{H}_2\text{O}$ by E. Petersen.

When ammonium fluoride is mixed with a soln. of vanadium trifluoride, E. Petersen found that a green precipitate of **ammonium hexafluovanadate**, $3\text{NH}_4\text{F} \cdot \text{VF}_3$, or $(\text{NH}_4)_3\text{VF}_6$, is formed. The green, microscopic octahedra are fairly soluble in water and in dil. acids; but they are almost insoluble in alcohol, and in soln. of the alkali fluorides. With a long-continued evaporation, the aq. soln. loses ammonia. If the aq. soln. be evaporated on a water-bath, **ammonium pentafluovanadate**, $(\text{NH}_4)_2\text{VF}_5$, or $2\text{NH}_4\text{F} \cdot \text{VF}_3$, is formed in emerald-green, octahedral crystals. The salt is soluble in water, and it crystallizes unchanged from its aq. soln.; it is sparingly soluble in alcohol. The mother-liquor from the preceding salt furnishes a dark green aggregate of crystals of **ammonium tetrafluovanadate**, $\text{NH}_4\text{F} \cdot \text{VF}_3$, or NH_4VF_4 . If a hydrofluoric acid soln. of potassium fluoride be treated with a soln. of vanadium trifluoride, a green crystalline powder of **potassium**

pentafluovanadite, $K_2VF_5 \cdot H_2O$, or $2KF \cdot VF_3 \cdot H_2O$, is deposited and the supernatant liquor becomes colourless. The precipitate is washed with dil. hydrofluoric acid, and dried in air. It is easily soluble in water and dil. acids, and insoluble in a soln. of potassium fluoride. It loses no water at 100° , a little is lost at 130° , and all is lost at 170° . The sodium salt is represented by $5NaF \cdot 2VF_3 \cdot H_2O$, or **sodium henafuodivanadite**, $Na_5V_2F_{11} \cdot H_2O$. It is formed like the potassium salt, and appears as a bright green, sparingly-soluble, crystalline powder. E. Petersen obtained what was thought to be **copper pentafluovanadite**, $CuVF_5$, by adding vanadium trifluoride to a soln. of copper carbonate in hydrofluoric acid. A. Piccini and G. Giorgis prepared **zinc pentafluovanadite**, $ZnF_2 \cdot VF_3 \cdot 7H_2O$, in emerald green crystals sparingly soluble in cold water, and partly decomposed by hot water; it is easily oxidized in hydrofluoric acid soln. Green **cadmium pentafluovanadite**, $CdF_2 \cdot VF_3 \cdot 9H_2O$, was prepared in a similar way. F. Ephraim and L. Heymann added the calculated proportion of thalious fluoride to a soln. of vanadium trioxide in hydrofluoric acid. The evaporation of the liquid furnished green, microscopic crystals of **thalious tetrafluovanadite**, $TlF \cdot VF_3 \cdot 2H_2O$. They are freely soluble in water. If an excess of thalious fluoride is used, or if conc. soln. of thalious fluoride and vanadic trifluoride are mixed, the cold, green microscopic crystals of **thalious pentafluovanadite**, $2TlF \cdot VF_3 \cdot H_2O$, are formed. The salt is soluble in water, forming a green soln.; with conc. sulphuric acid, hydrogen fluoride is given off; cold, dil. nitric acid dissolves the salt and at the same time oxidizes it. Dil. hydrochloric acid precipitates thalious fluoride; alkali-lye blackens the salt without dissolution. E. Petersen prepared small, dark green, monoclinic prisms of **cobalt pentafluovanadite**, $CoVF_5 \cdot 7H_2O$; and grass-green, monoclinic prisms of **nickel pentafluovanadite**, $NiVF_5 \cdot 7H_2O$, were also prepared.

O. Ruff and H. Lickfett found that **vanadium tetrafluoride**, VF_4 , is produced by the action of anhydrous hydrogen fluoride on vanadium tetrachloride, the reaction being started at -28° and the temp. allowed to rise to 0° in the course of 2 hrs. It is a brownish-yellow, loose powder, which is very hygroscopic, deliquescing in the air to a blue liquid; readily soluble in water (blue soln.) and acetone (green soln.); the sp. gr. is 2.9749 at 23° . Above 325° , it decomposes into vanadium pentafluoride and vanadium trifluoride. According to J. J. Berzelius, the evaporation of the blue soln., obtained by dissolving vanadium tetroxide in hydrofluoric acid, furnishes a brown mass which is soluble in water. If the evaporation proceeds spontaneously, it leaves a green syrup from which green crystals are obtained. The crystals form a green soln. with absolute alcohol. A. Guyard said that the dark green residue obtained by evaporating the alcoholic soln. can be heated to a high temp. without decomposition and at a red-heat, it furnishes hydrogen fluoride, and then a yellow vapour of anhydrous **vanadium oxydifluoride**, VOF_2 , or *vanadyl fluoride*. E. Petersen found that if the blue soln. of vanadium tetroxide in hydrofluoric acid be evaporated over sulphuric acid, blue pyramidal or prismatic crystals are formed of $VOF_2 \cdot nH_2O$, which corresponds with the composition of the complex fluorides derived from this oxydifluoride. According to O. Ruff and H. Lickfett, vanadium oxydifluoride is prepared by heating vanadyl dibromide in a current of anhydrous hydrogen fluoride, first at 150° – 200° and then at 600° – 700° for 6 hrs. It is yellow in colour, slightly soluble in acetone, but insoluble in other solvents. The sp. gr. is 3.3956 at 190° .

The salt **vanadium tetrafluoride**, VF_4 , has not been prepared, but E. Petersen found that if ammonium pentafluohypovanadate be dissolved in conc.—35 per cent.—hydrofluoric acid, bluish-green microscopic prisms of what is probably $NH_4V_2F_9 \cdot nH_2O$, **ammonium enneafuohypovanadate**, are produced. They crumble to a greyish-green powder when dry and evolve the smell of hydrogen fluoride. When dried at 100° the salt becomes $2NH_4F \cdot VOF_2$ —*vide infra*. If a soln. of vanadium tetroxide in hydrofluoric acid be treated with an excess of a soln. of ammonium fluoride, E. Petersen found that small, blue, octahedral crystals of **ammonium vanadylpentafluoride**, $3NH_4F \cdot VOF_2$, are formed. The crystals

are cubic, but being optically anomalous, they are doubly refracting. A. Piccini and G. Giorgis obtained the salt by reducing a hydrofluoric acid soln. of ammonium metavanadate with sulphur dioxide, neutralizing the liquid with ammonia, and adding a soln. of ammonium fluoride. The precipitate was moistened with a little water, pressed between bibulous paper, and dissolved in water. The first crop of crystals is ammonium vanadyltetrafluoride, and this is followed by the blue octahedra. A. Guyard proceeded similarly but used alcohol, and H. Baker, hydrogen sulphide, as the reducing agent instead of sulphur dioxide, and A. Piccini and G. Giorgis also reduced the vanadate electrolytically. The salt is freely soluble in water; sparingly soluble in alcohol; and very sparingly soluble in soln. of alkali fluorides. E. Petersen, and A. Piccini and G. Giorgis obtained bluish-green, monoclinic prisms of **ammonium vanadyltetrafluoride**, $2\text{NH}_4\text{F}\cdot\text{VOF}_2$, as just indicated; and H. Baker obtained the *monohydrate*, $2\text{NH}_4\text{F}\cdot\text{VOF}_2$; E. Petersen also obtained it by evaporating a soln. of the salt over sulphuric acid. H. Baker said that the blue monoclinic crystals have the axial ratios $a:b:c=0.9653:1:—$. The aq. soln. gives a precipitate with alcohol; and is not attacked by sulphuric acid. E. Petersen obtained dark blue crystals of **ammonium pentadecafluotetrahyppovanadate**, $7\text{NH}_4\text{F}\cdot 4\text{VOF}_2$, mixed with some crystals of the pentafluohyppovanadate, by evaporating over sulphuric acid a mixed soln. of equimolar proportions of ammonium fluoride and vanadium oxydifluoride. J. J. Berzelius noticed that vanadium oxydifluoride forms blue crystals of complex salts, with sodium and potassium fluoride, and they are soluble in water but not in alcohol. E. Petersen, and A. Piccini and G. Giorgis obtained sky-blue crystals of **potassium tetrafluohyppovanadate**, $2\text{KF}\cdot\text{VOF}_2$, by the methods used for the ammonium salt, keeping the oxydifluoride in excess. E. Petersen showed that if the potassium fluoride be in excess, pale blue crystals of **potassium tridecafluotrihyppovanadate**, $7\text{KCl}\cdot 3\text{VOF}_2$, are formed. They are washed with dil. hydrofluoric acid. The salt is sparingly soluble in water, and in soln. of alkali fluorides; but easily soluble in dil. acids. It does not lose weight at 120° , but hydrogen fluoride is lost at higher temp. E. Petersen also obtained blue crystals of **sodium tetradecafluotrihyppovanadate**, $8\text{NaF}\cdot 3\text{VOF}_2\cdot 2\text{H}_2\text{O}$, by the method used for the 7:3 potassium salt. The salt suffers no loss at 100° , and at 170° the loss is only 3.28 per cent. A. Piccini and G. Giorgis obtained blue crystals of **zinc tetrafluohyppovanadate**, $\text{ZnF}_2\cdot\text{VOF}_2\cdot 7\text{H}_2\text{O}$, by the electrolysis of a soln. of the calculated quantity of zinc oxide and vanadium pentoxide in hydrofluoric acid. The salt loses 6 mols. of water at 100° , and becomes colourless. It is decomposed by hot water, and can be recrystallized from hot, dil. hydrofluoric acid. The **cadmium tetrafluohyppovanadate**, $\text{CdF}_2\cdot\text{VOF}_2\cdot 7\text{H}_2\text{O}$, was prepared in a similar way. F. Ephraim and L. Heymann prepared **thallous tetrafluohyppovanadate**, $2\text{TlF}\cdot\text{VOF}_2$, by reducing a soln. of vanadium pentoxide in hydrofluoric acid with sulphur dioxide, and adding an excess of thallous fluoride. The bluish-green precipitate is microcrystalline. It gives off some hydrogen fluoride when exposed to air. It is freely stable in cold water, but is decomposed by hot water. The soln. reduces potassium permanganate.

Unsuccessful attempts have been made to isolate **vanadium pentafluoride**, VF_5 . J. J. Berzelius found that with a mixture of sodium fluoride and vanadate, and sulphuric acid, hydrogen fluoride is given off, while vanadium pentoxide and sodium sulphate remain. Warm hydrofluoric acid readily dissolves vanadium pentoxide, forming a colourless soln., which, when evaporated below 40° , leaves a colourless—E. Petersen said yellow or reddish-brown—mass of salt perfectly soluble in water. O. Ruff and H. Lickfett made the pentafluoride as a pure white sublimate when the tetrafluoride is heated in a current of nitrogen, the temp. being gradually raised from 300° to 650° , and the latter temp. maintained for two and a half hours. At the ordinary temp., it possesses an appreciable vap. press., and in moist air becomes yellow, owing to the formation of oxyfluorides. It is readily soluble in water, alcohol, chloroform, acetone, and light petroleum. When heated in sealed glass tubes it does not melt, even above 200° , but it readily attacks the walls of the tube.

Its sp. gr. is 2.1766 at 19° and its b.p. 111.2° at 758 mm. It is the only vanadium compound in which five halogen atoms are bound to one vanadium atom. J. J. Berzelius said that the salt loses part of its acid when strongly heated, yielding a red mass which still forms a colourless soln. with water, and at a higher temp., the hydrofluoric acid is expelled leaving behind vanadium pentoxide. A number of complex salts of vanadium pentafluoride has been formed. According to E. Petersen, if the mother-liquor obtained in the preparation of potassium vanadyl-pentafluoride be allowed to stand for some hours, it deposits aggregates of needles and prisms of **potassium vanadyldecafluorovanadate**, $4\text{KF.VF}_5.\text{VOF}_3$. The salt is washed with dil. hydrofluoric acid, and dried in air. It is soluble in water and dil. hydrofluoric acid, but sparingly soluble in soln. of potassium fluoride.

According to O. Ruff and H. Lickfett, **vanadium oxytrifluoride**, VOF_3 , is prepared from vanadyl trichloride in a manner similar to that described for the preparation of vanadium tetrafluoride; it may also be obtained by heating vanadium trifluoride to a red heat in a current of oxygen. It forms yellowish-white crusts, and is very hygroscopic, deliquescing in the air to a brownish-yellow soln. At 132°, when heated in glass tubes, it decomposes, red vanadium pentoxide being deposited; it then melts at about 300° and boils at 480°. In a current of oxygen, it sublimes at 130°. Its sp. gr. is 2.4591 at 20.5°. According to E. Petersen, if not too great an excess of ammonium fluoride be added to a soln. of vanadium pentoxide in hydrofluoric acid, and the soln. evaporated; or if ammonium vanadyltetrafluoride be dissolved in hydrofluoric and heated on a water-bath, and the soln. cooled, colourless, four-sided prisms of **ammonium pentavanadylhydropentacosifluoride**, $\text{HF}.9\text{NH}_4\text{F}.5\text{VOF}_3$, are produced. H. Baker's ammonium fluoxyvanadate, $3(\text{NH}_4)\text{HF}_2.2\text{VOF}_3$ is probably identical with this salt. The salt is freely soluble in water, but sparingly soluble in alkali fluorides.

E. Petersen prepared **potassium vanadylpentafluoride**, 2KF.VOF_3 , by mixing a soln. of potassium fluoride with a hydrofluoric acid soln. of vanadium pentoxide, and washing the white crystalline precipitate with dil. hydrofluoric acid. The microscopic, four-sided prisms give off some hydrogen fluoride on exposure to air, and also at 100°. The colour becomes reddish-brown when the salt is confined over sulphuric acid. E. Petersen obtained **potassium divanadylhydrodecafluoride**, $3\text{KF.HF}.2\text{VOF}_3$, by cooling a soln. of the vanadyldecafluorovanadate, or vanadyl-pentafluoride from a soln. of hydrofluoric acid, heated on the water-bath. The microscopic, rectangular prisms are stable in air, but during their drying, they smell feebly of hydrogen fluoride. The salt suffers an insignificant change in weight at 100°. H. Baker reported *potassium divanadyltrihydroenafluoride*, $3\text{KF}.3\text{HF}.2\text{VOF}_3$, to be formed from a soln. of potassium vanadylpentafluoride in hydrofluoric acid. E. Petersen suggested that this product is the same as his divanadylhydrodecafluoride. M. Travers obtained **sodium fluodivanadate**, $2\text{Na}_3\text{VO}_4.\text{NaF}.19\text{H}_2\text{O}$, in isomorphous association with sodium fluodisphosphate, $2\text{Na}_3\text{PO}_4.\text{NaF}.19\text{H}_2\text{O}$, by cooling the extract of bauxite with soda-lye.

The attempts to isolate *vanadyl fluoride* or **vanadium dioxyfluoride**, VO_2F , have not been successful, but complex salts have been prepared. A series of compounds of $\text{VOF}_3.\text{VO}_2\text{F}$ has also been reported. According to E. Petersen, and A. Piccini and G. Giorgis, when a soln. of vanadium pentoxide in hydrofluoric acid is mixed with enough ammonia for the soln. still to retain an acidic reaction, and evaporated, it furnishes *ammonium tetrafluodioxovanadate*, or **ammonium vanadyl-tetrafluoride**, $3\text{NH}_4\text{F.VO}_2\text{F}$, or $(\text{NH}_4)_3(\text{VO}_2)\text{F}_4$ —A. Werner gave $[\text{O}_2\text{VF}_4](\text{NH}_4)_3$. If the ammonia be in excess, some ammonium metavanadate is formed. E. Petersen dissolved vanadium pentoxide in a soln. of ammonium fluoride and extracted a little ammonium metavanadate from the vanadyltetrafluoride by hydrofluoric acid. H. Baker's pyramidal ammonium fluoxyvanadate, $12\text{NH}_4\text{F.V}_2\text{O}_5.2\text{VOF}_3$, is this salt. A. Piccini and G. Giorgis observed that the same compound is formed by the action of atm. oxygen on ammonium vanadylpentafluoride, or by adding ammonium fluoride to the same salt. The golden-yellow, octahedral crystals

are cubic, but they have an anomalous double refraction. The salt loses ammonia when warmed to 100°. P. G. Melikoff and P. Kasanezky found that when ammonium vanadyltetrafluoride, $3\text{NH}_4\text{F}\cdot\text{VO}_2\text{F}$, is treated with successive portions of hydrogen dioxide, *ammonium vanadyltrifluoride*, $2\text{NH}_4\text{F}\cdot\text{VO}_2\text{F}$, is first formed; and this behaves like a compound with the constitution $(\text{NH}_4\text{O})_2\text{VF}_3$; the fluorine is gradually replaced by oxygen, and the end-product is a pervanadate—*vide infra*, the potassium salt. The formula of the vanadyltetrafluoride is therefore written:

The intermediate products are:

F. Ephraim does not agree with this hypothesis. According to A. Piccini and G. Giorgis, when the aq. soln. of ammonium vanadyltetrafluoride is evaporated, a salt with less ammonium, namely, *ammonium pentafluotetroxydivanadate*, or **ammonium divanadylpentafluoride**, $3\text{NH}_4\text{F}\cdot 2\text{VO}_2\text{F}$, is formed in yellow plates which can be recrystallized from its aq. soln.; if the soln. in 10 per cent. hydrofluoric acid be slowly evaporated, the *monohydrate*, $3\text{NH}_4\text{F}\cdot 2\text{VOF}\cdot\text{H}_2\text{O}$, is formed. When an aq. soln. of ammonium pentavanadylhydroxypentacosifluoride—*vide infra*—is allowed to crystallize, it furnishes **ammonium tetravanadylhydrododecafluoride**, $7\text{NH}_4\text{F}\cdot\text{HF}\cdot 4\text{VO}_2\text{F}$, in white spherical aggregates, which form a yellow soln. with water. H. Baker's $6\text{NH}_4\text{F}\cdot 2\text{VOF}_3\cdot\text{V}_2\text{O}_5\cdot\text{H}_2\text{O}$ was thought by E. Petersen to be identical with this salt.

According to E. Petersen, if a soln. of vanadium pentoxide in hydrofluoric acid, warmed on the water-bath, be treated with potassium hydroxide until the liquid has a feeble acid reaction, golden-yellow crystals of **potassium vanadyltrifluoride**, $2\text{KF}\cdot\text{VO}_2\text{F}$, or $(\text{KO})_2\text{VF}_3$ —A. Werner gave $[\text{OVF}_5]\text{K}_2$ —separate as the soln. cools. The brown mass obtained by evaporating a soln. of vanadium pentoxide in hydrofluoric acid to dryness can be dissolved in hot water, and treated with a hot soln. of potassium fluoride; on cooling the filtered liquid, the same salt is obtained. Hydrated vanadium pentoxide dissolves readily in a hot soln. of potassium fluoride containing a little hydrofluoric acid; and the liquid, filtered from the white precipitate, furnishes crystals of the vanadyltrifluoride. F. Ephraim obtained the same salt by melting vanadium pentoxide with potassium fluoride, $6\text{KF} + \text{V}_2\text{O}_5 = \text{K}_2\text{O} + 2\text{K}_2(\text{VO}_2)\text{F}_3$; and also by crystallization from a soln. of potassium fluoride and potassium divanadylpentafluoride. The six-sided, prismatic crystals are straw-yellow, or golden-yellow; but if pure, F. Ephraim said that they would probably be white. Water splits this salt into the yellow divanadylpentafluoride; but the soln. in potassium fluoride is colourless. E. Petersen said that salt can be dried over sulphuric acid; and by careful heating it can be melted without decomposition. P. G. Melikoff and P. Kasanezky found that salt behaves like the ammonium salt towards hydrogen dioxide. The initial compound $(\text{KO})_2\text{VF}_3$ passes to a pervanadate, KVO_4 , or $6\text{K}_3\text{HV}_2\text{O}_{12}$, with the intermediate formation of

F. Ephraim does not accept this hypothesis. E. Petersen said that if an aq. soln. of potassium vanadyltrifluoride be crystallized, yellow aggregates of **potassium divanadylpentafluoride**, $3\text{KF}\cdot 2\text{VO}_2\text{F}$, are formed; and A. Piccini obtained the salt by crystallizing the same compound from a soln. of potassium fluoride.

H. Baker reported *potassium divanadyl dodecafluovanadate*, $6\text{KCl} \cdot \text{V}_2\text{O}_5 \cdot 2\text{VOF}_3 \cdot 2\text{H}_2\text{O}$, to be formed from a soln. of vanadium pentoxide in one of potassium hydrofluoride, but E. Petersen suggested that it is really potassium divanadylpentafluoride.

According to F. Ephraim, **barium vanadyl trifluoride**, $\text{BaF}_2 \cdot \text{VO}_2\text{F}$,

is obtained as a flocculent, light yellow precipitate on adding a soln. of vanadium fluoride to an excess of barium chloride. When calcium chloride is added to a soln. of an alkali vanadyl fluoride **calcium vanadyltrifluoride**, $\text{CaF}_2 \cdot \text{VO}_2\text{F}$, is formed. The complex fluoride then reacts with more chloride to produce a complex chloride: $2\text{Ca}(\text{VO}_2)\text{F}_3 + 3\text{CaCl}_2 = 3\text{CaF}_2 + 2\text{Ca}(\text{VO}_2)\text{Cl}_3$; in a similar manner, **magnesium vanadyltrifluoride**, and **ferric vanadyltrifluoride** are produced.

H. Baker prepared yellow, monoclinic prisms of **zinc oxydivanadyl octofluoride**, $\text{ZnF}_2 \cdot \text{ZnO} \cdot 2\text{VOF}_3 \cdot 14\text{H}_2\text{O}$, by evaporating a soln. of zinc carbonate and vanadium pentoxide in hydrofluoric acid. The axial ratios are $a : b : c = 0.93 : 1 : 0.83$, and $\beta = 134^\circ$. E. Petersen believed that this product is really **zinc vanadyltrifluoride**, $\text{ZnF}_2 \cdot \text{VO}_2\text{F} \cdot 7\text{H}_2\text{O}$, which was also prepared by A. Piccini and G. Giorgis. F. Ephraim and L. Heymann added a conc. aq. soln. of thallos fluoride to a soln. of vanadium pentoxide in hydrochloric acid, and obtained a flocculent precipitate of **thallos divanadylpentafluoride**, $3\text{TlF} \cdot 2\text{VO}_2\text{F}$, which soon crystallized. The salt is insoluble in water; and readily soluble in dil. sulphuric acid.

A. Piccini and G. Giorgis obtained **sodium vanadaylvvanadylheptafluoride**, $3\text{NaF} \cdot \text{VOF}_3 \cdot \text{VO}_2\text{F} \cdot \text{H}_2\text{O}$, on evaporating a soln. of 3 mols. of sodium carbonate and 2 mols. of vanadium pentoxide in hydrofluoric acid. After the precipitate has stood some days in contact with the mother-liquid, it forms yellow plates. H. Baker reported that **sodium fluodivanadate**, $2\text{Na}_3\text{VO}_4 \cdot \text{NaF} \cdot 19\text{H}_2\text{O}$, is formed when calculated proportions of vanadium trioxide, sodium carbonate, and sodium fluoride are melted together, and the aq. soln. of the cold mass allowed to crystallize.

It is also obtained from a soln. of the theoretical proportions of sodium fluoride and orthovanadate or pyrovanadate and sodium hydroxide. The salt can be recrystallized from dil. soda-lye without decomposition. It forms octahedral, cubic crystals. P. Hautefeuille could not prepare **calcium fluorthovanadate** analogous to wagnerite by fusing calcium fluoride with vanadium pentoxide. F. Fischer and K. Thiele found that the bluish-green soln. of vanadic acid dissolves lead carbonate. M. Amadori studied the f.p. of mixtures of lead orthovanadate and lead fluoride, and the results are summarized in Fig. 3. There is one compound formed: **lead fluotriorthovanadate**, *fluovanadinite*, or *fluovanadatapatrite*,

$\text{PbF}_2 \cdot 3\text{Pb}(\text{VO}_4)_2$, or $\text{Pb}_5\text{F}(\text{VO}_4)_3$, or, according to A. Werner, $[\text{Pb}\{(\text{PbVO}_3 \cdot \text{O})_2\text{Pb}\}]\text{F}_2$. M. Amadori found the m.p. of fluomimetite, $\text{Pb}_5\text{Cl}(\text{AsO}_4)_3$, to be 1042° , and of fluovanadinite, 916° , and for mixtures with 25, 50, and 75 per cent. of fluovanadinite, 1008° , 978° , and 944° respectively.

A. Ditte² has reported a number of fluovanadates whose nature has not been explained. F. Ephraim suggests that most of them are not chemical individuals, and when he tried, he could not verify A. Ditte's conclusion. A. Ditte found that a warm conc. soln. of ammonium fluoride dissolves a large quantity of soluble vanadium pentoxide, and the warm liquid deposits **ammonium tetrafluovanadate**, $\text{V}_2\text{O}_5 \cdot 4\text{NH}_4\text{F} \cdot 4\text{H}_2\text{O}$, in pale-yellow crystals very soluble in water. When heated, they lose water and hydrogen fluoride, and yield **ammonium difluovanadate**, $\text{V}_2\text{O}_5 \cdot 2\text{NH}_4\text{F}$. If the mother-liquor from the first crystals

FIG. 8.—Freezing-point Curves of Lead Fluoride and Orthovanadate.

is mixed with excess of vanadium pentoxide, filtered and cooled, it deposits the tetrafluovanadate in almost white, brilliant, nacrecus needles, readily soluble in cold water. With a cold soln. of ammonium fluoride and excess of vanadium pentoxide, the first product consists of indistinct yellow crystals of **ammonium octofluovanadate**, $V_2O_5 \cdot 8NH_4F \cdot 4H_2O$, followed by crystals of the compound tetrafluovanadate.

A. Ditte also found that when sodium fluoride is heated in a closed crucible with an excess of vanadium pentoxide it yields a crystalline, red mass, and when this is treated with tepid water, it yields an orange soln., which deposits orange-red crystals of **sodium tetrafluohexavanadate**, $3V_2O_5 \cdot 4NaF \cdot 18H_2O$. The mother-liquor when conc. yields lemon-yellow crystals of **sodium tetrafluovanadate**, $V_2O_5 \cdot 4NaF$. With an excess of the alkaline fluoride, the product is pale-yellow, and is only slowly attacked by water. If extracted with warm water and the soln. evaporated in vacuo, the salt is obtained in transparent, orange-red crystals, and the mother-liquor yields small, yellowish-white crystals of **sodium octofluovanadate**, $V_2O_5 \cdot 8NaF \cdot 3H_2O$.

A. Ditte observed that when an excess of vanadium pentoxide is fused with potassium fluoride in a platinum crucible, care being taken to prevent access of air, a brick-red crystalline mass is formed on cooling, and when this is treated with water, a residue of vanadium pentoxide is left, and a red soln. is obtained. The soln. first deposits a small quantity of potassium tetrafluovanadate, formed in consequence of access of air, and then orange-red plates of **potassium difluohexavanadate**, $3V_2O_5 \cdot 2KF \cdot 5H_2O$, which melts easily to a black liquid. The mother-liquor on further conc. deposits red, transparent prisms of **potassium difluovanadate**, $4V_2O_5 \cdot 2KF \cdot 8H_2O$. Contact with air is more completely avoided by heating the crucible at the bottom of a long glass tube. Under these conditions, the aq. soln. first deposits potassium difluohexavanadate, then ruby-red prisms of the *hexahydrate*, $3V_2O_5 \cdot 2KF \cdot 6H_2O$, and less soluble, lemon-yellow crystals of **potassium tetrafluohexavanadate**, $3V_2O_5 \cdot 4KF$. All these compounds are soluble in conc. sulphuric acid, with evolution of hydrogen fluoride and formation of a red soln. which becomes pale-green when dil. with much water. When an excess of potassium fluoride is employed, the residue is pale-yellow, and on treatment with cold water first yields a sat. soln. of potassium fluoride, in which the vanadium compounds are practically insoluble. A further quantity of water forms a yellow soln., which deposits small plates of **potassium difluotetrafluovanadate**, $3V_2O_5 \cdot 2KF \cdot 8H_2O$, and the mother-liquor when conc. in vacuo yields **potassium difluohexavanadate**, $3V_2O_5 \cdot 2KF \cdot 4H_2O$. The proportion of the residue least soluble in water has the composition of **potassium tetrafluodivanadate**, $V_2O_5 \cdot 4KF \cdot 3H_2O$. With a large excess of potassium fluoride, the soln. yields successively large, thin, brilliant, orange-yellow lamellae of the compound potassium difluohexavanadate; white crystals with a greenish-yellow tinge of **potassium octofluodivanadate**, $V_2O_5 \cdot 8KF \cdot 3H_2O$, and finally yellow crystals of dihydrated potassium tetrafluodivanadate. If air has free access and vanadium pentoxide is in excess, the residue is an orange-red mass with vitreous fracture, and when treated with hot water some vanadium pentoxide remains undissolved. The soln. first deposits potassium tetrafluovanadate, and afterwards lemon-yellow crystals of **vanadium tetrafluodivanadate**, $V_2O_5 \cdot 4KF$. Similar results are obtained with excess of potassium fluoride. Water first dissolves the excess of fluoride, and the soln. obtained by further treatment deposits yellowish-white crystals of dihydrated potassium octofluodivanadate. The action of potassium fluoride on vanadium pentoxide yields the compounds **potassium fluotetrafluovanadate**, $2V_2O_5 \cdot KF$; **potassium difluohexavanadate**, $3V_2O_5 \cdot 2KF$; **potassium fluodivanadate**, $V_2O_5 \cdot KF$; **potassium tetrafluohexavanadate**, $3V_2O_5 \cdot 4KF$; **potassium tetrafluodivanadate**, $V_2O_5 \cdot 4KF$; **potassium octofluodecavanadate**, $V_2O_5 \cdot 8KF$, which may be regarded as analogous to potassium chlorochromate. Their soln. give no coloration and no precipitate with ammonia. If these compounds are regarded as derived from an oxyfluoride, the latter must be $V_2O_4F_2$. Possibly the compounds do not actually exist in the fused mass, but the aq. soln. contains several different compounds, giving rise to conditions of equilibrium in which the crystallizable salts described are formed. A soln. of potassium fluoride dissolves vanadium pentoxide, and the liquid deposits greenish-white crystals of potassium octofluodivanadate, which is but slightly soluble in excess of the alkaline fluoride. As the colourless soln. cools it becomes yellow, and deposits lemon-yellow crystals of potassium tetrafluodivanadate.

§ 19. The Vanadium Chlorides and Oxychlorides

H. E. Roscoe¹ prepared **vanadium dichloride**, VCl_2 , by passing a mixture of hydrogen and vanadium tetrachloride through a glass tube heated to dull redness, when the dichloride collects in pale green crystals as a sublimate on the walls of the tube. If the current of gas is too rapid, or if insufficient hydrogen be present, some vanadium trichloride is formed; and if the temp. is too high, some vanadium metal is formed which forms a silicide with the glass. H. Moissan and A. Holt observed the formation of the dichloride and silicon tetrachloride when vanadium silicide is heated in chlorine. J. Meyer and R. Backa obtained the dichloride by the action of hydrogen chloride on ferrovandium at 300°–400°. A. Piccini and L. Marino obtained an aq. soln. of the dichloride by the electrolytic reduction of the trichloride, using a graphite anode. H. E. Roscoe found that the pale, apple-green, hexagonal plates have a sp. gr. 3.23 at 18°; the salt volatilizes in hydrogen or carbon dioxide without decomposition. The hygroscopic crystals gradually deliquesce in air to a brown liquid owing to the absorption of water and oxygen. They are at first not wetted by water, but swim on that liquid; however, they soon dissolve, forming a lavender-coloured soln. which decolorizes litmus, and indigo. According to A. Piccini and L. Marino, when the aq. soln. is evaporated, or when hydrochloric acid is added, hydrogen is evolved and the trichloride is formed. The reaction is very vigorous if a piece of platinum is present in the acid liquor. The dichloride is therefore a more vigorous reducing agent than chromous chloride. When the dichloride is heated to whiteness in nitrogen, some nitride is formed. For the action of heat, *vide infra*, vanadium trichloride. P. Pascal gave 139×10^{-5} for the mol. magnetic susceptibility of soln. of the dichloride. Alcohol forms a blue soln., and ether a green one. In aq. soln. the salt is oxidized to vanadium pentoxide by potassium permanganate.

According to H. E. Roscoe, **vanadium trichloride**, VCl_3 , is formed when the tetrachloride is heated; and when the tetrachloride is heated in a distillation flask, it boils with partial decomposition leaving a residue of the trichloride which can be dried in a current of carbon dioxide at 160°. The tetrachloride also decomposes slowly at ordinary temp. into the trichloride. The tetrachloride mixed with hydrogen furnishes a mixture of the trichloride and dichloride when passed through a red-hot tube. W. Halberstadt prepared the trichloride by warming the trisulphide in a current of chlorine. To remove sulphur chloride from the dark brown distillate, it is redistilled, and the red residue heated to 150° in a current of carbon dioxide. J. Meyer and R. Backa obtained the trichloride by the action of hydrogen chloride on vanadium at 300°–400°; and also by passing carbon dioxide through the tetrachloride at 140°–150°. H. E. Roscoe showed that at ordinary temp., vanadium trichloride furnishes tabular crystals the colour of peach blossoms. The sp. gr. is 3.00 at 18°. It does not volatilize in dry hydrogen, but at a red-heat it forms the dichloride, and at a higher temp. still, the metal. On heating vanadium trichloride in a current of nitrogen to a dark red-heat, it is decomposed into vanadium tetrachloride, which distils off, and into vanadium dichloride, which remains behind. The quantity of vanadium tetrachloride, which is formed according to the equation: $2VCl_3 = VCl_4 + VCl_2$, is determined for each temp. by the partial press. of the chlorine, since, together with the above reaction, a second

occurs, namely, $2\text{VCl}_4 = 2\text{VCl}_3 + \text{Cl}_2$. For the first reaction, the relation $[\text{VCl}_4]/[\text{VCl}_3]^2 = k_1$ holds, since the vap. press. of the VCl_2 in the presence of the solid is constant; for the second reaction, the relation $[\text{VCl}_3]^2[\text{Cl}_2]/[\text{VCl}_4]^2 = k_2$ holds. Both these equilibria exist at the same time, and $[\text{Cl}_2]/[\text{VCl}_4] = k_1 k_2$, that is, the quantity of vanadium tetrachloride formed by heating the trichloride is determined by the partial press. of the chlorine over the trichloride. It is consequently an easy matter to transform vanadium trichloride completely into the tetrachloride by heating it in a current of chlorine which is free from oxygen. Similar phenomena are observed when vanadium trichloride is heated at a dull red-heat in a current of carbon dioxide instead of nitrogen. Green vanadium dichloride, VCl_2 , is formed according to the equation $2\text{VCl}_3 \rightleftharpoons \text{VCl}_4 + \text{VCl}_2$. If the heating is carried out at a bright red-heat the carbon dioxide is reduced by the vanadium dichloride, with the result that vanadium oxychloride, VOCl , and carbon monoxide are formed, as shown by the equation: $3\text{VCl}_2 + 2\text{CO}_2 = 2\text{VOCl} + \text{VCl}_4 + 2\text{CO}$. On still stronger heating, the reaction goes further, according to the equation: $4\text{VCl}_2 + 3\text{CO}_2 = \text{V}_2\text{O}_3 + 2\text{VCl}_4 + 3\text{CO}$, and pure vanadium trioxide is left behind. Thus it is quite unnecessary to reduce vanadium trichloride in a current of hydrogen in order to obtain the dichloride. According to H. E. Roscoe, vanadium trichloride is very hygroscopic, and deliquesces in air to a dark brown liquid which with a drop of hydrochloric acid becomes green. When heated in air, it develops red vapours of vanadium oxytrichloride, and some vanadium pentoxide remains. W. Biltz studied the thermal dissociation of the trichloride. J. Meyer and R. Backa prepared **vanadium hexamminotrichloride**, $[\text{V}(\text{NH}_3)_6]\text{Cl}_3$, by the action of liquid ammonia on the halide. The compound is decomposed by water, $[\text{V}(\text{NH}_3)_6]\text{Cl}_3 + 3\text{H}_2\text{O} = \text{V}(\text{OH})_3 + 3\text{NH}_3 + 3\text{NH}_4\text{Cl}$; it is unstable in air: $[\text{V}(\text{NH}_3)_6]\text{Cl}_3 + \text{O} + 2\text{H}_2\text{O} = \text{NH}_4\text{VO}_3 + 3\text{NH}_4\text{Cl} + 2\text{NH}_3$, and in moist air forms the insoluble *hexahydrate*, $[\text{V}(\text{H}_2\text{O})_6]\text{Cl}_3$. These compounds resemble the corresponding compounds of iron and aluminium rather than those of chromium and cobalt. The trichloride is soluble in alcohol and in ether, forming brown soln. The aq. soln. is oxidized to vanadium pentoxide by potassium permanganate. According to W. Halberstadt, when an aq. soln. of vanadium trichloride is boiled with sodium thiosulphate, its colour changes from brown to blue and green. If the thiosulphate is present in large quantities, a dark precipitate, consisting of sulphide and oxide, is thrown down. When an electric current is passed through an aq. soln. of vanadium trichloride acidified with hydrochloric acid, a red soluble substance is formed at the positive pole.

W. Halberstadt, and J. Locke and G. H. Edwards prepared the *hexahydrate*, $\text{VCl}_3 \cdot 6\text{H}_2\text{O}$, by evaporating a soln. of vanadium trihydroxide in hydrochloric acid in vacuo, taking care to protect the soln. from atm. air during the operations. A. Piccini and N. Brizzi obtained the hexahydrate, by reducing a soln. of vanadium pentoxide in hydrochloric acid by means of the electric current. The green soln. of the trichloride so obtained is cooled with ice and salt, and precipitated by saturating it with hydrogen chloride. Vanadium trichloride, in acid or neutral soln., undergoes no change when kept in a sealed tube in an atm. of dioxide, and the crystalline salt remains unaltered for a considerable time in air kept dry by means of lime. The trichloride corresponds in composition with chromium trichloride, and resembles the violet modification of the latter both in chemical behaviour and when examined by the cryoscopic method.

J. Locke and G. H. Edwards obtained green crystals of **potassium tetrachlorovanadate**, KVCl_4 , from a mixture of vanadium trichloride and potassium chloride dissolved in conc. hydrochloric acid. A. Stähler obtained what he regarded as **potassium pentachlorovanadate**, K_2VCl_5 , analogous with the rubidium salt; also ammonium pentachlorovanadate, $(\text{NH}_4)_2\text{VCl}_5$; **rubidium pentachlorovanadate**, RbVCl_5 , was obtained by evaporating on the water-bath, in a current of hydrogen chloride, an aq. soln. of 3 grms. of hydrated vanadium trichloride and 2 grms. of rubidium chloride. The raspberry-red crystal powder was washed with absolute alcohol. It is sparingly soluble in water and in alcohol. By working in a similar

manner caesium pentachlorovanadite Cs_2VCl_5 , and **magnesium pentachlorovanadite**, MgVCl_5 , were obtained.

According to H. E. Roscoe, when the vapour of vanadium oxytrichloride is passed through a red-hot tube, in addition to the oxydichloride, **vanadium dioxychloride**, or *divanadyl chloride*, $\text{V}_2\text{O}_2\text{Cl}$, is formed as a brown, flocculent powder insoluble in water, and **vanadium oxychloride**, or *vanadyl chloride*, VOCl , as a yellow, crystalline powder resembling mosaic gold. The mol. formulæ are unknown. A. Safarik first prepared the former compound, and said that its sp. gr. is 3.64 at 20° ; and when heated in air, it becomes blue, and then glows with the formation of vanadium pentoxide. It is freely soluble in nitric acid. E. Wedekind and C. Horst gave 27.17×10^{-6} for the magnetic susceptibility.

H. E. Roscoe found that **vanadium tetrachloride**, VCl_4 , is formed by heating vanadium or vanadium nitride to redness in a current of dry chlorine freed from air; and removing any oxytrichloride by fractional distillation in chlorine. It is also produced by slowly passing the vapour of vanadium oxytrichloride mixed with chlorine through a red-hot layer of sugar-charcoal. The treatment was repeated two or three times with the product of the operation heated in a current of chlorine. Some trichloride always remains behind when the tetrachloride is vaporized. H. Moissan and A. Holt observed the formation of the tetrachloride when chlorine is passed over heated vanadium silicide; F. de Carli, over ferrovandium; and J. Koppel and co-workers prepared it by passing dry chlorine over crude vanadium obtained by the aluminothermite process, and removing the oxytrichloride by fractional distillation. W. Biltz and E. Keunecke gave directions for preparing the salt. C. Matignon and F. Bourion prepared the tetrachloride by passing a mixture of the vapour of sulphur monochloride and chlorine over heated vanadium pentoxide. The vapour of oxytrichloride first formed mixed with the sulphur monochloride vapour is made to pass through a 70-cm. tube heated to dull redness. The condensed product is then a mixture of sulphur monochloride and vanadium tetrachloride. This is separated by fractional distillation. J. Meyer and R. Backa made the tetrachloride by the action of chlorine on ferrovandium at dull redness.

H. Lessheim and co-workers discussed the electronic structure of the tetrachloride. H. E. Roscoe described vanadium tetrachloride as a dark reddish-brown, viscid liquid of sp. gr. 1.8584 at 0° , 1.8363 at 8° , and 1.8159 at 30° . For the action of heat, *vide supra*, vanadium trichloride. It does not freeze at -18° . J. Koppel and co-workers found that it solidifies in liquid air. W. Biltz and E. Keunecke gave -109° for the m.p. H. E. Roscoe found that the tetrachloride boils at 154° at 760 mm. press. O. Ruff and H. Lickfett gave 153.7° for the b.p. at 768 mm.; and W. Biltz and E. Keunecke, 148.5° at 755 mm. The vap. density is 6.78 between 205° and 215° when the theoretical value for VCl_4 is 6.68. The results are affected by the great tendency of the tetrachloride to split up into the trichloride and chlorine, even in the presence of an excess of chlorine. The tetrachloride decomposes slowly into the trichloride and chlorine, at ordinary temp., and more quickly at the b.p., or when the vapour is passed through a red-hot tube. This decomposition is accelerated by exposure to light. A. Voigt and W. Biltz found the electrical conductivity to be too small to measure. P. Pascal gave 66.2×10^{-5} for the mol. magnetic susceptibility of an aq. soln. of vanadium tetrachloride (hydrolyzed to V_2O_4). The reduction of the vapour of the tetrachloride by hydrogen in the presence of iron was studied by N. Parravano and C. Mazzetti. It forms white fumes in air, and when thrown in water, it is at once decomposed, forming a blue soln. of oxychloride. The tetrachloride does not absorb chlorine at -18° ; and when heated with bromine in a sealed tube at 180° , a solid mass is produced, which, when heated to 160° in a current of carbon dioxide, leaves a residue of the tribromide. J. Koppel and co-workers found that the tetrachloride yields a brown soln. with fuming hydrochloric acid. The tetrachloride reacts with alcohol, forming a blue soln.; and with ether, forming a deep red one. J. Koppel and co-workers found that the tetrachloride dissolves without change in chloroform, or in glacial acetic

acid. W. Biltz and E. Keuncke found that the tetrachloride does not react with liquid hydrogen sulphide at -78.5° . H. E. Roscoe said that the tetrachloride is oxidized to vanadium pentoxide by a soln. of potassium permanganate.

According to H. E. Roscoe, when vanadium oxytrichloride and zinc are heated in a sealed tube at 400° , zinc chloride, vanadium tetroxide, and a sublimate of **vanadium oxydichloride**, or *vanadyl dichloride*, VOCl_2 , are produced; if the crystals are then heated to 130° in a current of carbon dioxide, any adherent vanadium oxytrichloride is removed. The oxydichloride is also formed as a by-product when the vapour of the oxytrichloride and hydrogen are passed through a red-hot tube. Some dichloride and trichloride are formed at the same time. The oxydichloride forms green tablets which deliquesce on exposure to moist air; it is slowly decomposed by water; and it is freely soluble in nitric acid. J. Koppel and co-workers found that the oxydichloride dissolved in absolute alcohol or acetic acid forms complex chlorides with 2-4 mols of pyridine or quinoline.

H. E. Roscoe was unable to prepare **vanadium pentachloride**, VCl_5 , by the action of chlorine on vanadium tetrachloride at -18° , or by vaporizing the tetrachloride in an excess of chlorine. According to J. J. Berzelius, when vanadium pentoxide is dissolved in conc. hydrochloric acid, chlorine is evolved, and the pentoxide passes into soln. as if it were the tetroxide. The dark brown soln. does not dry up on evaporation, but furnishes a black liquid, soluble in water. If evaporated by heat, the liquid becomes blue. The blue soln. is also obtained if the vanadium pentoxide is associated with vanadium trioxide, sugar, alcohol, or hydrogen sulphide when it is attacked by the acid. The blue syrup obtained by evaporating the liquid shows no tendency to crystallize. It gives off hydrochloric acid at a gentle heat. A. Guyard, A. Safarik, and numerous others—*vide supra*, vanadium pentoxide—made observations on this subject. A. Ditte said that when the soln. of vanadic acid in hydrochloric acid is conc. by evaporation, the soln. becomes deep brown and deposits dark green, deliquescent crystals, which, when dried in vacuo over potassium hydroxide, have the composition of vanadium trioxydichloride, $\text{V}_2\text{O}_3\text{Cl}_3 \cdot 4\text{H}_2\text{O}$; or, according to J. K. Crow, found that the brown deliquescent mass obtained by evaporating the soln. of vanadium pentoxide in hot conc. hydrochloric acid, has the composition: $\text{V}_2\text{O}_2\text{Cl}_4 \cdot 5\text{H}_2\text{O}$, sometimes written $\text{V}_2\text{O}_4 \cdot 4\text{HCl} \cdot 3\text{H}_2\text{O}$, or hydrated vanadium oxydichloride, $\text{VOCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. E. F. Smith and J. G. Hibbs obtained the same substance as a reddish-brown, oily condensate by passing hydrogen chloride over sodium vanadate at 440° . It dissolves in water, forming a blue soln., and, when treated with conc. hydrochloric acid, or alcohol, the soln. is brown. The change in colour is attributed to the existence of two different hydrates. A. Safarik said that the same product is obtained when vanadium tri- or penta-oxide is treated with hydrochloric acid; and F. Ephraim, that the product of the reaction is identical with that produced by the action of water on vanadium oxytrichloride—*vide infra*. B. Brauner reported the complex **platinum hexachloroxyhypovanadate**, $\text{PtCl}_6 \cdot \text{VOCl}_2 \cdot 10\frac{1}{2}\text{H}_2\text{O}$

J. J. Berzelius, and J. F. W. Johnston prepared **vanadium oxytrichloride**, or *vanadyl trichloride*, VOCl_3 —also called *vanadyl chloride*—by passing dry chlorine over heated vanadium trioxide, or a mixture of vanadium trioxide and carbon at a red-heat, and removed chlorine from the yellow liquid by a current of dry air. H. E. Roscoe added that the distillate is claret-red from admixed tetrachloride, but this can be removed by repeated distillation over sodium. A. Safarik obtained a similar product by the action of dry chlorine on a mixture of finely-divided vanadium pentoxide and lampblack—or, according to H. E. Roscoe, sugar-charcoal. The product is purified by fractional distillation. R. Edson and D. McIntosh used this process. L. P'Hôte obtained the oxytrichloride by passing chlorine over an intimate mixture of vanadium sulphide, lampblack, and oil; C. Matignon and F. Bourion, by passing sulphur chloride vapour over heated vanadium pentoxide, and F. Ephraim, by the action of hydrogen chloride on vanadium pentoxide at 60° - 80° :

$V_2O_5 + 6HCl \rightleftharpoons 2VOCl_3 + 3H_2O$ —the water is removed by using a mixture of vanadium and phosphorus pentoxides—*vide supra*. H. V. A. Briscoe and H. F. V. Little prepared vanadium oxytrichloride by heating the pentoxide in a current of hydrogen so as to convert it into the trioxide, and afterwards heating the trioxide at dull redness in a current of chlorine, and collecting the oxytrichloride in a bulb, trapped with a U-tube containing conc. sulphuric acid, and cooled with ice: $3V_2O_3 + 3Cl_2 = 2VOCl_3 + V_2O_5$. F. E. Brown and J. E. Snyder used a similar process. O. Ruff and H. Lickfett passed chlorine over the pentoxide at a dull red-heat and found oxygen was evolved and the oxytrichloride formed. They also chlorinated a mixture of vanadium pentoxide and sulphur at ordinary temp., and obtained the oxytrichloride. The same product was obtained by heating vanadium trichloride in oxygen. F. Ephraim said that a soln. of vanadium oxytrichloride is obtained by the action of conc. hydrochloric acid on vanadium pentoxide; and J. Koppel and co-workers, by the action of a soln. of hydrogen chloride in acetic acid, ether, or alcohol on vanadium pentoxide or ammonium metavanadate. W. H. Furman, and L. E. Stout and G. C. Whitaker found that the acidified soln. can be kept some months without change.

A. Safarik, J. J. Berzelius, and H. E. Roscoe described vanadium oxytrichloride as a clear, mobile, pale yellow liquid at ordinary temp. A. Safarik gave 1.764 for the sp. gr. at 20°; L. l'Hôte, 1.854 at 18°; H. E. Roscoe, 1.841 at 14.5°, 1.836 at 17.5°, and 1.828 at 24°; and T. E. Thorpe, 1.865 at 0°, and 1.631 at the b.p. O. Masson, and J. A. Groshans compared the mol. vol. and b.p. of the family of chlorides. H. E. Roscoe did not freeze the liquid at -15°. J. J. Berzelius said that the b.p. is over 100°. A. Safarik gave 127°; H. E. Roscoe, 126.7° at 767 mm.; L. l'Hôte, 126.5°; and T. E. Thorpe, 127.19° at 760 mm. F. E. Brown and J. E. Snyder gave 124°-125° for the b.p. at 739 mm., or 127.19° at 760°. J. F. W. Johnston and A. Safarik found the vapour is greenish-yellow like that of chlorine. A. Safarik gave 6.41 for the vap. density at 227° when the theoretical value for $VOCl_3$ is 6.0; H. E. Roscoe gave 6.108 at 186°; and T. E. Thorpe, 8.564. A. A. Agafonoff measured the electrical conductivity of aq. soln. of vanadium oxytrichloride which become turbid and intensely yellow when kept in sealed vessels. The electrical conductivity undergoes a corresponding change. Thus, at 18°, a freshly prepared soln. containing a mol of vanadium oxytrichloride in 74.06 litres of water has a conductivity of 179.77, which increases to 200.83 after 46 days, and diminishes to 178.34 after a further 9 days. On heating a soln. 42 days old to 30°, 60°, 70°, and 80°, and cooling again to 18°, the values obtained for the conductivity were 192.95, 214.98, 218.97, and 216.96 (or, when slowly cooled, 202.93) respectively. N. Perrakis measured the magnetic properties.

According to H. E. Roscoe, when the vapour of the oxytrichloride is mixed with **hydrogen**, and passed through a red-hot tube, vanadium trioxide, solid oxychlorides, and a little vanadium tetrachloride are formed. According to J. J. Berzelius, when the liquid is exposed to **air**, a dense yellowish-red cloud of vanadium pentoxide and hydrochloric acid is evolved; and the liquid deliquesces rapidly, forming a dense red liquid covered with hydrated vanadium pentoxide; a small quantity of **water** renders the liquid turbid, $2VOCl_3 + 3H_2O = 6HCl + V_2O_5$; with a large proportion of water, it forms a pale yellow, transparent liquid having the taste of ferric chloride, and in a few days more, or when heated, the liquid becomes green, and then blue—chlorine is evolved and the liquid dissolves gold. A. Safarik said that when the pale yellow liquid is evaporated, it forms red hydrated vanadium pentoxide without becoming blue. F. E. Brown and J. E. Snyder found that the oxytrichloride dissolves **chlorine** readily at 0°, but the solubility decreases rapidly with rise of temp.; **bromine** is miscible with all proportions of the oxytrichloride at room temp.; and **iodine** is slightly soluble. F. Ephraim said that the soln. of the oxytrichloride in conc. **hydrochloric acid** is brown. F. E. Brown and J. E. Snyder found that **sulphur** is soluble in vanadium oxytrichloride, and after a time the liquid solidifies and sulphur dioxide is evolved; O. Ruff and H. Lickfett

represented the reaction $2\text{VOCl}_3 + \text{S} \rightarrow 2\text{VCl}_3 + \text{SO}_2$. F. E. Brown and J. E. Snyder found that **sulphuryl chloride** is miscible in all proportions with the oxytrichloride. Vanadium oxytrichloride was found by E. Uhrlaub, and H. E. Roscoe to absorb dry **ammonia** rapidly with the evolution of rauch heat and the formation of a white mass which partly sublimes; at a red-heat, vanadium nitride is formed. F. E. Brown and J. E. Snyder found that at room temp. the oxytrichloride is without action on red or white **phosphorus**, or **phosphorus pentoxide**, while **phosphorus trichloride** reduces vanadium oxytrichloride, forming a precipitate. The oxytrichloride is miscible in all proportions with **phosphorus oxychloride**, and then quickly reacts, forming a precipitate; and it has no action on **arsenic**, or on **bismuth**. H. E. Roscoe said that when the vapour of the oxytrichloride mixed with hydrogen is passed over red-hot **carbon**, dioxide is formed. According to F. E. Brown and J. E. Snyder, the following **hydrocarbons** are miscible in all proportions; they give red soln.; *n*-hexane, *n*-octane, benzene, toluene, petroleum ether, paraffin (when melted). Commercial kerosene and gasoline dissolve and then react, giving murky mixtures. Naphthalene and paraffin are soluble. The following liquid aldehydes react vigorously at room temp. giving insoluble products: anisic aldehyde, benzaldehyde, *n*-butyraldehyde, cinnamic aldehyde, *n*-heptaldehyde, salicylic aldehyde. β -hydroxybenzaldehyde and *o*-nitrobenzaldehyde, both solid, are soluble but not reactive. The following **organic halides** are miscible in all proportions: carbon tetrachloride, chloroform, ethyl bromide, ethyl chloride, ethyl iodide, *iso*-amyl bromide. J. Koppel and co-workers said that the oxytrichloride is insoluble in chloroform, while F. E. Brown and J. E. Snyder said that the two liquids are miscible in all proportions. J. J. Berzelius said that the trioxychloride forms with absolute **alcohol** a red, transparent mixture which changes colour more rapidly than the aq. soln., and ethyl chloride is formed. F. E. Brown and J. E. Snyder said that alcohol is miscible in all proportions with the oxytrichloride, and non-reactive. P. P. Bedson observed that when heated for 2 or 3 hrs. to 60° - 70° with **ether**, a complex $\text{VOCl}_3 \cdot (\text{C}_2\text{H}_5)_2\text{O}$ is formed. J. Koppel and co-workers found that the soln. in alcohol, ether, or **acetic acid** is dark red; and the alcoholic soln. forms complex salts with **pyridine**. F. E. Brown and J. E. Snyder found that the oxytrichloride is miscible in all proportions with **acetone**, and **acetic anhydride**; and it dissolves **benzophenone** without reaction. According to F. E. Brown and J. E. Snyder, no reaction occurs at ordinary temp. or at the b.p. with the following **metals**: potassium, sodium, copper, aluminium, tin, manganese, iron, nickel, or platinum. There was no evidence of soln. or reaction with the following **anhydrous salts**: aluminium chloride; ammonium molybdate; barium carbonate, chloride, nitrate, and sulphate; bismuth chloride, and sulphate; cadmium bromide, carbonate; calcium carbonate, chloride; ferric chloride; lead nitrate, sulphate; potassium acetate, bromate, bromide, carbonate, chlorate, chloride, chromate, dichromate, ferricyanide, hydroxide, iodide, nitrate, perchlorate, permanganate, pyroantimonate, pyrosulphate, sulphate, hydrosulphate hydrotartrate, thiocyanate; sodium acetate, arsenite, bromide, carbonate, chloride, hydroxide, iodide, nitrate, nitrite, sulphite; strontium carbonate, nitrate, and sulphate. It swells and blackens when boiled with the following **hydrated salts**: barium acetate, chlorate, and hydroxide; bismuth carbonate; potassium alum, antimonyl tartrate, chrome alum, ferrocyanide, oxalate, sodium carbonate, sodium cobaltinitrite, sodium tartrate; sodium ammonium hydrophosphate, hydroarsenate, dichromate, phosphate, hydrophosphate, dihydrophosphate, tartrate, tetraborate; strontium acetate, chloride, probably owing to the removal of water from the crystals and the subsequent hydrolysis of the oxytrichloride. According to J. J. Berzelius, the oxytrichloride can be boiled over potassium without decomposition, and H. E. Roscoe obtained a similar result with sodium and the heavy metals. J. J. Berzelius observed, however, that when potassium is strongly heated in the vapour of the oxytrichloride, it catches fire, producing the alkali chloride and vanadium oxide. H. E. Roscoe found that if the vapour mixed with hydrogen is passed over

heated sodium, a crust of sodium oxide is formed; and with magnesium, there is a vigorous reaction, forming magnesium chloride and oxide. V. Cuttica and co-workers found that when vanadium oxytrichloride is treated with magnesium oxide at ordinary temp. it forms a complex **magnesium oxychlorovanadate**, and with water it yields magnesium hexavanadate, $Mg_2V_6O_{17} \cdot 19H_2O$; when vanadium oxytrichloride is heated in a sealed tube with copper oxide at 150° – 160° , dark green **copper chlorometavanadate**, $Cu(VO_3)_2 \cdot CuCl$, *i.e.*, $Cu=O_2=VOCl \cdot CuVO_3$, is formed; lead oxide likewise yields brick-red **lead chlorometavanadate**, $Pb(VO_3)_2 \cdot PbCl_2$, *i.e.*, $Pb=O_2=VOCl$, at ordinary temp. thalious oxide yields deep brown **thalious chloro-dioxyvanadate**, $Tl_2O \cdot VOCl_3$, or $(TlO)_2VCl_3$, which, when treated with water, furnishes vanadyl chloride and the polyvanadate, $Tl_2O \cdot 3V_2O_5$. G. Carobbi fused a mixture of lead vanadate, lead chloride, and praseodymium vanadate (10 : 2 : 1) and obtained **lead praseodymium chlorovanadate**, $3(Pb, Pr)_3(VO_4)_2 \cdot PbCl_2$.

According to P. Hautefeuille,² **calcium chlorovanadate**, *calcium vanadato-wagnerite*, $CaCl_2 \cdot Ca_3(VO_4)_2$, or $Ca_2Cl(VO_4)$, or $Ca(VO_4)(CaCl)$, is formed when a mixture of calcium chloride and vanadium pentoxide is fused, and the product washed with water. The white crystals are isomorphous with wagnerite, and have a sp. gr. of 4.01. Magnesium chloride does not give *magnesium chlorovanadate*, but rather magnesia, and a vanadium oxychloride; but when a mixture of lead chloride, litharge, and vanadium pentoxide was similarly heated to dull redness, and the excess of chloride washed away, yellow, transparent, six-sided prisms of **lead chlorotriorthovanadate**, $3Pb_3(VO_4)_2 \cdot PbCl_2$, or $Pb_5Cl(VO_4)_3$, are formed. A. Ditte also made observations on this subject. E. Weinschenk obtained a similar product by heating lead chloride, ammonium metavanadate, and an excess of ammonium chloride in a sealed tube at 150° – 180° . H. E. Roscoe also obtained this compound by fusing a mixture of lead orthovanadate and lead chloride; and M. Amadori's study of the equilibrium conditions is summarized in Fig. 9. G. Cesaro obtained crystals of the compound by passing carbon dioxide into a soln. of the compound in alkali-lye.

The discovery of erythronium in the lead mineral from Zimapan, Mexico, has been previously described; it was shown that the discoverer, A. M. del Rio, himself gave up the idea that a new element was present, and believed that he had mistaken chromium for a new element. For a time, therefore, this mineral was regarded as a lead chromate. Thus, A. Brongniart called it *chromate de plomb brun*. After the rediscovery of erythronium by N. G. Sefström, under the name vanadium, the mineral was called *Vanadinbleierz* by G. Rose; and **vanadinite** by F. von Kobell. The same mineral has also been called *vanadium spar*, and *vanadium lead spar*. Analyses of the mineral from various localities have been reported by C. F. Rammelsberg, D. Lovisato, H. T. Stearns, A. Frenzel, N. Collie, H. von Struve, A. E. Norden-skjöld, A. Döring, H. F. Keller, F. A. Genth, P. Jannasch, and N. S. Maskelyne. The analyses show that the mineral is lead chlorotriorthovanadate. In some cases part of the vanadic acid is isomorphously replaced by phosphoric acid, or arsenic acid. A mineral with a high proportion of arsenic acid, from Lake Valley, New Mexico, was called by F. A. Genth and G. vom Rath *endlichite*—after F. M. Endlich. Some of the chlorine may be replaced; and lead may be partly replaced by calcium.

The **colour** of vanadinite ranges through deep ruby-red, light-brownish-yellow, straw-yellow, and reddish-brown. White crystals have not been observed; the artificial crystals are yellow. It is therefore assumed that the colour is produced by the vanadic acid; K. von Krätz-Koschlau and L. Wöhler assumed that

FIG. 9.—Freezing-point Curves of Mixtures of Lead Chloride and Orthovanadate.

the colour is produced by chromium but the hypothesis is non-proven. Vanadinite may occur in implanted globules or incrustations; and in prismatic **crystals** with smooth faces and sharp edges. The crystals are sometimes cavernous furnishing hollow prisms. The mineral also occurs in rounded forms, and in parallel groupings like pyromorphite. K. Vrba showed that the hexagonal crystals have pyramidal hemihedrism, and the axial ratio $a:c=1:0.71218$ —the values range from the $1:0.71121$ to $1:0.7495$ of S. L. Penfield. M. Amadori gave for the artificial crystals $1:0.71115$. No **cleavage** or **twinning** has been observed. The apparent twinning about the (1010)-plane observed by R. W. Sraith is produced by parallel growths. Crystals have been described by J. Barthoux, P. Comucci, J. D. Dana, W. Eissner, F. A. Genth, V. Goldschmidt, F. N. Guild, M. F. Heddle, A. L. Heisler, P. Krusch, A. Lacroix, D. Lovisato, W. F. Pettered, F. P. Paul, K. A. Redlich, W. Rodenbender, W. T. Schaller, A. Sigmund, B. Silliman, G. Smith, L. J. Spencer, H. T. Stearns, C. A. Tenne and S. Calderon, P. A. Wagner, M. Websky, F. Zambonini, and V. R. von Zepharovich. J. Schabus, and C. F. Rammelsberg showed that the crystals are isomorphous with pyromorphite and mimetite. M. Amadori observed the formation of solid soln. with lead fluotriorthovanadate; and also with lead chlorotriorthophosphate; and G. Carobbi and S. Restaino observed the formation of solid soln. with sodium, lanthanum, and praseodymium replacing part of the lead isomorphously. Pseudomorphs of vanadinite after pyromorphite were observed by N. von Kokscharoff, and pseudomorphs of descloizite after vanadinite, by A. Brunlechner. W. Eissner measured the effect of temp. ranging from -160° to 150° on the crystal-angles of vanadinite and found the results can be represented by a straight line—about $13'$ are involved in the change. A break was observed at 710° with the artificial mineral, and this is taken to be a **transition temperature** for α -vanadinite and β -vanadinite. For the **specific gravity** C. F. Rammelsberg gave 6.635–6.89; V. R. von Zepharovich, 6.98; D. Lovisato, 6.78 at 22.2° ; H. E. Roscoe, 6.707 at 12° ; H. von Struve, 6.863; H. F. Keller, 6.572; F. A. Genth, 6.862–7.809; and P. Jannasch, 6.88. The **hardness** is 2.75–3.0. T. Carnelley found that the **melting point** exceeds 802° ; M. Amadori, Fig. 9, gave 990° . The m.p. of mixture of chlorovanadinite with the following percentage proportions of related compounds are:

	0	20	50	80	100 per cent.
Chloropyromorphite . . .	990°	1012°	1056°	1116°	1156°
Chloromimetite . . .	990°	1010°	1062°	1096°	1140°
Fluovanadate . . .	990°	978° (25)	964°	942° (25)	916°

H. L. Bowman found the **index of refraction** of endlichite for the red *C*-line to be $\omega=2.341$, and $\epsilon=2.292$; and for the yellow *D*-line, $\omega=2.359$, and $\epsilon=2.311$; when the **birefringences** are $\omega-\epsilon=0.047$ respectively. For vanadinite, and red-light, $\omega=2.354$, $\epsilon=2.299$, and $\omega-\epsilon=0.055$. The optical character is negative. The pleochroism is ω , brownish-red, and ϵ , brownish-yellow. T. W. Case observed that the poor conductivity of vanadinite is not appreciably affected by light. E. E. Fairbanks gave 10.8–11.2 for the **dielectric constant** (water 81). The mineral is insoluble in **water**; it forms lead chloride and a green soln. with **hydrochloric acid**; lead sulphate with **sulphuric acid**; and it readily dissolves in **nitric acid**, forming a yellow soln. A. Lacroix said that when vanadinite is evaporated with a drop of nitric acid on a glass slip, a deep red stain is produced. P. Jannasch and H. F. Harwood found that if **carbon tetrachloride** vapour is passed over the heated mineral, all the vanadium is volatilized, and lead chloride remains.

§ 20. The Vanadium Bromides

H. E. Roscoe¹ prepared **vanadium tribromide**, VBr_3 , by passing dried bromine vapour, freed from air, over red-hot vanadium nitride, and removing the excess of bromine by a current of carbon dioxide; the same product was obtained by A. Safarik, and H. E. Roscoe by passing bromine over a red-hot mixture of vanadium pentoxide and carbon. The first product is the oxytribromide, then the oxydibromide, and finally the tribromide, which soon chokes up the tube with a sublimate. J. Meyer and R. Backa said that the tribromide is best obtained by the direct union of the elements. O. Ruff and H. Lickfett obtained it by the action of bromine on vanadium carbide at a dull red-heat. According to H. E. Roscoe, vanadium tribromide is a dark grey, amorphous opaque solid; it is very unstable, and gives off bromine at ordinary temp.; in moist air it rapidly deliquesces to a brown liquid which furnishes green vanadyl salts when treated with hydrochloric acid. According to J. Locke and G. H. Edwards, vanadium trihydroxide dissolves completely in hydrobromic acid, and, if air be excluded, the evaporation in vacuo furnishes crystals of the *hexahydrate*, $\text{VBr}_3 \cdot 6\text{H}_2\text{O}$. A. Ficcini and N. Brizzi reduced electrolytically a soln. of vanadium pentoxide in conc. hydrobromic acid, and allowed the green liquid, mixed with more conc. hydrobromic acid, to crystallize in a desiccator over lime, and sulphuric acid. The green, hygroscopic, crystalline powder is freely soluble in water, alcohol, and ether. The salt is hydrolyzed by water. The conc. aq. soln. is yellow or brown; and the acidic soln. green. The green soln. becomes blue on exposure to air. The alcoholic soln. is green. The aq. soln. gives a precipitate of thalious bromide when treated with a soln. of thalious sulphate. J. Meyer and R. Backa made **vanadium hexamminotribromide**, $[\text{V}(\text{NH}_3)_6]\text{Br}_3$, as in the case of the corresponding trichloride (*q.v.*). The properties of the two compounds are similar.

According to J. J. Berzelius, the blue soln. of vanadium tetroxide in hydrobromic acid turns green during its spontaneous evaporation; and in vacuo, it dries to a blue gum-like mass which, when gently heated, becomes violet-brown, but continues to be completely soluble in water. Alcohol precipitates from the syrupy aq. soln. a gelatinous mass which dissolves as the alcohol evaporates. The **vanadium tetrabromide**, VBr_4 , corresponding with the tetrachloride, has not been isolated. H. E. Roscoe found that when the tribromide is treated with an excess of bromine, there is no evidence of the formation of a higher bromide. R. F. Weiland and K. Feige prepared **vanadium heptabromoantimonite**, $\text{VBr}_4 \cdot \text{SbBr}_3 \cdot 7\text{H}_2\text{O}$ —*vide* antimony.

A. Guyard found that if vanadium pentoxide be treated with a mixture of bromine, water, and alcohol, a vigorous reaction sets in, and the liquid can be evaporated to dryness below 80° , without decomposition; and A. Ditte said that if a soln. of vanadium pentoxide in conc. hydrobromic acid be evaporated in vacuo, over sulphuric acid, and potassium hydroxide, crystals of **vanadium dihydroxytetrabromide**, $\text{V}_2\text{O}_3\text{Br}_2 \cdot 2\text{HBr} \cdot 7\text{H}_2\text{O}$, are formed. When treated with aq. ammonia, an ammonium hypovanadate, $(\text{NH}_4)_4\text{V}_2\text{O}_6$, is precipitated. A. Safarik made vanadium oxybromides by heating the more or less reduced pentoxide with bromine. H. E. Roscoe found that if vanadium oxytribromide be heated to 180° it quickly decomposes with bromine and **vanadium oxydibromide**, VOBr_2 ,

which appears as a brownish-yellow powder resembling ochre. If further heated it loses all its bromine and forms vanadium pentoxide. According to O. Ruff and H. Lickfett, if bromine vapour or, better still, a mixture of bromine and sulphur bromide vapour is passed over a mixture of vanadium pentoxide and sulphur at a red-heat, the distillate does not consist of vanadium oxytribromide, VOBr_3 , but of a product which, on being heated in a vacuum at 240° , leaves a residue of pure vanadium oxydibromide, VOBr_2 , sulphur bromide and bromine distilling away. The oxydibromide deliquesces rapidly in air, and forms a blue soln. with water. O. Ruff and H. Lickfett observed that if vanadium oxydibromide be heated to 360° , part of the compound sublimes undecomposed, and part decomposes leaving a violet residue of **vanadium oxybromide**, VOBr ; and if this compound be heated in vacuo, vanadium tribromide distills off leaving a residue of vanadium tribromide. The oxybromide yields violet, octahedral crystals of sp. gr. 4.0002 at 18° . The salt is very slightly soluble in water, acetic anhydride, ethyl acetate, and acetone.

H. E. Roscoe found that when the vapour of dry bromine is passed over vanadium pentoxide at a red-heat, the dense white vapours which are early produced, and which condense to a dark red liquid, are mainly **vanadium oxytribromide**, VOBr_3 . The liquid should be rectified by heating under reduced press.—say at 45° and 100 mm.—so as to expel the bromine. The dark red liquid has a sp. gr. 2.9673 at 0° , and 2.9325 at 14.5° . It distils readily at 130° – 136° . It slowly decomposes at ordinary temp., and suddenly at 180° , forming bromine and the oxydibromide. The liquid is very hygroscopic, and is rapidly decomposed in moist air.

According to A. Ditte, if a mixture of vanadium pentoxide, and calcium bromide with an excess of sodium bromide, be kept in a fused state for a short time, white crystals of **calcium bromotriorthovanadate**, $\text{Ca}_5\text{Br}(\text{VO}_4)_3$, or *calcium vanadatobromapatite*, $\text{Ca}_2\text{Br}_2 \cdot 3\text{Ca}_3(\text{VO}_4)_2$, are formed; and by using P. Hautefeuille's process for the corresponding chloride, tabular crystals of **calcium bromovanadate**, $\text{Ca}_2\text{Br}(\text{VO}_4)$, or $\text{Ca}=\text{VO}_4-\text{Ca}-\text{Br}$, or *calcium vanadatobromowagnerite*, $\text{Ca}_2\text{Br}_2 \cdot \text{Ca}_3(\text{VO}_4)_2$, are produced. Greyish-white hexagonal plates and prisms of **strontium bromotriorthovanadate**, $\text{Sr}_5\text{Br}(\text{VO}_4)_3$, or *strontium vanadatobromapatite*, $\text{Sr}_2\text{Br}_2 \cdot 3\text{Ca}_3(\text{VO}_4)_2$, and **strontium bromovanadate**, $\text{Sr}_2\text{Br}(\text{VO}_4)$, or *calcium vanadatobromowagnerite*, $\text{SrBr}_2 \cdot \text{Ca}_3(\text{VO}_4)_2$, were also produced. Hexagonal, greyish-white tablets of **barium bromotriorthovanadate**, $\text{Ba}_5\text{Br}(\text{VO}_4)_3$, or *barium vanadatapatite*, $\text{BaBr}_2 \cdot 3\text{Ba}_3(\text{VO}_4)_2$, were obtained in an analogous manner. A. Ditte prepared golden-yellow, hexagonal plates of **lead bromotriorthovanadate**, $\text{Pb}_5\text{Br}(\text{VO}_4)_3$, or *lead vanadatobromapatite*, $\text{PbBr}_2 \cdot 3\text{Pb}_3(\text{VO}_4)_3$, in a similar manner.

§ 21. The Vanadium Iodides

J. J. Berzelius,¹ and H. E. Roscoe were unable to prepare **vanadium triiodide**, VI_3 , by the action of iodine in the cold or at a higher temp. on vanadium pentoxide or trioxide, or nitride; nor could J. Meyer and R. Backa prepare this compound.

A. Piccini and N. Brizzi, however, made the *hexahydrate*, $\text{V}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, by dissolving vanadium pentoxide in hydriodic acid, and reducing the conc. soln. by electrolysis as in the analogous case of the tribromide or trichloride. The product is mixed with conc. hydriodic acid, and evaporated over calcium oxide, and sulphuric acid at 0° . If the aq. soln. be evaporated at ordinary temp., a brown residue is produced. The small, green, acicular crystals deliquesce in air to a brown liquid. The aq. soln. gives a precipitate of thallos iodide when treated with a soln. of thallos sulphate. The salt is soluble in alcohol.

A. Guyard observed no reaction occurs when vanadium pentoxide, iodine, water, and alcohol are digested together. According to J. J. Berzelius, the blue soln. of vanadium tetroxide in hydriodic acid rapidly becomes green on exposure to air, and when evaporated spontaneously, leaves a brown mass which is soluble in water, forming a dark brown soln., which gives off iodine when treated with sulphuric acid. By evaporating in vacuo the greenish-blue soln. of vanadium pentoxide in hydriodic acid, and removing the excess of iodine with powdered silver, A. Ditte obtained a black deliquescent mass of **vanadium trihydrotrioxypentaiodide**, $\text{V}_2\text{O}_5 \cdot 3\text{HI} \cdot 10\text{H}_2\text{O}$, and this, when kept some days in a desiccator, furnishes **vanadium dihydrotrioxytetraiodide**, $\text{V}_2\text{O}_5 \cdot 2\text{HI} \cdot 8\text{H}_2\text{O} \cdot \text{Aq.}$; ammonia acts on this salt as in the analogous case of the bromine compound.

By fusing a mixture of vanadium pentoxide, calcium iodide and an excess of potassium iodide, A. Ditte obtained colourless, hexagonal needles of **calcium iodotriorthovanadate**, $\text{Ca}_5\text{I}(\text{VO}_4)_3$, or *calcium vanadatiodapatite*, $\text{CaI}_2 \cdot 3\text{Ca}_3(\text{VO}_4)_2$; and similarly with **strontium iodotriorthovanadate**, $\text{Sr}_5\text{I}(\text{VO}_4)_3$, or *strontium-vanadatiodapatite*, $\text{SrI}_2 \cdot 3\text{Sr}_3(\text{VO}_4)_2$; and brown hexagonal prisms of **barium iodotriorthovanadate**, $\text{Ba}_5\text{I}(\text{VO}_4)_3$, or *barium vanadatiodapatite*, $\text{BaI}_2 \cdot 3\text{Ba}_3(\text{VO}_4)_2$.

§ 22. The Vanadium Sulphides and Oxy-sulphides

There are three well-defined vanadium sulphides: V_2S_2 , V_2S_3 , and V_2S_5 . J. J. Berzelius¹ mistook vanadium oxide, V_2O_2 , for vanadium, and when he described the two sulphides VS_2 and VS_3 , it must be understood that his V is to be replaced by V_2O_2 . J. J. Berzelius said that both compounds can be produced by wet and dry methods. W. E. Kay examined J. J. Berzelius' wet processes, and in the case of $(\text{V}_2\text{O}_2)\text{S}_4$ he found that when prepared by treating a soln. of sodium vanadate with hydrogen sulphides—pouring the liquor into an excess of dil. acid, washing the precipitate in a soln. of hydrogen sulphide; drying it in an atm. of carbon dioxide; and washing out the excess of sulphur with hot carbon disulphide—the product does not correspond with V_2S_5 or with $\text{V}_2\text{O}_2\text{S}_5$, and no definite formula can be assigned to it. Likewise in the case of the lower sulphides prepared by treating a soln. of vanadium pentoxide in hydrochloric acid and hydrogen sulphide; the precipitate was dissolved in fresh ammonium hydro-sulphide soln., and precipitated by pouring the soln. into an excess of dil. acid. The product corresponds neither with V_2S_3 nor with $\text{V}_2\text{O}_2\text{S}_3$. It is a mixture of variable composition. On the other hand, the sulphide prepared in the dry way by J. J. Berzelius was shown by W. E. Kay to be a true trisulphide, V_2S_3 , and he added that if

J. J. Berzelius had analyzed the product completely he would probably have ascertained the true nature of vanadium and of its compounds.

W. E. Kay showed that when compared with the oxides, the sulphides of vanadium are compounds of inferior stability; for whilst in the oxygen series the penta-compound is stable at redness in a neutral atm., in the sulphur series the penta- is converted into the tri-sulphide. Again, in hydrogen at intense redness, the trioxide is permanent; whilst the trisulphide is, under similar conditions, reduced to disulphide.

F. Hewett described a black mineral occurring at Minasragra, Peru, and it was named **patronite**—after A. R. Patrona. The observation of J. J. Bravo, and W. F. Hillebrand show that the black mineral has a complex composition but contains a large proportion of a vanadium sulphide—perhaps VS_4 .

W. E. Kay prepared **vanadium disulphide**, V_2S_2 , by heating vanadium trisulphide at a red-heat for 4–8 days in an atm. of hydrogen. It forms a black or a brownish-black powder with a bronze lustre, and sp. gr. 4.2–4.4. The disulphide rapidly absorbs oxygen, and when heated in air, gives off sulphur dioxide and passes through the stages of blue and black oxide into the fused crystalline pentoxide. If it be heated in a limited supply of air, free sulphur is also given off, the oxygen being retained by the vanadium. Boiling hydrochloric acid, both conc. and dil., and boiling dil. sulphuric acid attack the disulphide but very slightly; cold conc. sulphuric acid does not act upon it, but it is dissolved by the hot acid to a greenish-yellow soln. Dil. nitric acid attacks the trisulphide slowly, the soln. being coloured blue; with the hot dil. acid the action is more rapid, whilst by the conc. hot acid the substance is violently oxidized, and the soln. contains vanadic sulphate. Soda-lye, and aq. ammonia attack the vanadium trisulphide but slightly, either in the cold or on heating; yellow ammonium sulphide slowly dissolves the disulphide, forming a wine-red soln., whilst in the case of the freshly prepared colourless ammonium hydrosulphide the liquid acquires a purple tint. Potassium hydrosulphide acts slowly on the disulphide, yielding a violet-red soln. E. Wedekind and C. Horst gave 7.22×10^{-6} for the magnetic susceptibility.

J. J. Berzelius said that the lower oxide of vanadium does not combine with sulphur when a mixture of the two is heated, or when the vapour of sulphur is passed over the heated oxide. If vanadium trioxide be heated to redness in a current of hydrogen sulphide, **vanadium trisulphide**, V_2S_3 , as black powder, is formed; if the tetroxide be employed, the hydrogen sulphide first reduces it to the trioxide: $V_2O_4 + H_2S = S + V_2O_3 + H_2O$; and this then passes to the trisulphide: $V_2O_3 + 3H_2S = 3H_2O + V_2S_3$. A. Safarik obtained a similar result with vanadium pentoxide; and, according to W. E. Kay, any vanadium compound can be used. To prepare the trisulphide, W. E. Kay recommended heating the pentoxide in the vapour of carbon disulphide, when the trisulphide appears in greyish-black tablets resembling graphite. A. Safarik gave 4.7 for the sp. gr. of the powder at 21° ; and W. E. Kay gave 3.7 for the sp. gr. of the crystals and 4.0 for that of the powder. A. Karl said that vanadium sulphide is triboluminescent. E. Wedekind and C. Horst gave 8.95×10^{-6} for the magnetic susceptibility. When the trisulphide is heated in air or oxygen the trisulphide is oxidized similarly to the disulphide, but much less readily. Sulphur dioxide is evolved, and the blue and black oxides formed, these gradually passing into the pentoxide. The trisulphide is but slightly attacked by dil. or conc. hydrochloric acid, either in the cold or on heating. Hot dil. sulphuric acid also acts upon it but slowly, but by the conc. and hot acid it is more rapidly dissolved. Dil. nitric acid acts upon the trisulphide slowly in the cold and more rapidly on heating, forming a blue soln., as in the case of the disulphide; by the conc. acid it is readily oxidized in the cold, whilst in the case of the hot acid the oxidation proceeds with violence. Soda-lye, and aq. ammonia have a slight solvent action on the trisulphide. Yellow ammonium sulphide acts upon the substance slowly, forming a wine-red liquid; whilst with the colourless ammonium hydrosulphide a purple-coloured soln. is obtained, identical in appearance with that

formed in the case of the disulphide. The colour of the liquid produced on soln. in potassium hydrosulphide is violet-red.

J. J. Berzelius said that vanadium trisulphide unites with the more basic metal sulphides, forming **sulphovanadites**. The alkali sulphovanadites are said to be made by saturating an alkali vanadite with hydrogen sulphide; by mixing the vanadite with an alkali monosulphide; by dissolving hydrated vanadic trioxide in an alkali hydrosulphide; or by mixing a vanadium salt with an alkali hydrosulphide. To avoid the formation of a sulphovanadate, the vanadium salt should be free from vanadate, and the alkali hydrosulphide free from an excess of sulphur. The insoluble sulphovanadites are obtained by double decomposition. J. J. Berzelius described *ammonium, potassium, and sodium sulphovanadites* as being soluble in water, forming purple soln. resembling those of potassium permanganate; and they are rendered turbid by the heavy metal sulphides; *barium, strontium, and calcium sulphovanadites* are said to be reddish-brown salts sparingly soluble in water. These products are probably oxysulphovanadates. They want re-examining.

According to W. E. Kay, if a mixture of vanadium trisulphide and sulphur be heated to 400° , in the absence of air, a black powder of **vanadium pentasulphide**, V_2S_5 , is formed. The sp. gr. is 3.0. When the pentasulphide is heated in the air it gives off sulphur dioxide, and is converted into the black oxide, which, on further heating, passes into the fused pentoxide. If, however, the heat be very carefully applied, some free sulphur is first given off without this taking fire. Heated in a neutral atmosphere, the pentasulphide loses two atoms of sulphur, being converted into trisulphide. The pentasulphide is but slightly attacked by hot conc. hydrochloric acid, and by hot dil. sulphuric acid, whilst by conc. sulphuric acid it is slowly dissolved, forming a yellow soln. Hot dil. nitric acid dissolves the pentasulphide slowly, but completely; whilst by the conc. acid it is more energetically oxidized. Ammonia does not easily attack the pentasulphide, but it is readily dissolved by soda-lye especially on heating, forming a yellow soln. In this respect it differs markedly from the other vanadium sulphides which dissolve but slightly in soda-lye. The pentasulphide is slowly acted upon by the alkaline sulphides. With colourless ammonium hydrosulphide the soln. has the purple colour also yielded by the other vanadium sulphides. To obtain this colour in perfection, it is necessary that the hydrosulphide soln. shall be completely sat. with sulphuretted hydrogen, and the colour is best obtained by passing hydrogen sulphide to excess through ammonia soln., containing the pentasulphide in suspension. If the hydrogen sulphide be not present in excess, the liquid has a rich carmine-red colour. The soln. of pentasulphide in yellow ammonium sulphide is a brownish-red, whilst that in potassium hydrosulphide is wine-red. E. Wedekind and C. Horst gave 12.55×10^{-6} for the magnetic susceptibility.

J. J. Berzelius said that the higher sulphide combines with the more basic metal sulphides to form **sulphovanadates**. His salts were probably oxysulphovanadates. They were made by treating an aq. soln. of an alkali vanadate with hydrogen sulphide or ammonium hydrosulphite; by dissolving vanadium pentoxide in alkali hydrosulphide soln.; by dissolving the higher sulphide in soln. of alkali hydroxide, carbonate, or hydrosulphide; by fusing vanadium oxide with potassium carbonate and sulphur; and the insoluble sulphovanadates, by double decomposition. The dry sulphovanadates are blackish-brown. The potassium and sodium salts form reddish-brown aq. soln.; the barium, strontium, and calcium salts are sparingly soluble; and the others are insoluble. Acids precipitate the higher sulphide from soln. of the sulphovanadate, but the lower sulphide is decomposed at the same time making the soln. appear blue. Alcohol gives a dark red crystalline precipitate when added to the aq. soln.

Vanadium, unlike columbium and tantalum, forms a series of salt derivatives of sulphovanadic acid, and a number of well-crystallized salts have been prepared by wet and dry methods. G. Krüss and K. Ohnmais prepared a series of sulphovanadates, and oxysulphovanadates. They found that **ammonium orthosulphovanadate**, $(NH_4)_3VS_4$, is deposited in crystals when hydrogen sulphide is passed for several hours into an ice-cold sat. soln. of ammonium metavanadate in ammonium hydrate of sp. gr. 0.898, and the dark-violet soln., obtained in this way is kept for some days. It can be more conveniently prepared by adding a soln. of ammonium

hydrosulphide to a soln. of potassium metavanadate or sodium pyrovanadate; after a comparatively short time, ammonium sulphovanadate separates from the soln. in rhombic crystals with the axial ratios $a : b : c = 0.9825 : 1 : 1.742$, similar in appearance to those of potassium permanganate; its sp. gr. is 1.6202. The aq. soln. gives precipitates of sulphides or sulphovanadates with soln. of salts of copper, silver, zinc, and manganese, but not with salts of magnesium or the alkaline earths. G. Krüss and K. Ohnmais did not isolate **potassium orthosulphovanadate**, K_3VS_4 , but they obtained solid soln. or mixtures of ammonium and potassium orthosulphovanadates by treating a soln. of potassium vanadate in potash with hydrogen sulphide, and then mixing it under different conditions with a soln. of ammonium sulphovanadate in ammonium hydrosulphide; the analyses of these mixtures showed that they contained the normal ammonium salt, and most probably also the normal potassium salt.

G. A. Goyder described a mineral from Burra, South Australia, which was at first thought to be a copper vanadite, but later was shown to be **cuprous orthosulphovanadate**, Cu_3VS_4 . It was called sulvanite. It is bronze-yellow, with a metallic lustre. The sp. gr. is 4.0, and the hardness 3.5. It was also described by A. Dieseldorff. A. Carnot obtained what was thought to be impure cupric sulphovanadate by adding ammonium hydrosulphide to a soln. of a vanadate and a copper salt.

G. Krüss prepared **sodium oxytrisulphorthovanadate**, Na_3VS_3O , by melting a mixture of vanadium pentoxide and sodium carbonate with a large excess of sulphur, until all the free sulphur was vaporized or burnt. The cold powdered product was extracted first with alcohol, then with carbon disulphide, and again with alcohol. J. Locke obtained this salt by the action of hydrogen sulphide on red-hot sodium orthovanadate. The same salt was probably prepared by J. A. Norblad by melting a vanadiferous slag with sodium carbonate, sulphur, and carbon. G. Krüss said that the product is a reddish-brown crystalline powder, which melts with very little decomposition to a red liquid. It forms a red soln. with water; this rapidly decomposes and becomes green. The salt is sparingly soluble in alcohol. G. Krüss and K. Ohnmais prepared the *pentahydrate*, $Na_3VS_3O.5H_2O$, in crystals when a soln. of soda-lye of sp. gr. 1.122 (30 c.c.) is sat. with hydrogen sulphide, mixed with an aq. soln. (6 c.c.) of sodium pyrovanadate (3 grms.), and hydrogen sulphide passed through the ice-cold mixture for 4 hrs.; it forms small, dark reddish-brown, very deliquescent crystals, and gradually loses the whole of its water when heated.

G. Krüss and K. Ohnmais prepared **sodium trioxysulphorthovanadate**, $Na_3VSO_3.10H_2O$, as an oil when freshly-prepared sodium hydrosulphide is added to a boiling soln. of sodium pyrovanadate, the mixture boiled for a short time, and the ice-cold, filtered soln. treated with alcohol (3 vols.); after being repeatedly washed with cold alcohol, it solidifies to a mass of orange-red crystals. It melts at 18° , and its sp. gr. is 1.7727.

G. Krüss and K. Ohnmais prepared **potassium oxyhexasulphopyrovanadate**, $(NH_4)_4V_2S_6O$, by passing hydrogen sulphide into a soln. of ammonium metavanadate in aq. ammonia of sp. gr. greater than 0.898; on keeping the red soln. for some months at a low temp., a considerable quantity of the salt is deposited in crystals. It is rather darker in colour than the normal salt, and its sp. gr. is 1.7155. The aq. soln. gives precipitates of sulphides or sulphovanadates with soln. of salts of copper, silver, zinc, and manganese, but not with salts of magnesium or the alkaline earths. The corresponding **potassium oxyhexasulphopyrovanadate**, $K_4V_2S_6O.3H_2O$, can be prepared by treating an ice-cold soln. of potassium vanadate in potash-lye of sp. gr. 1.472, with hydrogen sulphide in absence of air; after a long time, the salt separates from the soln. in crystals resembling those of freshly-prepared potassium permanganate; it has a sp. gr. of 2.1443. When carefully heated at 150° , it is converted into the anhydrous salt, $K_4V_2S_6O$, but if heated too quickly, it melts to a cherry-red liquid, and, on continued heating, is

decomposed with liberation of sulphur. If the mother-liquor in the preparation of this salt be evaporated over phosphorus pentoxide, crystals of a *hemitrihydrate*, $2K_4V_2S_6O \cdot 3H_2O$, of sp. gr. 2.1195, are formed. J. Locke found that when sodium pyrovanadate is heated to 580° – 700° in a current of hydrogen sulphide, there is formed **sodium dioxypentasulphopyrovanadate**, $Na_4V_2S_5O_2$, in crystals which, in colour and lustre, resemble potassium permanganate; when the hot salt soln. is exposed to the air, it gives off sulphur dioxide, and is converted into sodium hypovanadate. The salt is very hygroscopic, and dissolves in water, to form a deep reddish-purple soln., rapidly changing in colour as hydrogen sulphide is given off, and finally becoming colourless. This colour change is accompanied by a remarkable alteration in the colour of the free sulphovanadic acid, which separates on addition of hydrochloric acid. From the freshly prepared soln., the precipitate is black, and from the nearly oxidized soln. is pale orange. These acids are, however, so unstable as to render their isolation in a pure state practically impossible. Unsuccessful attempts were made to prepare analogous salts of the heavy metals, but lead pyrovanadate alone yielded a definite compound—**lead pentoxydisulphopyrovanadate**, $Pb_2V_2S_2O_5$, as a black, lustrous, crystalline powder. L. Thompson's *argyllite* from Inverary, Scotland, is thought to be a lead sulphovanadate.

§ 23. The Vanadium Sulphates

A. Piccini¹ prepared **hypovanadous sulphate**, $VSO_4 \cdot 7H_2O$, by reducing a sulphuric acid soln. of vanadium pentoxide by means of an electric current in the absence of air. The violet-blue soln., when evaporated in vacuo over sulphuric acid furnished violet, monoclinic crystals of the salt. The crystals are isomorphous with those of ferrous sulphate with which it forms solid soln., $(Fe, V)SO_4 \cdot 7H_2O$; similarly also with magnesium sulphate, $(Mg, V)SO_4 \cdot 7H_2O$. Hypovanadous sulphate also forms mixed crystals with chromium and other sulphates—for V. Auger's observations, *vide supra*. These are decomposed on exposure to air. Amethyst-blue crystals of **ammonium hypovanadous sulphate**, $(NH_4)_2SO_4 \cdot VSO_4 \cdot 6H_2O$, or **ammonium sulphatohypovanadite**, $(NH_4)_2V(SO_4)_2 \cdot 6H_2O$, by the electrolysis of a sulphuric acid soln. of vanadium pentoxide containing ammonium sulphate. It is not so easily oxidized as hypovanadous sulphate. The crystals are monoclinic and isomorphous with the double salts of magnesium sulphate. The corresponding **potassium hypovanadous sulphate**, or **potassium sulphatohypovanadate**, $K_2V(SO_4)_2 \cdot 6H_2O$, was prepared in a similar way. It is not so highly coloured as the ammonium salt. All these salts dissolve in water, forming yellow or brownish-yellow soln. which in the presence of acids turn blue. Both the acidic and neutral soln. absorb oxygen from air with great rapidity. In a similar manner A. Piccini and L. Marino prepared **rubidium hypovanadous sulphate**, $Rb_2V(SO_4)_2 \cdot 6H_2O$, or **rubidium sulphatohypovanadite** contaminated with some rubidium alum.

J. T. Brierley² tried to make **vanadous sulphate**, $V_2(SO_4)_3$, by reducing a dil.

sulphuric acid soln. of vanadium pentoxide by zinc, but he could not separate the resulting zinc and vanadous sulphates. A. Stähler and H. Wirthwein prepared the anhydrous salt by slowly heating hexahydrated hydrovanaditodisulphuric acid to 180° in an atm. of carbon dioxide. The microcrystalline powder forms a yellowish-brown soln. with hydrochloric acid, and a green soln. with dil. sulphuric acid. J. Meyer and E. Markowicz obtained the *enneahydrate*, $V_2(SO_4)_3 \cdot 9H_2O$, and the *deca- or enneahydrate*, $V_2(SO_4)_3 \cdot 9$ (or 10) H_2O , from soln. acidified with a little dil. sulphuric acid. The *trihydrate*, $V_2(SO_4)_3 \cdot 3H_2O$, was also obtained from conc. sulphuric acid soln. J. T. Brierley reduced electrolytically a conc. soln. of the pentoxide in dil. sulphuric acid, using a platinum dish as cathode, and a platinum plate as anode, until a drop of the soln. shaken up with a little water gave a green coloration without any sign of blue. The conc. green trioxide soln. was then mixed with about twice its bulk of conc. sulphuric acid, and allowed to remain for 24 hrs. : at the end of that time the whole of the trioxide separated in combination with sulphuric acid as a pale green, sandy crystalline precipitate, which was placed upon a porous tile, washed with conc. alcohol until the free sulphuric acid was entirely removed, and then dried over sulphuric acid in a desiccator filled with an inert gas. The product was **vanadous hydrodisulphate**, $V_2O_3 \cdot 4SO_3 \cdot 9H_2O$, or $HV(SO_4)_2 \cdot 4H_2O$. Sulphate of tervalent vanadium dissolves in water, yielding a bright green soln., from which alkalis precipitate the hydrated trioxide as a dirty green, somewhat gelatinous mass, which is rapidly oxidized in the air. This green hydrated trioxide readily dissolves in a soln. of the foregoing green sulphate, forming a deep chocolate-coloured liquid, and on evaporation this liquid yields a shining green amorphous mass, which again dissolves in water, forming a brown soln. M. C. Boswell and J. V. Dickson found that vanadium sulphate is oxidized when fused with sodium hydroxide. A. S. Russell recommended vanadous sulphate in place of titanous sulphate as a reducing agent. It is rather more powerful in its action; indeed, it reduces titanous sulphate in the cold. A 0.1N-soln. in 10N- H_2SO_4 is not measurably oxidized when kept in a burette for an hour. It reduces all organic and inorganic substances reduced by titanous sulphate.

According to J. Meyer and E. Markowicz, the sulphates of tervalent vanadium representing **hydrovanaditodisulphuric acid**, $HV(SO_4)_2 \cdot nH_2O$, may be arranged in two classes. (i) Those obtained by reducing vanadyl salts electrolytically, represented by J. T. Brierley's *tetrahydrate*, $HV(SO_4)_2 \cdot 4H_2O$, or $[V(H_2O)_4](SO_4)(HSO_4)$, and its ammonium salt, $(NH_4)V(SO_4)_2 \cdot 4H_2O$; the salts prepared by A. Stähler and H. Wirthwein, namely, the *hexahydrate*, $HV(SO_4)_2 \cdot 6H_2O$, $[V(H_2O)_6](SO_4)(HSO_4)$ —by the electrolytic reduction of blue vanadyl sulphate. The green, finely crystalline powder is insoluble in alcohol, ether, acetic acid, or 60 per cent. sulphuric acid; the aq. soln. is green. There are also ammonium and rubidium salts. The hypothetical *dodecahydrate*, $HV(SO_4)_2 \cdot 12H_2O$, or $[V(H_2O)_6](SO_4)(NH_4SO_4)$, is represented by ammonium vanadic alum; and by G. Scagliarini and A. Airoidi's *vanadium pyridine sulphate*, $[V(C_5H_5N)(H_2O)_3](SO_4)(HSO_4)$. (ii) J. Meyer and E. Markowicz prepared a series of salts by adding variable quantities of sulphuric acid to a soln. of vanadium acetate in acetic acid. Thus, the *pentahydrate*, $HV(SO_4)_2 \cdot 5H_2O$, or $[V(H_2O)_4](SO_4)(HSO_4) \cdot H_2O$, was found to lose a mol. of water when allowed to stand over phosphorus pentoxide at room temp. and furnish the *tetrahydrate*, $HV(SO_4)_2 \cdot 4H_2O$, which is said not to be identical with J. T. Brierley's tetrahydrate, but rather an isomer. Aq. soln. of the salt furnishes the *hexahydrate*, $HV(SO_4)_2 \cdot 6H_2O$, which is said not to be identical with A. Stähler and H. Wirthwein's hexahydrate, but rather an isomer several of which are possible—e.g. $[V(SO_4)_2(H_2O)_2] \cdot 4H_2O$; $[V(SO_4)(H_2O)_4](HSO_4)$, etc.; and also the *octohydrate*, $HV(SO_4)_2 \cdot 8H_2O$, or $[V(H_4O_2)_4](SO_4)(HSO_4)$. A soln. in conc. sulphuric acid gives the *dihydrate*, $HV(SO_4)_2 \cdot 2H_2O$. Vanadous sulphate forms a series of complex salts with the alkali sulphates, forming a series of **vanadium-alums**, $RV(SO_4)_2 \cdot 12H_2O$. G. Canneri made a quinidine vanadium alum.

A. Piccini prepared **ammonium vanadous sulphate**, or *ammonium vanaditodisulphate*, or *disulphatovanadite*, $(\text{NH}_4)\text{V}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, by dissolving 5–10 grms. of ammonium metavanadate in sulphuric acid in the molar proportions 2 : 3 ; adding 100–200 c.c. of a sat. soln. of sulphur dioxide, and driving off the excess by heating the liquid on a water-bath ; making the liquid up to its original vol. with water, and electrolyzing the filtered soln. until the soln. is green without a trace of blue. The filtered soln. is then evaporated in vacuo for crystallization. A. Bültemann electrolyzed the soln. with a clean lead or platinum cathode and a porous diaphragm. The current efficiency is quantitative with cathodic current density up to 0.05 amp. per sq. cm. When crystallized from sulphuric acid, the crystals are blue, and when crystallized from neutral soln., red. This salt was made by A. Rosenheim and H. Yu Mong. J. Meyer and E. Markowicz observed that the pure alum is blue, and that the red colour is produced by traces of adsorbed trivalent vanadium hydroxide or oxide. R. Marc has previously shown that the adsorption of traces of foreign coloured substances by the surfaces of crystals may profoundly modify the colour. A. Piccini said that the violet or wine-red crystals are less intensely coloured than the corresponding chrome alum. The diakisdodecahedral crystals belong to the cubic system. The index of refraction for red-light is 1.5070 ; for yellow-light, 1.4751 ; for green-light, 1.4784 ; blue-light, 1.4839 ; and for violet-light, 1.4858. The crystals are extremely soluble in water ; 100 parts of water at 10° dissolve 39.76 parts of salt. J. Locke gave 1.210 mols per litre at 25°. The conc. aq. soln. is chrome-green, and on dilution with water it becomes greenish-yellowish brown, brownish-yellow, and finally pale yellow—if sulphuric or hydrochloric acid be added, the soln. becomes green. When confined over sulphuric acid, at 25°–30°, about eight-ninths of the water of crystallization is lost ; at 230° all is lost ; and at 300°, the salt decomposes. J. Locke gave 45° for the temp. at which the salt melts in its water of crystallization. In addition to vanadium ammonia alum, or the *dodecahydrate*, $\text{NH}_4\text{V}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, J. T. Brierley obtained the *tetrahydrate*, $(\text{NH}_4)\text{V}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$; and A. Stähler and H. Wirthwein found that hexahydrated hydrovanaditodisulphuric acid furnishes the *hexahydrate* of the ammonium salt, $(\text{NH}_4)\text{V}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$. By treating a soln. of vanadium pentoxide in dil. sulphuric acid in the molar proportion 1 : 2, reducing with sulphuric acid as in the case of the ammonium salt just described, adding sodium sulphate, and reducing electrolytically, A. Piccini found that the syrupy liquid so obtained can be crystallized by keeping it at 0° for a long time. The cubic crystals of **sodium vanadous sulphate**, or *sodium disulphatovanadite*, $\text{NaV}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, melt at 9° in their water of crystallization. This salt was made by A. Rosenheim and H. Yu Mong. A. Piccini prepared **potassium vanadous sulphate**, or *potassium disulphatovanadite*, $\text{KV}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, in a similar way. This salt was made by A. Rosenheim and H. Yu Mong, and E. Renschler. A. Bültemann said that the crystals behave like those of the ammonium salt. According to A. Piccini, the violet, diakisdodecahedral crystals belong to the cubic system ; they melt in their water of crystallization at 20°. The sp. gr. is 1.782 at 20°/4°. F. A. Henglein studied the mol. vol. of the potassium, rubidium, and cesium salts. They are freely soluble in water, and crystallize only at a low temp. below 10° ; 100 parts of water at 10° dissolve 1984 parts of salt. The dil. soln. are yellow ; the conc. soln., brownish-yellow ; and the syrupy liquid, green. In air, the soln. changes slowly. The crystals lose a part of their water of crystallization when confined over sulphuric acid ; at 100°, 35 per cent. is lost in 12 hrs. ; and all is expelled at 230°. The salt melts at 20° in its water of crystallization. A. Piccini obtained **rubidium vanadous sulphate** or *rubidium vanaditodisulphate*, or *disulphatovanadite*, $\text{RbV}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, in a similar manner. The cubic crystals are similar and show no cleavage. A. Bültemann found that the crystals behave like those of the ammonium salt. A. Piccini said that the sp. gr. is 1.915 at 20°/4°. The index of refraction for red-light is 1.4689 ; for green-light, 1.4758 ; and for violet-light, 1.4799. The absorption spectrum has bands in the red, green, and violet. The crystals are less soluble than the ammonium

salt, for 100 parts of water dissolve only 2.56 parts of salt at 10°. Dil. aq. soln. are yellow or brownish-yellow and become green when an acid is added. They do not change in weight with 24 hrs.' exposure to air; at 100°, they lose water and become yellowish-green; at 230°, the water is all expelled; and at 300°, decomposition occurs. J. Locke found that the salt melts at 64° in its water of crystallization. In addition to the *dodecahydrate* just described, A. Stähler and H. Wirthwein obtained the *hexahydrate*, $\text{RbV}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, as in the case of the corresponding ammonium salt. A. Piccini prepared **caesium vanadous sulphate** or *caesium disulphatovanadite*, $\text{CsV}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, by the method employed for the other alums. A. Bültemann said that the crystals from sulphuric acid soln. are amethyst-violet and from neutral soln., ruby-red. A. Piccini added that the diakisdodecahedral crystals are cubic, with no cleavage. The sp. gr. is 2.033 at 20°/4°. The index of refraction for red-light is 1.4757; for yellow-light, 1.4780; for green-light, 1.4807; and for violet-light, 1.4878. The crystals are sparingly soluble in cold water, for 100 parts of water at 10° dissolve only 0.464 part of salt. They are more soluble in hot water so that the salt is readily crystallized from aq. soln. The neutral soln. prepared by heat are always brownish-yellow, never green. They lose some water at 100°; all is lost at 230°; and decomposition occurs at 300°. J. Locke said that the salt melts at 82° in its water of crystallization. F. Ephraim studied the mol. vols. of the potassium, rubidium, and caesium vanadium alums. A. Piccini prepared **thallium vanadous sulphate**, or *thallium disulphatovanadite*, $\text{TlV}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, by the method employed for the other alums. The reddish-violet, diakisdodecahedral crystals belong to the cubic system. The sp. gr. is 2.342 at 20°/4°. The index of refraction for medium red-light is 1.5070; for green, 1.5138; and for violet, 1.5219. The salt readily dissolves in hot water, but less so in cold water. 100 parts of water at 10° dissolve 11.06 parts of the salt. The crystals gradually alter when exposed to air; and lose a part of their water over sulphuric acid; more is lost at 100°, and all at 230°. The residue is yellowish-green. J. Locke said that the salt melts at 48° in its water of crystallization.

According to I. Koppel and E. C. Behrendt,³ vanadyl sulphates or hypovanadic sulphates are produced by reducing quinquevalent to quadrivalent vanadium with sulphur dioxide. The normal hydrated vanadyl sulphate or hypovanadic sulphate, $(\text{VO})\text{SO}_4 \cdot n\text{H}_2\text{O}$, separates if the liquid contains up to 3 mols of sulphuric acid per mol of vanadium pentoxide reduced; and acid sulphates, $(\text{VO})\text{SO}_4 \cdot m\text{H}_2\text{SO}_4 \cdot n\text{H}_2\text{O}$, if more sulphuric acid be present. There are two forms of normal **vanadyl sulphate**, $(\text{VO})\text{SO}_4$, or $\text{V}_2\text{O}_4 \cdot 2\text{SO}_3$, or VO_2SO_3 —the one is soluble, the other insoluble. (i) The *soluble-form* was prepared by J. J. Berzelius by saturating dil. sulphuric acid with hydrated vanadium tetroxide, and evaporating the soln. to dryness at a gentle heat or in vacuo. If the soln. be allowed to evaporate spontaneously it appears green, and a green oxide separates out, the soln. then becomes blue. B. W. Gerland found that the insoluble form becomes soluble if heated with water in a sealed tube 150°–200° for some hours, and the solid can be obtained by the evaporation of the liquid over sulphuric acid. J. K. Crow obtained it by evaporating the soln. of the dihydrate; if the evaporation be slow, over conc. sulphuric acid, the insoluble sulphate may be formed. A. Guyard treated vanadium pentoxide with a mixture of alcohol, water, and sulphuric acid; or evaporated to dryness a conc. soln. of vanadic sulphate and alcohol. The blue, gum-like product is soluble in water and in alcohol. If heated for a long time at 100°, it becomes brown; and if heated out of contact with air, vanadium pentoxide remains. It dissolves in fused potassium hydrosulphate. (ii) The *insoluble-form*, according to B. W. Gerland, is obtained by boiling the soluble form or one of the hydrates for a short time with sulphuric acid. The anhydrous sulphate is thus precipitated as a heavy, greyish-green, sandy powder. According to C. Eichner, if vanadium pentoxide be heated with sulphuric acid in the presence of sodium or potassium sulphate, a precipitate of vanadyl sulphate first appears, and the double sulphates of quadri- and quinquevalent vanadium with potassium or soda. If ammonium

sulphate be present, ammonium vanadium sulphate is formed, and it decomposes at a high temp., and the products reduce quadrivalent vanadium to the tervalent state. I. Koppel and E. C. Behrendt said that the anhydrous sulphate undergoes a reversible transformation with boiling sulphuric acid: $V_2O_4 + SO_3 \rightleftharpoons SO_2 + V_2O_5$. According to B. W. Gerland, the microscopic crystals of the insoluble sulphate are quite insoluble in cold water even after several months' digestion; water acquires a pale blue colour after it has been boiled for a long time with the anhydrous sulphate. The solvent action of the water is favoured if a little hydrochloric or sulphuric acid be present; and all becomes soluble, if the salt be heated with a little water in a sealed tube at 150° – 200° ; with more water a slight green sediment is formed. Dil. alkaline soln. decompose the anhydrous sulphate, forming a brown hydroxide which is readily soluble in acids.

The equilibrium conditions of the hydrates of vanadyl sulphate have not been worked out. A number of hydrates were reported by B. W. Gerland, and I. Koppel and E. C. Behrendt, but some of them may be mixtures representing arbitrary stages in the process of dehydration. For example, by drying the pentahydrate at 100° , B. W. Gerland obtained the *hemitrihydrate*, $2VOSO_4 \cdot 3H_2O$, but I. Koppel and E. C. Behrendt obtained the *hemipentahydrate*, $2VOSO_4 \cdot 5H_2O$, under this condition. B. W. Gerland obtained the *hemitridecahydrate*, $2VOSO_4 \cdot 13H_2O$, by exposing the crystals of the hemiheptahydrate, to moist air; and I. Koppel and E. C. Behrendt, by mixing vanadium pentoxide with less than 3 mols of sulphuric acid, reducing the soln. with sulphur dioxide, and evaporating the liquid over sulphuric acid. The dark blue, prismatic crystals effloresce in dry air.

J. J. Berzelius prepared the *dihydrate*, $VOSO_4 \cdot 2H_2O$, by reducing a soln. of vanadium pentoxide in a warm mixture of equal parts of sulphuric acid and water, and evaporating the filtrate to a small vol. The pale blue crystalline crust is probably an acid salt because alcohol extracts acid from it; the mother-liquor is decanted, and the crust washed with alcohol, and then left in alcohol for some time. The product is thus converted into a bulky sky-blue powder consisting of minute scaly crystals; this is washed in alcohol, and dried in vacuo over sulphuric acid or calcium chloride. This salt was also prepared in a similar way by J. K. Crow, and I. Koppel and E. C. Behrendt; but B. W. Gerland did not succeed in making this hydrate. I. Koppel and E. C. Behrendt did not make it by evaporating a soln. of the sulphate at different temp., or by dehydrating one of the higher hydrates. J. J. Berzelius said that in moist air, the dry salt deliquesces to a syrup, which, on exposure to air at ordinary temp., deposits rhombic crystals the colour of hydrated cupric sulphate. The presence of a slight excess of sulphuric acid facilitates the crystallization. When heated in a closed vessel, water, sulphur dioxide, and sulphur trioxide are successively evolved, and molten vanadium pentoxide remains. It dissolves very slowly in water at 10° ; but the process of dissolution is faster in water at 60° , and still more rapid in boiling water, forming a blue soln. It deliquesces in warm moist air. It is only slightly soluble in absolute alcohol, but quite soluble in alcohol of sp. gr. 0.835. B. W. Gerland prepared blue crystals of the *hemiheptahydrate*, $2VOSO_4 \cdot 7H_2O$, by heating the insoluble normal sulphate with water in a sealed tube at 100° – 200° ; evaporating the liquid to dryness over sulphuric acid; and allowing it to stand for a week moistened with alcohol. J. K. Crow obtained this hydrate by evaporating a soln. of hydrated vanadium tetroxide in sulphuric acid; treating the residue with absolute alcohol until all acid is removed, and pressing the deliquescent mass between filter-paper. I. Koppel and E. C. Behrendt could not obtain the heptahydrate in this way, but they prepared it by evaporating at 80° a soln. of vanadyl sulphate as nearly neutral as possible. The salt was recrystallized from water at 80° . If the soln. be evaporated at 90° , or if the heptahydrate be dried at 90° , dark blue crystals of the *trihydrate*, $VOSO_4 \cdot 3H_2O$, are formed. According to B. W. Gerland, the liquid, obtained by heating the insoluble anhydrous sulphate with water in a sealed tube at 150° – 200° , when evaporated over sulphuric acid furnishes a blue transparent, gummy mass

which when moistened with alcohol and left under a loose cover, gradually assumes a crystalline form; the analysis corresponds with the *pentahydrate*, $\text{VOSO}_4 \cdot 5\text{H}_2\text{O}$. It can be recrystallized by evaporating the alcoholic soln. at a low temp. I. Koppel and E. C. Behrendt obtained it from the soln. obtained by allowing the hydrated acid sulphate to deliquesce in air; the crystals are washed by alcohol, and ether. The salt effloresces in air. At 100° , it loses $2\frac{1}{2}$ mols of water; at 125° , it loses another mol of water; and at 150° , it forms the monohydrate, $\text{VOSO}_4 \cdot \text{H}_2\text{O}$.

I. Koppel and E. C. Behrendt prepared **vanadyl dihydrotrisulphate**, $2(\text{VO})\text{SO}_4 \cdot \text{H}_2\text{SO}_4$, by heating one of the hydrates at 200° ; or by heating the pentahydrate with four times its weight of conc. sulphuric acid at 190° . The green, sandy powder consists of microscopic, quadratic plates, and is sparingly soluble in water. The *hemihydrate*, $2(\text{VO})\text{SO}_4 \cdot \text{H}_2\text{SO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, was obtained as a grey, sandy powder consisting of microscopic, four-sided plates, by evaporating a soln. of the sulphuric acid soln. of the sulphate at 175° , or drying the pentahydrate at this temp. It is very slowly dissolved by water. B. W. Gerland, and I. Koppel and E. C. Behrendt prepared the *dihydrate*, $2(\text{VO})\text{SO}_4 \cdot \text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, by evaporating the sulphuric acid soln. of the sulphate at 150° , or drying the pentahydrate at this temp. The pale blue, quadratic plates are slowly dissolved by cold water, and rapidly by hot water. The crystals slowly deliquesce in air. The pale blue crystalline crust obtained by J. J. Berzelius in the preparation of dihydrated vanadyl sulphate, when washed with cold water or alcohol, and dried over sulphuric acid, furnishes the *trihydrate*, $2(\text{VO})\text{SO}_4 \cdot 2\text{H}_2\text{SO}_4 \cdot 3\text{H}_2\text{O}$. B. W. Gerland obtained it by evaporating the blue soln. of vanadium tetroxide in dil. sulphuric acid to a syrup; mixing it with conc. sulphuric acid; and, when cold, removing the excess of acid, washing with cold water or alcohol, and drying in vacuo over sulphuric acid. The salt was also prepared by J. K. Crow. I. Koppel and E. C. Behrendt recommended washing the salt with alcohol, and ether. The pale blue needles absorb moisture from the air, forming a thick, blue liquid. At 100° , the salt slowly gives off water. It dissolves very slowly in cold water, more rapidly in hot water; and it is very sparingly soluble in alcohol. J. K. Crow prepared the *pentahydrate*, $2(\text{VO})\text{SO}_4 \cdot \text{H}_2\text{SO}_4 \cdot 5\text{H}_2\text{O}$, by evaporating on a water-bath a soln. of vanadium tetroxide in sulphuric acid; draining the pale blue crystals on a porous tile; washing with ether, and pressing between bibulous paper. I. Koppel and E. C. Behrendt also prepared this salt. J. K. Crow found that the microscopic, pale blue, quadratic plates deliquesce in air to a blue syrup; they dissolve slowly in cold water, and rapidly in hot water; they are very sparingly soluble in absolute alcohol, and insoluble in ether. B. W. Gerland reported the *tetradecahydrate*, $2(\text{VO})\text{SO}_4 \cdot \text{H}_2\text{SO}_4 \cdot 14\text{H}_2\text{O}$, to be formed by evaporating a soln. of the trihydrate to a syrup; mixing the residue with conc. alcohol, and repeatedly washing the residue with alcohol. A blue waxy mass is obtained. Neither J. K. Crow, nor I. Koppel and E. C. Behrendt could prepare this hydrate. W. T. Schaller described a *pentadecahydrate* occurring as a mineral in blue granular aggregates, spherulites, or mammillary masses as an efflorescence on patronite; it has composition $\text{V}_2\text{O}_4 \cdot 3\text{SO}_3 \cdot 16\text{H}_2\text{O}$, or $2\text{VOSO}_4 \cdot \text{H}_2\text{SO}_4 \cdot 15\text{H}_2\text{O}$, at Minasragra, Peru; and he called it **minasragrite**. It is triclinic or monoclinic and pleochroic with α , deep blue; β , pale blue; and γ , colourless. The indices of refraction are $\alpha=1.515$, $\beta=1.525$, and $\gamma=1.545$; E. S. Larsen gave $\alpha=1.518$, $\beta=1.530$, and $\gamma=1.542$. The optical character is negative. It is very soluble in cold water.

J. J. Berzelius, A. Guyard, and B. W. Gerland made a complex salt with potassium sulphate. I. Koppel and E. C. Behrendt found that vanadyl sulphate forms complex salts with the sulphates of ammonium and the alkalis. If a soln. of vanadium pentoxide in an excess of dil. sulphuric acid be reduced with sulphur dioxide, and then treated with 2-3 mols of ammonium sulphate; the mixture evaporated first on the water-bath and then at a higher temp., until crystallization sets in; and the product washed with cold water, then with alcohol, and ether, and dried over conc. sulphuric acid, pale blue, microscopic tablets of **ammonium**

divanadyl trisulphate, $(\text{NH}_4)_2\text{SO}_4 \cdot 2\text{VOSO}_4 \cdot \text{H}_2\text{O}$, are formed. The crystals are stable in dry air, but deliquesce in moist air; they are slowly but copiously dissolved by cold water. If dried at 175° to constant weight, all the water of crystallization is expelled. The corresponding **potassium divanadyl trisulphate**, $\text{K}_2\text{SO}_4 \cdot 2\text{VOSO}_4$, was obtained in a similar manner. It behaves very like the ammonium salt, and is freely soluble in water. Similarly with **sodium divanadyl trisulphate**, $\text{Na}_2\text{SO}_4 \cdot 2\text{VOSO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$.

By treating a conc. aq. neutral soln. of ammonium divanadyl trisulphate with alcohol, **ammonium vanadyl disulphate**, $(\text{NH}_4)_2\text{SO}_4 \cdot \text{VOSO}_4 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, is formed; and the same salt is produced when a soln. of 11.7 grms. of ammonium metavanadate, 10 c.c. conc. sulphuric acid, and 100 c.c. of water is reduced with sulphur dioxide, and then treated with alcohol. The deep blue, oily liquid is separated from the upper layer, which also forms a precipitate. When the oil has stood for about 8 days, during which time it has been in contact with alcohol, renewed daily, it furnishes a dark blue microcrystalline powder which is freely soluble in water, and in a mixture of alcohol and conc. sulphuric acid. It loses all its water at 175° . By a similar method, **potassium vanadyl disulphate**, $\text{K}_2\text{SO}_4 \cdot \text{VOSO}_4 \cdot 3\text{H}_2\text{O}$, was obtained with properties like those of the ammonium salt; similarly with **sodium vanadyl disulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{VOSO}_4 \cdot 4\text{H}_2\text{O}$. According to A. Rosenheim and H. Yu Mong, the ammonium, sodium, and potassium sulphates of quadrivalent vanadium decompose in boiling sulphuric acid: $2\text{V}^{\text{IV}} = \text{V}^{\text{III}} + \text{V}^{\text{V}}$, yielding a crystalline sulphate, $\text{V}_2\text{O}_3(\text{SO}_4)_2$, and a series of insoluble double sulphates, $\text{MV}(\text{SO}_4)_2$. C. Eichner observed that the appearance of trivalent vanadium in these experiments is due to the presence of ammonium vanadate in the vanadium pentoxide—*vide supra*, the action of sulphuric acid on vanadium pentoxide in the presence of ammonium sulphate.

J. J. Berzelius evaporated a nitric acid soln. of vanadyl sulphate to dryness and obtained a red, deliquescent crystalline mass, which later observations show was **vanadium trioxydisulphate**, $\text{V}_2\text{O}_5 \cdot 2\text{SO}_3$, or $\text{V}_2\text{O}_3(\text{SO}_4)_2$. C. J. Fritzsche made it by dissolving hydrated vanadium pentoxide in 20 parts of conc. sulphuric acid at 100° , and heated the mixture rapidly to drive off fumes of sulphur trioxide. The product is washed with conc. sulphuric acid, pressed on porous tiles to remove the excess of acid, and dried over sulphuric acid. B. W. Gerland made the same compound by heating the dioxytrisulphate to 326° . The sulphate was also made by L. Münzing, A. Guyard, and A. Rosenheim and H. Yu Mong. The pale red crystals are stable in the absence of moisture; and when heated in a retort they give off fuming sulphuric acid. They deliquesce in moist air and are decomposed by water with the separation of hydrated vanadium pentoxide. J. J. Berzelius found that when a soln. of vanadium pentoxide in conc. sulphuric acid is diluted with half its vol. of water, and the excess of sulphuric acid expelled at the lowest possible temp., **vanadium dioxytrisulphate**, $\text{V}_2\text{O}_5 \cdot 3\text{SO}_3$, or $\text{V}_2\text{O}_2(\text{SO}_4)_3$, is formed. B. W. Gerland added a little perchloric acid in order to prevent reduction by the flame gases, and the formation of insoluble vanadyl sulphate. The ruby-red crystals are probably octahedra. In air, they rapidly deliquesce to a brown syrup which mixes with water or alcohol without turbidity. It passes into the trioxydisulphate at about 326° . A. Ditte said that the *tetrahydrate*, $\text{V}_2\text{O}_5 \cdot 3\text{SO}_3 \cdot 4\text{H}_2\text{O}$, or $\text{V}_2\text{O}_2(\text{SO}_4)_3 \cdot 4\text{H}_2\text{O}$, or $\text{V}_2(\text{OH})_4(\text{SO}_4)_3 \cdot 2\text{H}_2\text{O}$, is formed in hygroscopic, small, yellow crystals from a soln. of vanadium pentoxide in hot conc. sulphuric acid. L. Münzing said that A. Ditte's salt is the same as that prepared by J. J. Berzelius—*vide supra* for V. Auger's observations. P. Pascal gave 115×10^{-5} for the mol. magnetic susceptibility of soln. of $\text{V}_2\text{O}_2\text{SO}_4$ —*vide supra*, vanadium—and N. Perrakis also measured the magnetic properties. L. E. Stout and G. C. Whitaker, and N. H. Furman found the acidified soln. can be kept months without change. V. Auger and C. Eichner observed that when a sulphuric acid soln. of vanadium pentoxide is slowly reduced, there is a point at which the orange soln. becomes dark blue changing to a clear blue when the acid vanadyl sulphate is formed. If the orange soln.

and the blue soln. are mixed in equal proportions, an indigo-blue soln. is produced. The spectral observations of the soln. indicate that a *vanadic vanadyl sulphate* is formed, $\text{HSO}_4 \cdot \text{VO}(\text{OH}) \cdot \text{SO}_4 \cdot \text{V}(\text{OH})_2 \cdot \text{HSO}_4$; but the salt could not be isolated.

B. W. Gerland found that **ammonium vanadium tetroxydisulphate**, or *ammonium tetroxydisulphatodivanadate*, $(\text{NH}_4)_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot 2\text{SO}_3 \cdot 4\text{H}_2\text{O}$, is formed from a mixture of conc. soln. of ammonium sulphate and vanadium dioxide trisulphate, evaporated over sulphuric acid. The reddish-brown needles are freely soluble in cold water without the separation of vanadium pentoxide. He made **potassium vanadium tetroxydisulphate**, or *potassium tetroxydisulphatodivanadate*, $\text{K}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot 2\text{SO}_3 \cdot 6\text{H}_2\text{O}$, in an analogous manner. A. Werner and R. Huber obtained a complex of the type **vanadium chromic dichlorodecaquodisulphate**, $[\text{CrCl}_2(\text{H}_2\text{O})_4](\text{SO}_4)_2[\text{V}(\text{H}_2\text{O})_6]$, and with Cr, Fe, or Al in place of V; but J. Meyer and L. Speich did not obtain the corresponding selenate.

§ 24. Vanadium Carbonates, Nitrates, and Phosphates

I. Koppel and co-workers¹ reported that **ammonium vanadyl carbonate**, $7\text{VO}_2 \cdot 2(\text{NH}_4)_2\text{O} \cdot 16\text{H}_2\text{O}$, is obtained by dissolving ammonium metavanadate in the minimum quantity of sulphuric acid and reducing with sulphur dioxide, neutralizing with ammonia, and, after evaporating to a small bulk, dropping slowly into a cold sat. soln. of ammonium carbonate until the precipitate formed redissolves only slowly. The liquid is then filtered and conc. over sulphuric acid. It forms violet crystals somewhat sparingly soluble in water, soluble in alkalis to a brown soln., and in acids to a blue soln.; even in closed vessels it decomposes slowly with evolution of ammonia.

J. J. Berzelius² found that when the hydrated lower oxides of vanadium, or vanadium tetroxide are dissolved in dil. nitric acid, a blue soln. is obtained which is not further oxidized by even boiling nitric acid; but when spontaneously evaporated, the soln. becomes green and deposits red crystals which still retain a little nitric acid. According to A. Guyard, the tetroxide is oxidized by nitric acid to the pentoxide, and a mixture of nitric acid and alcohol does not reduce vanadium

pentoxide. He added that a soln. of **vanadyl nitrate** can be obtained by double decomposition between silver or barium nitrate and vanadyl chloride or sulphate respectively. If the soln. be evaporated, the nitrate is decomposed with the separation of the pentoxide. J. J. Berzelius also found that dil. nitric acid dissolves a little vanadic acid, forming a yellow soln. which, when spontaneously evaporated, leaves a reddish mass from which water dissolves a little **vanadic nitrate**. J. Meyer and R. Backa found that by moistening the hexamminotrichloride or tribromide with nitric acid, **vanadium hexamminotrintrate**, $[V(NH_3)_6](NH_3)_3$, is formed. The properties resemble those of the hexamminotrichloride (*q.v.*). S. M. Tanatar and E. K. Kurowsky prepared **beryllium oxynitratovanadate**, $Be(NO_3)_mBe_3(VO_4)_2 \cdot nBeO$.

When a mixture of vanadium tetra- and penta-oxides is boiled with a soln. of an alkali phosphate, **hypovanadatovanadatophosphates**, or *vanadylvanadium-phosphates*, are produced. They are also obtained by melting the mixed oxides with alkali phosphates while air is excluded. J. J. Berzelius³ evaporated a mixed soln. of sodium hydrophosphate and vanadyl phosphate with nitric acid, and obtained yellow crystalline masses which were slowly dissolved by water, and the soln. dried to a yellow viscid mass, soluble in water. J. Howaldt, and J. Meisel consider that the so-called vanadylvanadium phosphates or the hypovanadato-vanadatophosphates are not usually chemical individuals, but rather isomorphous mixtures of vanadates and phosphates in which the hypovanadate radicle plays the part of a strong base like K_2O , or $(NH_4)_2O$. O. W. Gibbs prepared **sodium hypovanadatohexadecavanadatoicosiphosphate**, $8Na_2O \cdot V_2O_4 \cdot 8V_2O_5 \cdot 10P_2O_5 \cdot 74H_2O$, by cooling a boiling soln. of calcined ammonium metavanadate and sodium hydrophosphate. The green, scaly crystals are insoluble in water. W. T. Schaller described green, rectangular plates of a mineral from Sincos, Peru, and he called it **sincosite**. Its analysis corresponds with **calcium hypovanadatophosphate**, $CaO \cdot V_2O_4 \cdot P_2O_5 \cdot 5H_2O$. The sp. gr. is 2.84. The crystals closely resemble those of torbernite in shape, habit, and optical properties. Most of the crystals are uniaxial, but some are biaxial; nearly all become biaxial on keeping. The biaxial form probably corresponds with a lower hydrate, which reverts to the uniaxial form when stored in a desiccator over dil. sulphuric acid. E. S. Larsen also examined the mineral. The indices of refraction are $\epsilon=1.655$ and $\omega=1.680$, or $\alpha=1.675$, $\beta=1.690$, and $\gamma=1.693$. The optical axial angle $2E=16^\circ$ to 83° . The pleochroism is shown by its colours, colourless, pale yellow, or greyish-green. O. W. Gibbs prepared **potassium hexahypovanadatododecavanadatotetracosiphosphate**, $7K_2O \cdot 6V_2O_4 \cdot 6V_2O_5 \cdot 12P_2O_5 \cdot 40H_2O$, by cooling a boiling soln. of potassium tetravanadate and an excess of potassium hydrophosphate. The dark green, cubic crystals are decomposed by water, and a hot aq. soln. yields green crystals of **potassium heptavanadatododecavanadatotetracosiphosphate**, $7K_2O \cdot 7V_2O_4 \cdot 6V_2O_5 \cdot 12P_2O_5 \cdot 52H_2O$. It is related to uranite. It is strongly pleochroic; the index of refraction $\epsilon=1.655$ and $\omega=1.680$. The sp. gr. is 2.84, and the hardness low. It is soluble in dil. acids. O. W. Gibbs obtained **mercurous hypovanadatovanadatophosphate** by the action of mercurous chloride on ammonium hypovanadatohexacontavanadatotetraphosphate.

E. F. Smith and F. F. Exner reported that **ammonium diphosphatovanaditungstate**, $(NH_4)_2O \cdot P_2O_5 \cdot V_2O_3 \cdot WO_3 \cdot nH_2O$, occurs in the mother-liquor remaining after digesting wolframite with aqua regia. The hydrated tungstic acid is dissolved in aq. ammonia, and the ammonium paratungstate crystallized out. The fractional crystallization of the mother-liquor furnishes this salt in black, octahedral crystals. A. Rogers obtained **ammonium tetraphosphatododecavanaditotetratessaracontatungstate**, $15(NH_4)_2O \cdot 2P_2O_5 \cdot 6V_2O_3 \cdot 44WO_3 \cdot 106H_2O$, by boiling for 6 hrs. a mixture of a gram of ammonium phosphate, 15 grms. of ammonium tungstate, 1.1 grms. of vanadium trioxide, 25 c.c. aq. ammonia, and 700 c.c. of water, evaporating the soln. to a sp. gr. 1.030, and allowing it to stand for some time. The black octahedra are soluble in water; insoluble in alcohol, ether, and benzene; dil. nitric and hydro-

chloric acids produce a small change of colour when boiled with the crystals; and boiling conc. hydrochloric acid gives a yellow precipitate but no chlorine. A. Rogers and E. F. Smith made **ammonium stannic phosphatovanaditotungstate** by the action of a boiling soln. of 30 grms. of ammonium tungstate and 100 c.c. of water on an excess of stannic hydroxide, and then adding 2 grms. of ammonium phosphate and hydrated vanadium trioxide. Black, octahedral crystals are obtained on evaporating the soln.

According to J. J. Berzelius,⁴ vanadium tetroxide dissolved in a slight excess of phosphoric acid furnishes a blue soln., which, when evaporated below 50°, furnishes small blue crystals of **vanadyl phosphate**. They are to be washed free from phosphoric acid by alcohol. The crystals deliquesce rapidly in air. The water is all expelled by heat leaving a white, porous, spongy, deliquescent mass which forms a blue soln. with water; at a higher temp., the salt fuses, forming a black mass, thought to be *vanadyl pyrophosphate*, which is insoluble in water. The conc. soln. of vanadyl phosphate mixed with anhydrous alcohol, gives a gelatinous, greyish-blue precipitate which is thought to be a basic salt. It does not deliquesce in air and is partially dissolved by water. If this phosphate be dissolved in nitric acid, and the soln. evaporated, nitrous fumes are evolved, and the syrupy liquid, on cooling, forms a lemon-yellow, crystalline crust. The nitric acid is removed by washing with cold water. The salt is slowly soluble in water, forming a yellow soln. Water of crystallization is expelled by heat. J. J. Berzelius, and C. Friedheim and M. Szamatolsky made yellow crystals of **vanadyl orthophosphate**, $H_2(VO_2)PO_4 \cdot 4\frac{1}{2}H_2O$, or $V_2O_5 \cdot P_2O_5 \cdot 2H_2O \cdot 9Aq.$, by dissolving vanadium pentoxide in syrupy phosphoric acid, allowing the soln. to stand for about 12 hrs., and evaporating in vacuo. The vanadates, arsenates, and phosphates are replaced isomorphously in many minerals. This subject has been studied by M. Amadori with the lead minerals—*vide supra*. The m.p. of mixtures of lead orthophosphate and orthovanadate were found to be:

Vanadate	0	25	50	85	100 per cent.
M.p.	1114°	996°	980°	962°	952°

for mixtures of fluopyromorphite and fluovanadinite:

Fluovanadinite	0	25	50	75	90	100 per cent.
M.p.	1098°	1052°	1012°	970°	935°	916°

and for mixtures of chloropyromorphite and chlorovanadinite:

Chlorovanadinite	0	20	50	80	100 per cent.
M.p.	1156°	1116°	1056°	1012°	990°

These results and optical observations agree with the complete isomorphism of these salts. N. Collie described a **calcium lead chlorovanadatophosphate** or a *calcium vanadatopyromorphite* occurring as a mineral in Leadhills.

A. Ditte reported the *vanadatophosphoric acids* or *phosphatovanadic acids*: $V_2O_5 \cdot P_2O_5 \cdot 14H_2O$, and $2V_2O_5 \cdot 3P_2O_5 \cdot 9H_2O$; and O. W. Gibbs, $6V_2O_5 \cdot 7P_2O_5 \cdot 3H_2O \cdot 34Aq.$, but C. Friedheim could not confirm this, and assumed that the reports are based either on analyses of impure materials, or inadequate methods of analysis. According to C. Friedheim, the so-called vanadatophosphoric acids and their salts can be divided into two groups: The members of the one group, called the **luteo-vanadatophosphates**—from *luteus*, yellow—are yellow, and indefinitely crystalline. The alkali salts are not very soluble in water, and are decomposed by that liquid. They were made by J. J. Berzelius, O. W. Gibbs, A. Ditte, and C. Friedheim, (1) from a mixture of phosphoric acid and vanadium pentoxide; (2) from phosphates and vanadates in an acid soln.; (3) from phosphates and vanadium pentoxide; and (4) from vanadates and phosphoric acid. For example, O. W. Gibbs, and C. Friedheim prepared **ammonium luteovanadatophosphate**, $(NH_4)_2O \cdot V_2O_5 \cdot P_2O_5 \cdot H_2O$, or $(NH_4)H(VO_2)PO_4$, by evaporating a soln. of ammonium metavanadate with five or six times the theoretical amount of phosphoric acid introduced

as ammonium phosphate and nitric acid. The pale yellow crystalline mass is sparingly soluble in water, and when the yellow soln. is heated, it decomposes, becoming orange or red in colour. Salts of silver, barium, mercury, and lead furnish mixed precipitates of phosphates and vanadates. C. Friedheim also prepared the hydrate $(\text{NH}_4)\text{H}(\text{VO}_2)\text{PO}_4 \cdot 4\text{H}_2\text{O}$. A soln. of ammonium metavanadate forms with dil. phosphoric acid a yellow or reddish-yellow **ammonium luteodivanadato-phosphate**, $(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, or $(\text{NH}_4)(\text{VO}_2)_2\text{PO}_4 \cdot 7\text{H}_2\text{O}$. It is soluble in a little water without decomposition.

By evaporating the mother-liquid left after the preparation of the purpureo-salt, A. Ditte obtained yellow six-sided prisms with the composition $5(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 4\text{P}_2\text{O}_5 \cdot 24\text{H}_2\text{O}$; and a mixed hot soln. of ammonium hexavanadate and phosphate, yellow plates of $5(\text{NH}_4)_2\text{O} \cdot 3\text{V}_2\text{O}_5 \cdot 2\text{P}_2\text{O}_5 \cdot 24\text{H}_2\text{O}$. C. Friedheim could not verify this, and suggested that these formulæ are the result of inaccurate analyses. By fusing a mixture of phosphoric acid and vanadium pentoxide, J. J. Berzelius obtained a pale yellow glass soluble in water—if a trace of vanadium tetroxide be present, the colour is uranium-green.

C. Friedheim and K. Michaelis obtained a yellowish-green mass of **potassium vanadatophosphate**, $\text{K}_2(\text{VO}_2)\text{PO}_4$, by evaporating a soln. of equimolar proportions of potassium dihydrophosphates and metavanadate on a water-bath. The soln. gives precipitates with barium chloride and silver nitrate. They also prepared **potassium luteodivanadatodiphosphate**, $3\text{K}_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 2\text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, from the mother-liquor of the purpureodocosivanadatodiphosphate. C. Friedheim and M. Szamatolsky prepared **potassium luteodivanadatophosphate**, $\text{K}_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, from a soln. of potassium metavanadate in dil. phosphoric acid. A. Rosenheim and K. H. Yang found that with soln. containing the different proportions of phosphoric acid, the solid phase had the molar composition $\text{P}_2\text{O}_5 \cdot \text{V}_2\text{O}_5 \cdot \text{H}_2\text{O}$:

H_3PO_4	22.7	31.7	42.0	46.5	57.0	84 per cent.
Solid phase	1.08:1:7.3	1.05:1:6.8	1.15:1:4.3	1.18:1:6.3	1.15:1:7.0	1.24:1:7.2

and by using soln. of phosphates and vanadates sufficiently dilute—say 2 to 3N—it is possible to prepare **ammonium vanadatophosphate**, $(\text{NH}_4)_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$; **ammonium divanadatophosphate**, $(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$; **potassium vanadatophosphate**, $2\text{K}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5$; and $1\frac{1}{2}\text{K}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 2\frac{1}{2}\text{H}_2\text{O}$; and **potassium divanadatophosphate**, $\text{K}_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$. The sodium salts were not prepared. The electrical conductivity of the potassium divanadatophosphate gave from $v=128$, $\lambda=255$; $v=256$, $\lambda=285$; $v=512$, $\lambda=316$; and $v=1024$, $\lambda=328$.

O. W. Gibbs reported **silver luteodivanadatodiphosphate**, $2\text{Ag}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, to be formed by adding an excess of silver nitrate to a soln. of ammonium vanadatophosphate mixed with some ammonium phosphate. The sulphur-yellow, crystalline precipitate was washed with very dil. nitric acid. It is sparingly soluble in hot and cold water. He also obtained yellow **mercurous luteovanadatophosphate** in an analogous way.

The members of the other group, called the **purpureovanadatophosphates**—from *purpura*, purple—are deep red and form alkali salts which can be recrystallized from aq. soln. They are prepared by dissolving vanadium pentoxide in alkali phosphates or alkali vanadates in phosphoric acid, without heating the mixture to a high temp. For example, C. Friedheim and M. Szamatolsky dissolved vanadium pentoxide in a warm soln. of ammonium phosphate, and obtained garnet-red, octahedral crystals of **ammonium purpureododecavanadatophosphate**, $7(\text{NH}_4)_2\text{O} \cdot 12\text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 2\text{H}_2\text{O} \cdot 24\text{Aq}$. The salt is fairly soluble in water, and it can be crystallized from the soln. at 50° – 60° . The soln. is decomposed by acids and alkali-lees; and salts of the heavy metals give mixed precipitates.

A. Ditte's salt, $3(\text{NH}_4)_2\text{O} \cdot 4\text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 16\text{H}_2\text{O}$, is supposed by C. Friedheim to be the purpureo salt just described; and the same remark applies to O. W. Gibb's salt, $20\text{V}_2\text{O}_5 \cdot \text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O} \cdot 53\text{Aq}$. J. J. Berzelius also obtained a red compound by evaporating the red soln. of vanadium pentoxide in phosphoric acid.

C. Friedheim and M. Szamatolsky obtained **potassium purpureododecavanadato-phosphate**, $7K_2O.12V_2O_5.P_2O_5.26H_2O$, from the ammonium salt and potassium chloride; and C. Friedheim and K. Michaelis, **potassium purpureodocosivanadato-diphosphate**, $13K_2O.22V_2O_5.2P_2O_5.58H_2O$, by warming a dil. soln. of potassium dihydrophosphate and metavanadate, mixed in the cold. On cooling the liquid, rectangular plates of dark brown crystals separate; a second crop of crystals furnishes **potassium purpureopentacosivanadatodiphosphate**, $15K_2O.25V_2O_5.2P_2O_5.76H_2O$. C. Friedheim regarded the luteo-compounds as salts in which the vanadium acts as a base towards the stronger phosphoric acid:

Vanadylphosphate

Vanadatophosphate

Divanadatophosphate

where R represents NH_4 or a univalent metal. The purpureo-compounds are considered to be acid vanadates in which the phosphoric acid is in part replaced by vanadic acid.

A series of salts of the heteropoly acids—**phosphatovanadatotomybdates**—were prepared by O. W. Gibbs,⁵ H. Jacoby, F. Toggenburg, P. Schulz, A. Hinsen, H. Stamm, etc. The list is quite a long one. Unfortunately, the available tests for chemical individuality are quite inadequate. In some cases a product seems to have had a different composition every time it has been made and analyzed. In a number of cases, studied by H. Jacoby, and F. Toggenburg, the ratios $V_2O_5 : MoO_3$ is 3 : 15, 4 : 14, 5 : 13, 6 : 12, and 7 : 11, so that the sum of the two components is 18. Very few regularities have been noticed, so that the subject is in an empirical stage. The only thing possible, therefore, is a tabulation of the results. It is convenient to refer them to decreasing proportions of molybdic acid, with decreasing proportions of vanadic and phosphoric acids as supplementary groups. J. R. Cain and J. C. Hostetter concluded that in the co-precipitation of vanadic acid and ammonium phosphomolybdate there is a partition of the vanadic acid between the soln. and the solid phase; the maximum adsorption by the solid phase occurs between 40° and 50° with 2N- HNO_3 soln. The effect of dilution is to lower the adsorption, and the effect is hindered in the presence of ammonium nitrate. The so-called ammonium phosphatovanadatotomybdates probably form a series of solid soln. in which the end members are ammonium phosphomolybdate and ammonium phosphovanadate. This is in agreement with the observations of E. T. Wherry on the optical properties of salts of complex acids.

O. W. Gibbs prepared **ammonium tetraphosphatodivanadatoctotessaramolybdate**, $7(NH_4)_2O.2P_2O_5.V_2O_5.48MoO_3.30H_2O$, as an orange-red, crystalline precipitate by boiling a soln. of ammonium phosphomolybdate and metavanadate in hydrochloric acid. It is sparingly soluble in cold water, and decomposed by hot water; H. Jacoby could not obtain this salt, but obtained instead **ammonium tetraphosphatodivanadatoctotessaramolybdate**, $7(NH_4)_2O.2P_2O_5.V_2O_5.42MoO_3.42H_2O$. P. Schulz prepared red crystals **ammonium diphosphatohexavanadatoctodecamolybdate**, $6(NH_4)_2O.P_2O_5.3V_2O_5.18MoO_3.40H_2O$, by adding 48 grms. of ammonium metavanadate to a soln. of phosphatotomybdic acid heated on a water-bath. When the cold soln. is treated with a sat. soln. of ammonium chloride, red crystals are formed. He also obtained $7(NH_4)_2O.P_2O_5.3V_2O_5.18MoO_3.31H_2O$, by mixing aq. soln. of the component salts. The salt can be crystallized unchanged from its aq. soln. With barium chloride, the aq. soln. gives the ammonium barium salt, $2(NH_4)_2O.4BaO.P_2O_5.17MoO_3.46H_2O$; and with ammonia, the aq. soln. is partially decomposed. F. Toggenburg produced **ammonium diphosphatohexavanadatoheptadecamolybdate**, $6(NH_4)_2O.P_2O_5.3V_2O_5.17MoO_3.40H_2O$, by dissolving 7.8 grms. of ammonium metavanadate, 3.84 grms. of molybdic acid in 500 c.c. of warm water, and then adding 21.35 c.c. aq. ammonia of sp. gr. 0.956. The red, octahedral crystals are soluble in water: the

conc. soln. gives a small precipitate with ammonia; and with potassium chloride a crystalline precipitate slowly forms. A. Düsterwald could not make this by direct synthesis; but he obtained **ammonium diphosphatoctovanadatoheptadecamolybdate**, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 17\text{MoO}_3 \cdot 40\text{H}_2\text{O}$.

H. Jacoby prepared red crystals of **ammonium diphosphatodecavanadato-pentadecamolybdate**, $2(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 32\text{H}_2\text{O}$, by evaporating the soln. produced by the action of a conc. soln. of mercuric chloride on a sat. soln. of the phosphatododecavanadatododecamolybdate. If the mother-liquor remaining after the preparation of the 42-molybdate be treated with ammonia, and the soln. rapidly cooled, brown crystals of **ammonium diphosphatohexavanadatopentadecamolybdate**, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 41\text{H}_2\text{O}$, are formed; and H. Jacoby also obtained $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 39\text{H}_2\text{O}$, by warming a soln. of yellow ammonium phosphatomolybdate with ammonium vanadate for a long time on a water-bath; or by mixing 21.1 grms. of ammonium metavanadate, 64.8 grms. of molybdic acid, and 6.9 grms. of ammonium dihydrophosphate with water and adding 10.67 c.c. to aq. ammonia of sp. gr. 0.956 soln. furnishes ruby-red crystals. A. Düsterwald prepared **ammonium diphosphatohexavanadatopentadecamolybdate**, $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 39\text{H}_2\text{O}$, as well as $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 37\text{H}_2\text{O}$. P. Schulz obtained the *icosihydrate* by adding ammonium 3:7-molybdate to a boiling soln. of vanadium phosphate, and afterwards evaporating the liquid over sulphuric acid. H. Lahrman also prepared this salt, and he showed that the composition was not changed by five fractional crystallizations. The sp. gr. of H. Jacoby's salt is 2.9045; and the sp. gr. of the deep brownish-red aq. soln., sat. at 18°, is 1.144, and 100 c.c. contain 24.45 grms. of salt. Hydrogen dioxide colours the soln. first black and then green; boiling hydrochloric acid reduces the soln.; conc. sulphuric acid gives a yellow soln.; ammonia gives an orange-yellow liquid which with an excess of ammonia is gradually decolorized; nitric acid gives a yellow soln., and then gives a precipitate of ammonium phosphatomolybdate; alcohol precipitates a yellow, and ether a purple-red oily liquid; soda-lye gives a yellow crystalline precipitate soluble in excess; potassium chloride gives a red crystalline precipitate with conc. soln.; barium chloride gives no precipitate with dil. soln.; mercuric chloride gives no precipitate. Mercurous nitrate and lead acetate give yellow precipitates; silver nitrate gives a brown one.

O. W. Gibbs dissolved yellow ammonium (1.22-1.24) phosphatomolybdate in a boiling soln. of ammonium metavanadate, and, when the soln. was allowed to stand for some hours, obtained ruby-red octahedral crystals of **ammonium diphosphatohexadecavanadatotetradecamolybdate**, $8(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 8\text{V}_2\text{O}_5 \cdot 14\text{MoO}_3 \cdot 50\text{H}_2\text{O}$. It can be recrystallized from its aq. soln. in hot water; and the soln. gives precipitates with potassium bromide, silver nitrate, barium chloride, mercurous nitrate, lead acetate, and trimethylammonium chloride. F. Toggenburg obtained red flakes of *octocosihydrated ammonium diphosphatoctovanadatotetradecamolybdate*, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 14\text{MoO}_3 \cdot 28\text{H}_2\text{O}$, as a by-product along with the diphosphatodecavanadatododecamolybdate; from the mother-liquor in the preparation of the same salt; and by evaporating on the water-bath a conc. aq. soln. of 40 grms. of the diphosphatododecavanadatododecamolybdate, 10.2 grms. of ammonium dimolybdate to about half its vol. The liquid is cooled with ice, and the crystals washed and drained on a porous tile. A second crop of crystals is produced by evaporating the mother-liquid. The red cubic or octahedral crystals decompose as they dissolve in water; and the aq. soln. gives a precipitate with ammonia; a white decomposition product with barium chloride; and a red microcrystalline precipitate with potassium chloride. H. Stamm obtained a *pentadecahydrate* with the best crop of crystals. H. Lahrman prepared $8(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 14\text{MoO}_3 \cdot 24\text{H}_2\text{O}$, from a soln. of diphosphatohexavanadatopentadecamolybdate in 350 c.c. of water and 6 mols of aq. ammonia, by evaporation first over the water-bath, and finally over phosphoric pentoxide. The sp. gr. of the reddish-black, octahedral crystals is 3.012 at 24°. The salt is decomposed by water. A. Düsterwald could not

make this salt by direct synthesis; but he obtained **ammonium diphosphatohexavanadatotetradecamolybdate**, $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 14\text{MoO}_3 \cdot 17\text{H}_2\text{O}$; and **ammonium diphosphatohexavanadatotridecamolybdate**, $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 13\text{MoO}_3 \cdot 31\text{H}_2\text{O}$.

H. Stamm obtained **ammonium diphosphatodecavanadatotridecamolybdate**, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 13\text{MoO}_3 \cdot 29\text{H}_2\text{O}$, in the first crop of crystals resulting from the evaporation of a soln. of 300 grms. of ammonium diphosphatodecavanadatotetradecamolybdate in a litre of hot water; the second crop of crystals were $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 12\text{MoO}_3 \cdot 24\text{H}_2\text{O}$. The *dotricontahydrate* was obtained by mixing warm soln. of phosphatomolybdic acid and ammonium metavanadate and adding ammonia and phosphoric acid. The deep red crystals can be recrystallized from water. The aq. soln. sat. at 18° has a sp. gr. 1.0797, and 100 c.c. contain 25.53 grms. of salt. With potassium chloride the soln. furnishes $5\text{V}_2\text{O}_5 \cdot (\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 13\text{MoO}_3 \cdot 25(29 \text{ or } 30)\text{H}_2\text{O}$; and barium chloride, $\text{BaO} : (\text{NH}_4)_2\text{O} : \text{P}_2\text{O}_5 : \text{V}_2\text{O}_5 : \text{MoO}_3 : \text{H}_2\text{O}$, 3 : 3 : 1 : 4 : 16 : 39 and 4 : 2 : 1 : 5 : 13 : 45; and with ammonia, it furnishes $8(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 13\text{MoO}_3 \cdot 26(\text{or } 33)\text{H}_2\text{O}$. F. Toggenburg obtained **ammonium diphosphatodecavanadatotridecamolybdate**, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 13\text{MoO}_3 \cdot 37\text{H}_2\text{O}$, as a by-product in the preparation of the 1 : 1 : 4 : 14 : 28-salt by the recrystallization of the 8 : 1 : 6 : 12 : 64-salt; also from 67.2 grms. of molybdic acid, 31.2 grms. ammonium metavanadate, in about 500 c.c. of hot water; the red soln. was mixed with 21.36 c.c. of ammonia of sp. gr. 0.956, and 22 c.c. of syrupy phosphoric acid. The soln., sat. at 18° , has a sp. gr. 1.090; and 100 c.c. contain 15.43 grms. of salt. The aq. soln. of the brownish-red, efflorescent, octahedral crystals behave very like the 7 : 1 : 7 : 11 : 36-salt—*vide infra*. This salt is decomposed when an attempt is made to crystallize the aq. soln.

H. Jacoby, and A. Düsterwald prepared **ammonium diphosphatododecavanadatododecamolybdate**, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 6\text{V}_2\text{O}_5 \cdot 12\text{MoO}_3 \cdot 41\text{H}_2\text{O}$, by warming a soln. of phosphatomolybdic acid and ammonium metavanadate on the water-bath; and evaporating the filtered soln. over sulphuric acid. It was also obtained by dissolving 288 grms. of molybdic acid and 234.4 grms. of ammonium metavanadate in about 500 c.c. of water; and after standing some hours in the cold, adding 110 c.c. of phosphoric acid containing 215 grms. P_2O_5 per litre. The liquid is diluted with water, warmed on a water-bath, and the filtered liquid allowed to crystallize over sulphuric acid. The ruby-red, octahedral crystals have a sp. gr. 2.4107; the sp. gr. of the soln., sat. at 18° , is 1.099. Hydrogen dioxide colours the soln. almost black, which becomes red, yellow, and green when boiled; with hydrochloric acid of sp. gr. 1.12, the colour becomes red, and then yellow, and when boiled, a reduction occurs; dil. sulphuric acid colours the soln. dark brown, then red, and with boiling yellow; conc. sulphuric acid gives a yellow soln.; nitric acid colours the soln. red, then yellow, and it precipitates ammonium phosphatomolybdate; soda-lye gives orange-yellow precipitates with conc. soln.; phosphoric acid, diphosphatodecavanadatohexamolybdate; absolute alcohol, orange-yellow and orange-red precipitates; trimethylamine, an orange-red precipitate; ether, a purple-red precipitate; potassium chloride and barium chloride, crystalline precipitates with conc. soln.; silver nitrate gives a brown precipitate; mercuric chloride forms diphosphatodecavanadatopentadecamolybdate; and lead acetate, an orange-red precipitate. When a soln. of 100 grms. of the salt in 100 c.c. of water is mixed with 40 c.c. of aq. ammonia of sp. gr. 0.96, an orange precipitate of $8(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 6\text{V}_2\text{O}_5 \cdot 12\text{MoO}_3 \cdot 64\text{H}_2\text{O}$, is formed; and, according to H. Stamm, brownish-red crystals of $7(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 6\text{V}_2\text{O}_5 \cdot 12\text{MoO}_3 \cdot 33\text{H}_2\text{O}$, are produced when a soln. of 35 grms. of $8(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 13\text{MoO}_3 \cdot 30\text{H}_2\text{O}$, in the smallest possible amount of water is evaporated over sulphuric acid. A. Düsterwald prepared **ammonium diphosphatohexavanadatopentadecamolybdate**, $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 39\text{H}_2\text{O}$. H. Lahrman prepared **ammonium diphosphatodecavanadato-**

dodecamolybdate, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 12\text{MoO}_3 \cdot 24\text{H}_2\text{O}$, as an orange precipitate, from a soln. of a mol of the 5 : 1 : 3 : 15 : 39-salt mixed with 2-4 mols of ammonia. The sp. gr. is 2.9073 at 24°. It is always insoluble in cold water. H. Stamm obtained the salt by adding ammonia to the 6 : 1 : 5 : 13 : 29-salt. A mixture of 8 mols of ammonium metavanadate ; 2, of orthophosphoric acid ; 12, of molybdic acid ; and 4, of ammonia, was found by H. Lahrman to furnish deep ruby-red crystals of $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 12\text{MoO}_3 \cdot 39\text{H}_2\text{O}$, of sp. gr. 2.8272 at 24°. The sp. gr. of the aq. soln., sat. at 18°, is 1.0932 ; and 100 c.c. contain 26.24 grms. of salt. A. Düsterwald prepared **ammonium diphosphatodecavanadatohenamolybdate**, $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 33\text{H}_2\text{O}$.

F. Toggenburg obtained brownish-red crystals of **ammonium diphosphatotetradecavanadatohenamolybdate**, $7(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 7\text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 36$ (or 37) H_2O , accompanied by the pale yellow spangles of 8 : 1 : 6 : 12 : 64-salt ; and separated the two by repeated levigation. It was also obtained by heating 81 grms. of ammonium metavanadate and 79.2 grms. of molybdic acid in about a litre of water ; mixing the soln. with 33 c.c. of syrupy phosphoric acid (4 mols) ; evaporating the liquid to about one-third its vol. ; and crystallizing over sulphuric acid. The dark brown crystals can be crystallized unchanged from the aq. soln., the sp. gr. of the soln., sat. at 18°, is 1.074 ; and 100 c.c. contain 13.25 grms. of the salt. The aq. soln. is coloured black by hydrogen dioxide ; hydrochloric acid of sp. gr. 1.12, colours the soln. red, then yellow, and reduction occurs on boiling the mixture ; dil. sulphuric acid gives no precipitate, and when boiled, the soln. becomes red and then yellow ; conc. sulphuric acid gives a small, orange precipitate which does not dissolve when the mixture is boiled ; dil. nitric acid behaves like conc. sulphuric acid ; phosphoric acid has no influence on the salt ; conc. soda-lye gives an orange precipitate soluble in excess ; potassium chloride gives a red precipitate which slowly dissolves when the temp. is raised ; barium chloride gives an orange, crystalline precipitate with conc. soln. ; silver nitrate, mercurous nitrate, and mercurous chloride give brown or reddish-brown precipitates. When treated with aq. ammonia, the salt, $9(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 7\text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 39\text{H}_2\text{O}$, is formed in brownish-red octahedral crystals ; A. Hinsen prepared $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 7\text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 34$ (or 43) H_2O , in brownish-red octahedra, from an aq. soln. of 100 grms. of ammonium 7 : 3-molybdate and 104 grms. of ammonium vanadatophosphate ; when treated with ammonia, it furnishes $8(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 7\text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 30\text{H}_2\text{O}$. H. Jacoby prepared **ammonium diphosphatoctovanadatohenamolybdate**, $4(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 37\text{H}_2\text{O}$, by mixing a soln. of a mol of the 6 : 1 : 6 : 12 : 41-salt with 5 mols of orthophosphoric acid. Yellow crystals are obtained by evaporating the soln. over sulphuric acid. The first crop of crystals are those of pale red ammonium phosphatovanadate.

O. W. Gibbs reported that crystals of **ammonium diphosphatodecavanadato-dodecamolybdate**, $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 5\text{V}_2\text{O}_5 \cdot 10\text{MoO}_3 \cdot 24\text{H}_2\text{O}$, can be obtained from the mother-liquor obtained in the preparation of the 8 : 1 : 8 : 14 : 50-salt ; but H. Jacoby could not verify this. A. Hinsen obtained **ammonium diphosphatoheptadecavanadatoenneamolybdate**, $6(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 7\text{V}_2\text{O}_5 \cdot 9\text{MoO}_3 \cdot 28$ (33 or 37) H_2O , by fractionally crystallizing a soln. obtained by boiling 259.38 grms. of ammonium phosphatomolybdate in 200 c.c. of water in which 80 grms. of ammonium metavanadate, or an acid vanadate was dissolved. The first crop of crystals is ammonium metavanadate, this is followed by the dark red octahedra of the required salt. It can be recrystallized from its aq. soln. with potassium chloride, the aq. soln. furnishes the potassium salt indicated below ; with barium chloride, the barium salt ; and with ammonia, the 8 : 1 : 7 : 11 : 30-salt.

P. Schulz prepared **potassium diphosphatotetравanadatoicosimolybdate**, $5\text{K}_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 2\text{V}_2\text{O}_5 \cdot 20\text{MoO}_3 \cdot 53\text{H}_2\text{O}$, by dissolving 30 grms. of ammonium metavanadate in a boiling soln. of 132 grms. of phosphato (1 : 24) molybdic acid. On evaporating the pale red soln. over sulphuric acid, it furnishes pale red crystals of this salt. The aq. soln. gives with ammonium chloride $\text{K}_2\text{O} \cdot 5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5$.

$2V_2O_5 \cdot 20MoO_3 \cdot 52H_2O$; and with barium chloride, $2K_2O \cdot 2BaO \cdot P_2O_5 \cdot 2V_2O_5 \cdot 18MoO_3 \cdot 47H_2O$. A. Düsterwald prepared **potassium diphosphatododecavanadatoctodecamolybdate**, $9K_2O \cdot P_2O_5 \cdot 5V_2O_5 \cdot 18MoO_3 \cdot 30H_2O$; and **potassium diphosphatododecavanadatohenamolybdate**, $8K_2O \cdot P_2O_5 \cdot 5V_2O_5 \cdot 11MoO_3 \cdot 14H_2O$. W. Engel prepared by double decomposition with the sodium salts and potassium chloride: **potassium diphosphatododecavanadatododecamolybdate**, $6K_2O \cdot P_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot 48H_2O$; **potassium diphosphatohexavanadatopentadecamolybdate**, $6K_2O \cdot P_2O_5 \cdot 3V_2O_5 \cdot 15MoO_3 \cdot 35H_2O$; **potassium diphosphatoctovanadatotetradecamolybdate**, $6K_2O \cdot P_2O_5 \cdot 4V_2O_5 \cdot 14MoO_3 \cdot 31H_2O$; **potassium diphosphatotetradecavanadatohenamolybdate**, $6K_2O \cdot P_2O_5 \cdot 7V_2O_5 \cdot 11MoO_3 \cdot 37H_2O$; and **potassium diphosphatoctodecavanadatoenneamolybdate**, $6K_2O \cdot P_2O_5 \cdot 9V_2O_5 \cdot 9MoO_3 \cdot 43H_2O$. F. Toggenburg prepared **potassium diphosphatododecavanadatotridecamolybdate**, $6K_2O \cdot P_2O_5 \cdot 5V_2O_5 \cdot 13MoO_3 \cdot 23H_2O$, by treating ammonium diphosphatodovanadato-tridecamolybdate with potassium chloride. The aq. soln. of the red, rhombic crystals furnishes a brick-red crystalline powder of **potassium diphosphatotetradecavanadatohenamolybdate**, $7K_2O \cdot P_2O_5 \cdot 7V_2O_5 \cdot 11MoO_3 \cdot 22H_2O$, which is decomposed by water. A. Hinsen prepared **potassium diphosphatoheptadecavanadatoenneamolybdate**, $7K_2O \cdot P_2O_5 \cdot 7V_2O_5 \cdot 9MoO_3 \cdot 25H_2O$, by evaporating an aq. soln. of 10 mols of potassium metavanadate and 4 mols of potassium phosphatomolybdate. The red, rhombic plates can be recrystallized from water.

P. Schulz prepared **ammonium potassium diphosphatotetравanadatoicosimolybdate**, $5(NH_4)_2O \cdot K_2O \cdot P_2O_5 \cdot 2V_2O_5 \cdot 20MoO_3 \cdot 52H_2O$, by treating a cold soln. of dodecammonium diphosphatohexavanadatododecamolybdate, with 1.5 vols. of a soln. of potassium chloride, and evaporating over sulphuric acid. He also prepared pale red crystals of **ammonium potassium diphosphatohexavanadatoctodecamolybdate**, $(NH_4)_2O \cdot 6K_2O \cdot P_2O_5 \cdot 3V_2O_5 \cdot 18MoO_3 \cdot 43H_2O$, from a cold soln. of tetradecammonium diphosphatohexavanadatododecamolybdate and 1.5 vols. of a soln. of potassium chloride. H. Jacoby obtained a red, crystalline powder of **ammonium potassium diphosphatohexavanadatopentadecamolybdate**, $(NH_4)_2O \cdot 4K_2O \cdot P_2O_5 \cdot 3V_2O_5 \cdot 15MoO_3 \cdot 36H_2O$, by treating decammonium diphosphatohexavanadatopentadecamolybdate, with a coldsat. soln. of potassium chloride; H. Stamm, pale red crystals of **ammonium potassium diphosphatoctovanadatotetradecamolybdate**, $(NH_4)_2O \cdot 5K_2O \cdot P_2O_5 \cdot 4V_2O_5 \cdot 14MoO_3 \cdot 31H_2O$, by evaporating the mother-liquor left during the preparation of **ammonium potassium diphosphatododecavanadatotridecamolybdate**, $(NH_4)_2O \cdot 5K_2O \cdot P_2O_5 \cdot 5V_2O_5 \cdot 13MoO_3 \cdot 25(29 \text{ or } 30)H_2O$, by treating dodecammonium diphosphatododecavanadatotridecamolybdate, or diphosphatoctovanadatotetradecamolybdate, with a sat. soln. of potassium chloride; H. Jacoby, red crystals of **ammonium potassium diphosphatododecavanadato-dodecamolybdate**, $(NH_4)_2O \cdot 5K_2O \cdot P_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot 46H_2O$, by treating the corresponding ammonium salt with a soln. of potassium chloride; H. Jacoby, and F. Toggenburg, brick-red crystals of **ammonium potassium diphosphatotetradecavanadatohenamolybdate**, $(NH_4)_2O \cdot 6K_2O \cdot P_2O_5 \cdot 7V_2O_5 \cdot 11MoO_3 \cdot 25H_2O$, from hexadecammonium diphosphatododecavanadatododecamolybdate and a soln. of potassium chloride; H. Jacoby, **ammonium potassium diphosphatododecavanadatododecamolybdate**, $(NH_4)_2O \cdot 6K_2O \cdot P_2O_5 \cdot 6V_2O_5 \cdot 10MoO_3 \cdot 38H_2O$, from the mother-liquor of the preceding salt; and A. Hinsen, **ammonium potassium diphosphatotetradecavanadatoenneamolybdate**, $\{K_{0.9}(NH_4)_{0.1}O\}_{14} \cdot P_2O_5 \cdot 7V_2O_5 \cdot 9MoO_3 \cdot 29H_2O$, from a soln. of the corresponding ammonium salt and a sat. soln. of potassium chloride. W. Blum obtained no precipitate by adding cupric sulphate to a soln. of diammonium phosphatovanadatomolybdate.

W. Engel prepared **sodium diphosphatododecavanadatododecamolybdate**, $6Na_2O \cdot P_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot 48H_2O$, from 308.7 c.c. of a soln. of sodium tetramolybdate with 0.1655 gm. MoO_3 per c.c., 30.87 c.c. of phosphoric acid with 0.2300 gm. P_2O_5 per c.c., and 95.94 grms. of sodium vanadate. The sp. gr. was 2.05575. He measured the conductivity of the aq. soln. of the salt. W. Engel prepared **sodium diphosphatohexavanadatopentadecamolybdate**, $6Na_2O \cdot P_2O_5 \cdot$

$3V_2O_5 \cdot 15MoO_3 \cdot 48H_2O$, from a soln. of 123.6 c.c. of the sodium tetramolybdate soln. just indicated, 6.2 c.c. of the phosphoric acid soln., and 9.52 grms. of sodium vanadate. The sp. gr. was 2.4856. He also measured the conductivity of the aq. soln. W. Engel also prepared **sodium diphosphatoctovanadatotetradecamolybdate**, $6Na_2O \cdot P_2O_5 \cdot 4V_2O_5 \cdot 14MoO_3 \cdot 48H_2O$, from a soln. of 313.04 c.c. of sodium tetramolybdate with 0.1288 grms. MoO_3 per c.c., 12.46 c.c. of phosphoric acid with 0.2279 gm. P_2O_5 per c.c., and 25.596 grms. sodium vanadate $2Na_2O \cdot 3V_2O_5$. The sp. gr. of the salt was 2.59705. He also measured the electrical conductivity. J. Contzen prepared **sodium diphosphatodecavanadatotridecamolybdate**, $6Na_2O \cdot P_2O_5 \cdot 5V_2O_5 \cdot 13MoO_3 \cdot 43H_2O$, from 129.56 c.c. of phosphomolybdic acid with 0.1805 gm. of $P_2O_5 \cdot 24MoO_3$ per c.c., 6.64 c.c. of phosphoric acid with 0.1197 gm. P_2O_5 per c.c., 100 c.c. of water, 3.392 grms. of soda, and 18.98 grms. of acid sodium vanadate, $2Na_2O \cdot 3V_2O_5 \cdot 18H_2O$. The sp. gr. of the salt was 2.0413. W. Engel prepared **sodium diphosphatotetradecavanadatohenamolybdate**, $6Na_2O \cdot P_2O_5 \cdot 7V_2O_5 \cdot 11MoO_3 \cdot 44H_2O$, from a soln. of 369 c.c. of sodium tetramolybdate as previously employed, 18.69 c.c. of the phosphoric acid and 50.94 grms. of sodium vanadate. The sp. gr. of the salt was 2.54462. He also measured the electrical conductivity. A. Düsterwald prepared **sodium diphosphatoctovanadatopentadecamolybdate**, $6Na_2O \cdot P_2O_5 \cdot 4V_2O_5 \cdot 15MoO_3$, associated with ammonium chloride. J. Contzen prepared **sodium diphosphatohexadecavanadatodecamolybdate**, $7Na_2O \cdot P_2O_5 \cdot 8V_2O_5 \cdot 10MoO_3 \cdot 44H_2O$, from 139.13 c.c. of the soln. of sodium molybdate, 139.13 c.c. of phosphoric acid, 48.43 grms. of acid sodium vanadate, and 14.57 grms. of molybdic acid. The black octahedral crystals have a sp. gr. 2.0308. W. Engel prepared **sodium diphosphatoctodecavanadatoenneamolybdate**, $6Na_2O \cdot P_2O_5 \cdot 9V_2O_5 \cdot 9MoO_3 \cdot 30H_2O$, from a soln. of 134.2 c.c. of the sodium tetramolybdate previously used, 8.31 c.c. of the phosphoric acid, and 25.45 grms. of the sodium vanadate. The sp. gr. of the salt was 2.4853. J. Contzen prepared **sodium diphosphatoicosivanadatoctomolybdate**, $7Na_2O \cdot P_2O_5 \cdot 10V_2O_5 \cdot 8MoO_3 \cdot 48H_2O$, from 27.82 c.c. of sodium molybdate, 118.63 c.c. of phosphoric acid, 60.54 grms. of acid sodium vanadate, and 20.18 grms. of molybdic acid. The black octahedral crystals have a sp. gr. 2.7983.

W. Engel prepared by double decomposition with the sodium salt and barium chloride: **barium diphosphatotetradecavanadatohenamolybdate**, $6BaO \cdot P_2O_5 \cdot 7V_2O_5 \cdot 11MoO_3 \cdot 44H_2O$; and **barium diphosphatoctodecavanadatoenneamolybdate**, $6BaO \cdot P_2O_5 \cdot 9V_2O_5 \cdot 9MoO_3 \cdot 56H_2O$. P. Schulz prepared dark red crystals of **potassium barium diphosphatotetranadatodecamolybdate**, $2K_2O \cdot 2BaO \cdot P_2O_5 \cdot 2V_2O_5 \cdot 18MoO_3 \cdot 47H_2O$, by treating a cold soln. of decapotassium diphosphatotetranadatoicosimolybdate, with 1.5 vols. of a cold soln. of barium chloride; and pale red crystals of **ammonium barium diphosphatohexavanadatoheptadecamolybdate**, $2(NH_4)_2O \cdot 4BaO \cdot P_2O_5 \cdot 3V_2O_5 \cdot 17MoO_3 \cdot 46H_2O$, by the action of a cold soln. of barium chloride on one of tetradecammonium diphosphatohexavanadatoctodecamolybdate; H. Stamm, dark brown crystals of **ammonium barium diphosphatoctovanadatotetradecamolybdate**, $3(NH_4)_2O \cdot 3BaO \cdot P_2O_5 \cdot 4V_2O_5 \cdot 14MoO_3 \cdot 39H_2O$, from the mother-liquor obtained in the preparation of the next two salts, or by treating the corresponding ammonium salt with a soln. of barium chloride; H. Stamm, pale red crystals of **ammonium barium diphosphatodecavanadatotridecamolybdate**, $2(NH_4)_2O \cdot 4BaO \cdot P_2O_5 \cdot 5V_2O_5 \cdot 13MoO_3 \cdot 46H_2O$, by the action of barium chloride on dodecammonium diphosphatodecavanadatotridecamolybdate; a 10 per cent. soln. of barium chloride converts dodecammonium diphosphatoctovanadatotetradecamolybdate into $3(NH_4)_2O \cdot 4BaO \cdot P_2O_5 \cdot 5V_2O_5 \cdot 13MoO_3 \cdot 40H_2O$; F. Toggenburg, a brick-red crystalline powder of **ammonium barium diphosphatoctovanadatotridecamolybdate**, $2(NH_4)_2O \cdot 4BaO \cdot P_2O_5 \cdot 4V_2O_5 \cdot 13MoO_3 \cdot 37H_2O$, by treating a conc. soln. of the corresponding ammonium salt with barium chloride; H. Jacoby, reddish-brown crystals of **ammonium barium diphosphatodecavanadato-dodecamolybdate**, $(NH_4)_2O \cdot 5BaO \cdot P_2O_5 \cdot 6V_2O_5 \cdot 12MoO_3 \cdot 49H_2O$, by treating the corresponding ammonium salt with barium chloride; F. Toggenburg, reddish-

brown crystals of **ammonium barium diphosphatotetradecavanadato decamolybdate**, $2(\text{NH}_4)_2\text{O} \cdot 4\text{BaO} \cdot \text{P}_2\text{O}_5 \cdot 7\text{V}_2\text{O}_5 \cdot 10\text{MoO}_3 \cdot 13\text{H}_2\text{O}$, from a conc. soln. of the heptadecammonium diphosphatotetradecavanadatohenamolybdate and barium chloride; and A. Hinsen, reddish-brown **ammonium barium diphosphatododecavanadato octomolybdate**, $\{(\text{NH}_4)_{0.167}\text{Ba}_{0.916}\text{O}\}_8 \cdot \text{P}_2\text{O}_5 \cdot 6\text{V}_2\text{O}_5 \cdot 8\text{MoO}_3 \cdot 38\text{H}_2\text{O}$, by the action of barium chloride on dodecammonium diphosphatotetradecavanadatoenneamolybdate. O. W. Gibbs prepared orange **mercurous phosphatovanadato molybdate** by the action of mercurous nitrate on a soln. of ammonium diphosphatohexadecavanadatoheptadecamolybdate. H. Lahrmann obtained orange-yellow **lead diphosphatoctovanadatopentadecamolybdate**, by the action of lead nitrate on the ammonium salt; **lead diphosphatoctovanadatotetradecamolybdate** from lead nitrate and the ammonium salt; and **lead diphosphatohexavanadatotridecamolybdate**, from the ammonium salt and lead nitrate; F. Toggenburg, **lead diphosphatoctovanadatotridecamolybdate** from lead nitrate and the ammonium salt; H. Lahrmann, and H. Stamm, **lead diphosphatoctovanadatododecamolybdate** from lead nitrate and the ammonium salt; F. Toggenburg, **lead diphosphatotetradecavanadatohenamolybdate** from lead nitrate and the ammonium salt; and S. Jacobowitz, dark red **lead diphosphatoctodecavanadatohexamolybdate** by the action of lead nitrate on a soln. of the ammonium salt.

O. W. Gibbs prepared **ammonium hexaphosphatodivanadatohexacontatungstate**, $10(\text{NH}_4)_2\text{O} \cdot 3\text{P}_2\text{O}_5 \cdot \text{V}_2\text{O}_5 \cdot 60\text{WO}_3 \cdot 60\text{H}_2\text{O}$, by adding hydrochloric acid to a boiling soln. of tungsten phosphate (22-24:1) and ammonium metavanadate in aq. ammonia. The lemon-yellow crystalline precipitate was washed with a dil. soln. of ammonium nitrate and dried. It is insoluble in cold water and sparingly soluble in hot water, it is soluble in a soln. of ammonium phosphate; in aq. ammonia; and in a soln. of ammonium carbonate. A. Rogers prepared **ammonium tetraphosphatohexadecavanadatotetratritungstate**, $13(\text{NH}_4)_2\text{O} \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{V}_2\text{O}_5 \cdot 34\text{WO}_3 \cdot 86\text{H}_2\text{O}$, by evaporating the filtrate from the mixture obtained by boiling for 6 hrs. a gram of ammonium phosphate, 15 grms. ammonium tungstate, 3 grms. of ammonium vanadate, 20 c.c. aq. ammonia, and 700 c.c. water. The dark red octahedral and cubic crystals are sparingly soluble in cold and hot water, and insoluble in alcohol, ether, carbon disulphide, benzene, and nitrobenzene. They are not attacked by dil. nitric and hydrochloric acids; conc. hydrochloric acid forms a yellow precipitate, and gives off chlorine; conc. nitric acid gives a yellow precipitate, alkali-lye, a yellow precipitate; mercuric nitrate, a yellow precipitate; silver nitrate, a dark red precipitate; and in ammoniacal soln., the heavy metal salts give coloured precipitates. O. W. Gibbs dissolved ammonium phosphotungstate in a boiling soln. of ammonium metavanadate, and after the soln. had stood for some time, obtained orange or garnet-red crystals of **ammonium diphosphatohexavanadatohexadecatungstate**, $5(\text{NH}_4)_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{V}_2\text{O}_5 \cdot 16\text{WO}_3 \cdot 37\text{H}_2\text{O}$; the salt can be recrystallized from its aq. soln. O. W. Gibbs⁶ prepared orange-red crystals of **potassium hexaphosphatoctovanadatoctodecatungstate**, $8\text{K}_2\text{O} \cdot 3\text{P}_2\text{O}_5 \cdot 4\text{V}_2\text{O}_5 \cdot 18\text{WO}_3 \cdot 32\text{H}_2\text{O}$, by dissolving sodium phosphatotungstate in a boiling soln. of ammonium vanadate, and adding an excess of potassium bromide; if an aq. soln. of this salt be crystallized, it furnishes orange-brown crystals of **potassium diphosphatodivanadatoheptatungstate**, $3\text{K}_2\text{O} \cdot \text{P}_2\text{O}_5 \cdot \text{V}_2\text{O}_5 \cdot 7\text{WO}_3 \cdot 11\text{H}_2\text{O}$. When a boiling soln. of hydrated vanadium pentoxide in one of barium phosphatotungstate is cooled, red, octahedral crystals of **barium hexaphosphatotetranadatohexacontatungstate**, $18\text{BaO} \cdot 3\text{P}_2\text{O}_5 \cdot 2\text{V}_2\text{O}_5 \cdot 60\text{WO}_3 \cdot 144\text{H}_2\text{O}$, are formed. They are decomposed by hot water. A. Rogers obtained no precipitate by adding neutral soln. of copper nitrate to a soln. of $3(\text{NH}_4)_2\text{O} \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{V}_2\text{O}_5 \cdot 34\text{WO}_3 \cdot 86\text{H}_2\text{O}$; with mercurous nitrate, yellow precipitates of **mercurous phosphatovanadatotungstates** are produced with the various ammonium phosphatovanadatotungstates—*vide supra*, hypovanadatophosphates.

G. Canneri⁷ suggested that the phosphatovanadatotungstates are members of three limiting series of solid soln. Soln. rich in tungstic acid—say 4.8 grms.

ammonium metavanadate in 200 c.c. of water to which are added 40 grms. of ammonium metatungstate, and phosphoric acid eq. to 14 grms. P_2O_5 —yield red crystals of the type, **ammonium hydrophosphatodivanadatoctotungstate**, $(NH_4)_6H[P(W_2O_7)_4(V_2O_6)_2].nH_2O$; while soln. rich in vanadic acid—say 9.75 grms. ammonium metavanadate, 40 grms. ammonium metatungstate, and 9 grms. of P_2O_5 —yield ruby-red or wine-red crystals of the type, **ammonium hydrophosphatotrivanadatohexatungstate**, $(NH_4)_6H[P(W_2O_7)_3(V_2O_6)_3].25H_2O$; and soln. still richer in vanadic acid—say 14.5 grms. ammonium metavanadate, 40 grms. of ammonium metavanadate, and 8.9 grms. of P_2O_5 —yield reddish-brown, or pitch-black crystals of the type, **ammonium hydrophosphatotetranadatotetratungstate**, $(NH_4)_6H[P(W_2O_7)_2(V_2O_6)_2].25H_2O$. F. Rodolico found for the limiting series, $(NH_4)_6H[P(W_2O_7)_x(V_2O_6)_y]$ with 40.06 per cent. WO_3 , and 32.86 per cent. V_2O_5 , the axial ratio $a : c = 1 : 0.9932$; and for the one with 64.22 per cent. WO_3 and 12.09 per cent. V_2O_5 , $a : c = 1 : 1.0011$.

CHAPTER LV

COLUMBIUM

§ 1. The History of Columbium and Tantalum

IN 1801, C. Hatchett¹ described a heavy, black stone with golden streaks of mica. It had been sent along with various specimens of iron-ore to the British Museum from Massachusetts, and was labelled as having come from Nautneauge, the Indian name for a place which could not be identified because the locality had since been assigned a European name. Analysis showed that the ore contained iron along with about 75 per cent. of an unknown substance of a metallic nature which gave coloured precipitates with potassium ferrocyanide (olive-green), and tincture of galls (orange); and it formed a blue or purple glass when fused with ammonium phosphate. C. Hatchett said that it is one of those metallic substances which retain oxygen with great tenacity and are therefore difficult to reduce. It gave an acidic oxide which reddened litmus, expelled carbon dioxide from carbonates, and formed combinations with the fixed alkalies. Unlike other metallic acids, it refused to unite with ammonia. The oxide was not changed by nitric acid; it formed colourless soln. with sulphuric and hydrochloric acids from which a white flocculent precipitate was obtained with the fixed alkalies, and ammonia; water also precipitated it in a state of sulphate from the sulphuric acid soln. C. Hatchett concluded:

These properties completely distinguish it from the other acidifiable metals—*viz.* arsenic, tungsten, molybdena, and chromium; as to the other metals lately discovered, such as uranium, titanium, and tellurium, they are still farther removed from it. . . . This new metal differs from tungsten and other acidifiable metals by a more limited degree of oxidation; for, unlike these, it seems to be incapable of retaining oxygen sufficient to enable the total quantity to combine with the fixed alkalies. . . . Considering, therefore, that the metal which has been examined is so very different from those hitherto discovered, it appeared proper that it should be distinguished by a peculiar name; and, having consulted with several of the eminent and ingenious chemists of this country, I have been induced to give it the name **columbium**.

A year later, A. G. Ekeberg found a new element in some Finnish and Swedish—Kimito and Ytterby—minerals—tantalites and yttrotantalites—resembling columbite. This mineral had previously been regarded as a form of cassiterite or a form of wolfram. He called the new element **tantalum**—from Tantalus of Grecian mythology—in allusion to the tantalizing difficulties he encountered in trying to dissolve the mineral in acids; and J. J. Berzelius investigated the oxides of tantalum. The mineral was also analyzed by A. F. Gehlen, H. A. von Vogel, and M. H. Klaproth. W. H. Wollaston suggested that tantalum and columbium were the same element; but this hypothesis was not confirmed. T. Thomson, A. G. Ekeberg, J. J. Berzelius, and F. Wöhler observed that the sp. gr. of specimens of columbite from different localities varies considerably, and the earths derived from pyrochlore, and some Bavarian tantalites have some peculiar properties. In 1844, H. Rose announced the existence of two new elements in a sample of columbite from Bodenmais—one was similar to A. G. Ekeberg's tantalum; and the other was called **niobium**—from Niobe, the mythological daughter of

Tantalus. C. Hatchett's columbium and H. Rose's niobium probably contained a little tantalum.

A couple of years later, H. Rose announced the existence of yet a third new element in the columbite of Bodenmais, and he called it *pelopium*—from Pelops, the mythological brother of Niobe. In 1853, H. Rose showed that the assumed pelopic acid and niobic acid are different states of oxidation of the element niobium; and C. W. Blomstrand, and J. C. G. de Marignac showed that H. Rose's *Unterniobsäure* was really niobic acid, and his *Niobsäure* was a mixture of tantalic and niobic acids. C. W. Blomstrand also showed that H. Rose's *Unterniobchlorid* is really an oxychloride. J. C. G. de Marignac established the isomorphism of the fluorides of tantalum and columbium. R. Hermann showed that both niobic and tantalic acids are contained in tantalite from Kimito, Finland, and columbite from Bodenmais, Bavaria. Since niobium discovered by H. Rose in 1844 is the same element as columbium discovered by C. Hatchett over 40 years earlier, it was pointed out by J. L. Smith, and P. Nicolardot, very properly, that it is more fitting to retain the term columbium for the element, and abandon niobium. The latter term, however, is still retained in Germany.

In addition to the unverified *pelopium*, some other elements belonging to this family of the elements have been announced prematurely. Thus, in 1860, F. von Kobell announced the presence of a new element in different minerals; and he called it *dianium*—after Diana of Greek mythology—and the mineral was called *dianite*. C. W. Blomstrand, and J. C. G. de Marignac, however, showed that dianium is really columbium. R. Hermann reported a new element *ilmenium*—from the Ilmen Mountains, Urals—in samarskite and in aschynite, but J. C. G. de Marignac showed that ilmenium is really a mixture of tantalum and columbium. R. Hermann also introduced *neptunium* as a new element which he obtained from the Connecticut mineral; but A. Larsson showed that neptunium, like dianium, is identical with columbium. E. F. Smith and co-workers also were unable to find R. Hermann's neptunium in any of the minerals they examined.

§ 2. The Occurrence of Tantalum and Columbium

Columbium and tantalum do not occur in nature in the free state. The minerals containing these elements are scarce. The two elements usually occur associated with one another, forming the acidic component of minerals with the basic element

calcium, the rare earths, uranium, manganese, and iron. F. W. Clarke and H. S. Washington¹ estimated that columbium and tantalum constitute 0.003 per cent. of the igneous rocks of the earth's crust; J. H. L. Vogt gave 0.000000*n* per cent. The earth's crust probably contains a little more columbium than tantalum. W. Vernadsky gave 0.0₄1 and 0.0₄8 for the percentage proportions and 0.0₄5 and 0.0005 for the atomic proportions respectively of columbium and tantalum. These elements have not been reported in minerals derived from extra-terrestrial sources—meteorites; but H. A. Rowland² placed columbium in the list of minerals whose lines appear in the solar spectrum; and tantalum in the list of doubtful elements shown in the solar spectrum. M. N. Saha also placed tantalum in the "doubtful" list.

Rather more minerals are known containing columbium free from tantalum, than tantalum minerals free from columbium. Both columbites and tantalites often contain more or less titanium, zirconium, germanium, tin, and tungsten. The columbium minerals samarskite, wöhlerite, pyrochlore, euxenite, yttrotalite, fergusonite, and the columbite of Greenland often contain columbium associated with only traces of tantalum; while the other columbium minerals are associated with a larger proportion of tantalum. The melanocerites of Norway, and skogbölite contain only a very small proportion of columbium; and in the tantalites of Finland and Sweden, yttrotalite, tapiolite, ixiolite, and microlite, the tantalum usually predominates. Most of these minerals have been described in connection with the rare earths—5. 38, 3—or in connection with the columbato-silicates—6. 40, 48. The more important occurrences are as follow:

Adelpholite—see the rare earths; **aeschnyite** has 51.45 per cent. Cb_2O_5 and TiO_2 , etc.; **ainolite**, a Finnish cassiterite, contains a tantalite; **ampangabellite** has 43.7 to 50.6 per cent. $(\text{Cb.Ta})_2\text{O}_6$ —D. Guimaraes described a variety containing rather more titanium; **annerödite** has 48.15 per cent. $(\text{TaCb})_2\text{O}_5$; **arrhenite** is a variety of columbotitanite; **betafite**, a hydrated uranyl columbate with 35.5 per cent. Cb_2O_5 and traces of columbium; **blomstrandite**—see tapiolite; **chalcolamprite** has 59.93 per cent. Cb_2O_5 ; **columbite** or **niobite**, 60.46–83.2 per cent. of Cb_2O_5 and Ta_2O_5 ; **epistolite** is a sodium titanosilico-columbate, $\text{Na}_7\text{Ti}(\text{CbO})_3(\text{SiO}_4)_5 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, or $\text{Na}_{10}\text{Cb}_4\text{Si}_9\text{O}_{33} \cdot 10\text{H}_2\text{O}$; **eschmrite** resembles euxenite in many respects; **eschwegeite**, a hydrated yttrium tantalocolumbotitanate, $2\text{Ta}_2\text{O}_5 \cdot 4\text{Cb}_2\text{O}_5 \cdot 10\text{TiO}_2 \cdot 5\text{Y}_2\text{O}_3 \cdot 7\text{H}_2\text{O}$, described by D. Guimaraes³ and named after W. L. Eschwege; **eucolite** has up to 2.35 per cent. Ta_2O_5 and 3.52 per cent. Cb_2O_5 ; **eudelolite** has 59.65 per cent. Cb_2O_5 ; **eudialyte**—see eucolite; **euxenite** has 34.21 to 36.04 per cent. Cb_2O_5 and Ta_2O_5 ; **fergusonite** has 15.52–48.17 per cent. Cb_2O_5 and 6.40–49.36 per cent. Ta_2O_5 ; **haddamite**—see the rare earths; **hatchettolite**—see the rare earths; **hjelmitite** has 3.63–16.35 per cent. Cb_2O_5 and 54.52–72.16 per cent. Ta_2O_5 ; **ilmenorutite** is a complex titanocolumbotantalate; **ishikawaite**, a rare earth columbate; **ixiolite**, a variety of tapiolite having, 7.63–19.24 per cent. Cb_2O_5 and 63.58–70.49 per cent. of Ta_2O_5 ; or an iron tantalite, $\text{Fe}(\text{Cb.Ta})_2\text{O}_6$, containing tin and manganese; **kochelite**—see the rare earths; **koppite**—see the rare earths; **lavenite** has up to 5.20 per cent. $(\text{Ta.Cb})_2\text{O}_5$; **maripolite**—a syenitic rock carrying columbium and tantalum oxides; **microlite** is a variety of pyrochlore or a calcium tantalate; **mossite** is an iron columbotantalate having 82.92 per cent. Cb_2O_5 and Ta_2O_5 ; **noblite** has 50.43 per cent. of $(\text{Ta.Cb})_2\text{O}_5$; **plumbonite** has 46.15 per cent. Cb_2O_5 ; **polycrase** has about 24–26 per cent. Cb_2O_5 and Ta_2O_5 ; **polymignite** is a titanozirconite having 1.35–42.17 per cent. Ta_2O_5 and 6.37–11.99 per cent. Cb_2O_5 ; **pyrochlore** has 47.13–62.18 per cent. Cb_2O_5 , 5.38–13.52 per cent. TiO_2 , etc.; **risorite**—see the rare earths; **rogersite**—see tapiolite; **rutherfordite**—see the rare earths; **samarskite** has 47.47–50.17 per cent. Cb_2O_5 and Ta_2O_5 , etc.; **samiresite**, a hydrated uranyl columbate with 45.8 per cent. Cb_2O_5 and 3.7 per cent. Ta_2O_5 ; **sanidinite** is a calcium silicozirconate with 1.68 per cent. Cb_2O_5 and 0.21 per cent. Ta_2O_5 ; **siplite**—see the rare earths; **skogbölite**, a variety of tapiolite having 84.44 per cent. Cb_2O_5 and Ta_2O_5 ; **strüverite**—see ilmenorutite; **tantalite**, and **neotalantalite** have 7–40 per cent. Cb_2O_5 , 42.15–76.34 per cent. Ta_2O_5 , up to 6.20 per cent. TiO_2 , etc.; **tapiolite** has 11.22 per cent. Cb_2O_5 and 73.91 per cent. Ta_2O_5 ; **toddite**—a variety of columbite; **tritonite** contains 3.63 per cent. Ta_2O_5 , zirconia, etc.; **tyrite**—see the rare earths; **uranotaltalite** is a uraniferous tantalate; **vietinghofite** has 51 per cent. $(\text{Cb.Ta})_2\text{O}_5$; **wöhlerite** has 14.41 per cent. Cb_2O_5 , but C. F. Rammelsberg found no tantalum; **yttrogarnet** contains 2.97 per cent. of Ta_2O_5 and Cb_2O_5 ; **yttrolimenite** is a columbate of the rare earths; **yttrotaltalite** has 13.15 per cent. Cb_2O_5 , 49.36 per cent. Ta_2O_5 , etc.

H. Rose found columbium and tantalum in *perowskite*, and in *pyrite*; H. Caron,

and G. T. Prior, in cassiterite and other stanniferous minerals; T. L. Phipson, L. Weiss, E. T. Wherry, W. F. Hillebrand, and A. Carnot, in *wolframite*; T. Scheerer, in *pitchblende*; H. St. C. Deville, in *cryolite*; G. T. Prior, in the *guarimite* of Monte Somma; and F. Zambonini, in the *dysanalyte* of Monte Somma; and also in *vesbine* from Vesuvius; D. Guimaraes found the two oxides in a radioactive mineral from Minas Geraes, Brazil; and G. Carobbi, in the *schulite* from Traversella.

§ 3. The Extraction of Columbium and Tantalum Oxides

The pentoxides of the two elements are together extracted from the minerals and afterwards separated. The concentration of tantalum minerals was discussed by A. W. Gregory.¹ If only columbium is required, the mineral selected will be one containing as little tantalum as possible—*e.g.* some of the columbites of low sp. gr.—whereas if tantalum alone is required tantalites of high sp. gr. or fergusonite will be employed. A special treatment for removing titanium oxide may be necessary. As in the analogous case with zirconium, the elements—particularly columbium—seem to behave differently in the presence of titanium. As W. Crookes expressed it, when associated with titanium, the individuality of the elements seems to be destroyed. The reactions which the elements undergo when alone, do not necessarily occur when titanium is present. It seems as if a complex salt of titanium and columbium or tantalum is formed. The behaviour of aluminium hydroxide in the presence of beryllium towards soln. of ammonium carbonate is another example observed by C. A. Joy.

The opening of the mineral.—This can be effected by fusing the finely powdered mineral at a bright red-heat with from 3 to 8 times its weight of *potassium hydrosulphate*. J. J. Berzelius employed a platinum crucible; and J. C. G. de Marignac, an iron crucible. G. Chesneau fortified the potassium hydrosulphate with half its weight of sulphuric acid. The cold mass is digested with water which precipitates most of the columbium and tantalum as hydrated pentoxides. These are contaminated with silica, titania, zirconia, ferric, stannic, and tungstic oxides. L. Weiss and M. Landecker said that the mixture filters badly, and the wash-water is liable to be turbid. If the residue be digested with hydrochloric acid, some of the desired earths pass into soln. J. J. Berzelius recommended washing the residue with boiling water, and, after drying and calcining, heating it with a mixture of sulphuric and hydrofluoric acids so as to drive off the silica. W. E. von John recommended removing the silica by fusing the mixture with sodium hydroxide and washing the product with luke-warm water. The sodium columbate and tantalate so produced are not soluble in alkali-lye, whereas the silicate is soluble in that menstruum. J. J. Berzelius recommended digesting the residue remaining after washing the cake, resulting from the hydrosulphate fusion, digesting for some days with a warm soln.

of ammonium hydrosulphide so as to remove the stannic and tungstic oxides, and convert the iron oxide into the sulphide. The residue is washed with a dil. soln. of ammonium hydrosulphide, and the iron sulphide removed by treatment with hot, conc. hydrochloric acid. C. F. Rammelsberg, and R. D. Hall and E. F. Smith recommended dil. hydrochloric acid. R. F. Weinland and L. Storz said that the hydrochloric acid dissolves considerable quantities of the hydrated columbium and tantalum oxides. The iron is held very tenaciously, and L. Weiss and M. Landecker recommended removing the iron by dissolving the freshly precipitated hydrates in a mixture of oxalic and tartaric acids, adding ammonia, and passing a current of hydrogen sulphide which precipitates only the iron. The complex columbic and tantalic oxalates crystallize well from the filtrates, and yield columbic and tantalic oxides on ignition. They also recommended removing all the impurities excepting titanic oxide by suspending the mixture in sulphuric acid, adding hydrogen dioxide, and saturating the soln. with sulphur dioxide. The columbic and tantalic acids are precipitated with any insoluble sulphates. These are removed by dissolving the earth acids with warm sulphuric acid and hydrogen dioxide. According to O. Hahn and H. Gille, the solubilities of titanic, columbic, and tantalic acids have not confirmed the efficacy of the process of L. Weiss and M. Landecker. Titanic and columbic acids are practically completely soluble in acid hydrogen dioxide, but tantalic acid when precipitated hot is almost insoluble, and when precipitated cold is only partly soluble. In mixtures, the different acids influence one another differently according to the conditions. Tantalic acid lowers the solubility of columbic acid, whilst titanic acid may increase the solubility of tantalic acid or may itself be rendered less soluble. The ultra-microscope indicates that in acid hydrogen dioxide soln., titanic acid forms a true soln., whilst columbic and tantalic acids form colloidal soln. H. Rose said that the ammonium hydrosulphide process for removing tin and tungsten is not satisfactory, and he recommended fusing the earth-acids with three times its weight of a mixture of sodium carbonate and sulphur in a porcelain crucible; washing the cold product with water, and then with hydrochloric acid. The sodium salts remaining were then fused with potassium hydrosulphate, and the cold cake treated with water. M. E. Pennington removed the tin and tungsten as sulphasalts after fusion with sodium thiosulphate. R. D. Hall and E. F. Smith said that the tin and tungsten are rapidly removed by crystallizing the complex fluorides a couple of times from hydrofluoric acid. H. W. Foote and R. W. Langley purified the mixture of earth-acids by fusion with six times its weight of ammonium hydrofluoride; adding hot water, and enough hydrofluoric acid to give a clear soln. Ammonia is then added, and the precipitate washed with ammoniacal water. It is then heated with a little conc. sulphuric acid to drive off the fluorine. The residue is again treated with water and ammonia to obtain the purified earth acids. H. Biltz and C. Kircher removed sulphur by heating the oxide in ammonia, and afterwards heating the product in oxygen. The above method with some modifications was also used by F. Ott, W. Muthmann and co-workers, R. Hermann, R. D. Hall, E. F. Smith, M. E. Pennington, C. W. Blomstrand, W. B. Giles, G. Chesneau, E. Wedekind and W. Maas, O. W. Gibbs, H. Biltz and L. Gonder, W. P. Headen, T. B. Osborne, J. L. Smith, J. C. G. de Marignac, G. T. Prior, O. Ruff and E. Schiller, R. J. Meyer and O. Hauser, and G. W. Sears and L. Quill.

G. W. Sears opened columbite and tantalite by fusion with sodium pyrosulphate—7 grms. per gram of ore—and compared the results obtained by working at 770°–900°, and using hydrofluoric acid, and sulphuric acid as solvents. The compounds formed by the fusion are probably tantalates and columbates rather than sulphates or complex sulphates. The results show that variations in the proportions of flux, and of the time of heating have little influence on the solubility of the product. Conc. sulphuric acid is more effective than hydrofluoric acid in separating columbium and tantalum by dissolving the columbium and leaving the tantalum undissolved; indeed, a complete separation of the two elements can be obtained

by treating the fusion made at 825°–875°. The soln. of columbium is unaffected by cold 6*N*-H₂SO₄, but is almost completely precipitated from hot soln.

The powdered mineral columbite—was opened up by O. W. Gibbs by evaporating it to dryness with a soln. of three times its weight of *potassium hydrofluoride*; dissolving the mixture in hot water and hydrofluoric acid. On cooling, crystals of potassium oxyfluocolumbate separate out, and by recrystallization can be freed from iron and manganese. The mineral can also be fused with the potassium hydrofluoride, treated with water, and the filtered soln. evaporated to dryness, and the fluorine expelled by heating the residue with sulphuric acid. When the soln. is boiled with water, the earth-acid hydrates are precipitated. W. M. Barr used potassium hydrofluoride for opening up euxenite, and æschynite; J. L. Smith, for samarskite; and H. W. Foote and R. W. Langley, for stibiotantalite. M. E. Pennington said that the decomposition of columbite by this process is faster than is the case with the potassium hydrosulphate fusion process. W. B. Giles emphasized the difficulties attending this process.

W. B. Giles recommended opening up columbite by fusion with *potassium carbonate*:

The powdered mineral is mixed with two and a quarter parts of potassium carbonate and introduced into a steel crucible fitted with a lid, which is in turn placed in a plumbago crucible, also fitted with a cover, which is then filled up partly with powdered and partly with lumps of wood charcoal. After placing the whole in a furnace and exposing it for an hour to a most intense heat, the mass, owing to the action of the reducing gases, will contain the heavier metals, either as such (tin, copper) or else as lower oxides (iron, manganese), whilst the tantalum and niobium may be extracted as soluble potassium compounds with water. The soln. is then treated as usual for their separation.

A. Joly heated powdered hjelmite with a mixture of one-fifth its weight of dry *sodium carbonate*, and one-eighth its weight of sugar charcoal for 5 to 6 hrs. in a graphite crucible at a high temp. The tantalum, columbium, and titanium were converted into carbides and nitrides. The product was digested with boiling, conc. hydrochloric acid. The dried residue was heated in a current of chlorine. The residue was treated with boiling hydrochloric acid; and the soln. treated with water to precipitate the mixed earth-acids. The mixture can be purified by dissolving it in hydrochloric acid at 70°–80°, and the soln. treated with sulphur dioxide to re-precipitate the earth-acids. H. S. Cooper treated materials containing tantalum and iron with chlorine at a temp. exceeding 450° so as to form chlorides of these elements; the tantalum chloride is then hydrolyzed in a soln. containing 5 per cent. hydrochloric or sulphuric acid, or a 20 per cent. of sodium chloride, so as to prevent the hydrolysis of the iron chloride.

M. E. Pennington tried fused *borax* for opening up the mineral with poor results. J. Morozewicz found that mariupolite is decomposed by dil. hydrochloric acid, and the rare earths pass into soln. The tantalic and columbic acids can be separated from the insoluble residue when treated with hydrofluoric and sulphuric acids. A. G. Ekeberg, E. S. Simpson, W. B. Giles, and H. Rose opened the mineral by fusion with *alkali hydroxide* in a nickel, iron, silver, or gilded platinum crucible; extracted the product with water acidified with hydrochloric acid, and boiled the soln. with dil. acid to precipitate the tantalic and columbic acids. H. Moissan heated columbite mixed with *carbon* in an electric furnace for 7 or 8 mins. and obtained a regulus containing tantalum and columbium and 2.18–2.34 per cent. of carbon, but no graphite. The alloy was converted into the potassium fluosalts and separated as indicated below. F. L. Hahn and W. Franke opened up columbates and tantalates by heating them at 250°–300° with carbon tetrachloride, and extracting the product with acid.

The separation of titanium from the columbium and tantalum oxides.—This is a difficult separation. (1) H. Rose recommended washing the product obtained from the potassium hydrosulphate fusion with cold water, and R. Hermann, with hot water; but J. C. G. de Marignac, and L. Weiss and M. Landecker showed that

the results are very bad. (2) J. C. G. de Marignac found that the fractional crystallization of the double fluorides of potassium from hydrofluoric acid is a long operation, and is not suitable for small quantities. G. Krüss and L. F. Nilson, M. E. Pennington, H. Lange, and E. F. Smith and co-workers did not get good results by this process. E. F. Smith showed that the process separates the potassium fluocolumbates and fluotantalates, and that the titanium accumulates with the fluocolumbate. R. D. Hall and E. F. Smith obtained good results by crystallization from a mixture of hydrogen dioxide and hydrofluoric acid; and L. Weiss and M. Landecker, from a hydrochloric acid soln. of the complex fluorides. W. Muthmann and co-workers boiled with hydrochloric acid the cake obtained from the potassium hydrosulphate fusion. (3) G. Krüss and L. F. Nilson boiled the mixture of complex fluorides with water for about 12 hrs., restoring, from time to time, the water lost by evaporation. The insoluble acid salt is said to be free from titanium. The liquid is evaporated for crystallization and the crystals washed with cold water, dissolved in hot water, and the operation repeated. (4) M. E. Pennington obtained unsatisfactory results by volatilization in a current of hydrogen fluoride; but C. W. Blomstrand obtained fair results by the fractional volatilization of the chlorides—titanium tetrachloride being more volatile than the pentachlorides of columbium and tantalum. A. Knop passed chlorine over a red-hot mixture of the oxides with carbon; and R. D. Hall heated the mixed oxides in a current of carbon tetrachloride or of sulphur monochloride. E. F. Smith said the results are not satisfactory. (5) F. Ott precipitated the columbic oxide by adding sulphuric acid to the soln. in hydrochloric acid and obtained a product which he believed to be free from titanium. (6) According to L. Weiss and M. Landecker, a compound of titanium and columbium oxides appears to be formed in alkaline fusion of mixtures containing titanium; this is hindered by the addition of an oxidizing agent to the alkali. For quantitative estimation, sodium nitrate is used. After dissolving in water and filtering, very little titanium remains in soln., and this is completely precipitated by hydrogen sulphide without carrying down the other earth-acids. Sodium peroxide and borax gave incomplete separations. A mixture of six parts potassium cyanide and one part potassium hydroxide effects complete separation, the titanium becoming insoluble. Sodium carbonate and sulphite, and various acid mixtures, fail to give a complete separation. (7) E. Demarçay boiled a soln. of the potassium oxyfluo-salts just neutralized with ammonia, and found that the titanium is not precipitated. R. D. Hall obtained good results by repeating the operation three times. E. F. Smith did not get good results by fractional precipitation with ammonia; R. D. Hall and E. F. Smith, with other bases, with potassium iodate, sodium hydrophosphate, or formoxime. (8) H. Lange found that if the precipitated mixture of titanitic, columbic, and tantalic acid be treated twice with a warm, 20 per cent. soln. of ammonium salicylate, with constant stirring, the titanitic acid is quantitatively removed. The subject was discussed by A. R. Powell and W. R. Schoeller.

The separation of the columbium and tantalum.—H. W. Foote and R. W. Langley found that a fair estimate be made of the relative proportions of a mixture of columbic and tantalic oxides from the sp. gr. which are respectively 4.552 and 8.710. J. C. G. de Marignac's process for the separation of tantalum and columbium is based on the different solubilities of potassium fluotantalate, K_2TaF_6 , and potassium fluocolumbate, $K_2CbOF_5 \cdot H_2O$, or $K_4CbOF_7 \cdot H_2O$; one part of the latter salt is soluble in 12–13 parts of cold water, while one part of the former is soluble in 150–157 parts of cold water. The separation is tedious, and is considered as follows:

It is convenient to use four platinum dishes—"A" dish, 7.5 cms. in diameter; "B" dish, 9 cms.; "C" dish, 6 cms.; and "D" dish, 5 cms. in diameter—for the separation. Fuse the (weighed) mixed oxides of columbium and tantalum in a platinum crucible with eight times their weight of potassium carbonate. When solution is complete, cool the mass. Digest the cake in water. If any remains insoluble, filter, ignite the residue, and fuse

with a little potassium carbonate. Add the aq. extract to the main soln. Boil the mixture with dil. hydrochloric acid to precipitate the columbic and tantallic acids. Collect the precipitate on a filter-paper; wash into, say, dish "C." The filter-paper, folded inside out, is placed in dish "D," covered with hot water, and a few drops of hydrofluoric acid are added. Warm the mixture on a hot plate for a few minutes. Pour the soln. into dish "C." Repeat the washing of the filter-paper with very dil. hydrofluoric acid, and finish by washing the paper four times with hot water. *First Crop of Crystals.*—The dish "C" now contains all the columbium and tantalum oxides. Put the dish on a hot plate. If soln. be not complete in a few minutes, add another drop of hydrofluoric acid, but avoid an excess of this acid. Add slowly, with constant stirring, a boiling aq. soln. of 0.7 gm. of potassium fluoride to the boiling soln. in basin "C." Evaporate the contents to about 10 c.c. Wash down the sides of the basin with a few drops of hot water. Cool the vessel slowly to about 15°. Decant the clear soln. containing the columbium and part of the tantalum, through a 7-cm. filter-paper into dish "B." Wash the felted mass of crystals of potassium fluorotantalate four times with cold water. *Second Crop of Crystals.*—Evaporate the mixed filtrate and washings down to about 5 c.c. Cool the soln. slowly as before. Decant the soln. through a 5.5-cm. filter-paper into dish "A." Wash the crystals four times with cold water. If flat plates of potassium-columbium oxyfluoride are present, wash the mass until they are removed. *Third Crop of Crystals.*—Evaporate the soln. to dryness on a water-bath. Cool, add one drop of hydrofluoric acid. Run 1–5 c.c. water from a burette into the soln. Heat the vessel quickly to dissolve the residue. Add 0.1 gm. of potassium fluoride dissolved in 1 c.c. of water. Note the volume of the soln. for "correction a." Cool the soln. for about an hour at 15° or less; filter it into a small platinum dish; and wash three or four times with a few drops of water at 15° or less. Note the vol. of the liquid used for the washing—"correction b." In making the corrections allow for a, 1 c.c. of water dissolves 0.002 gm. of Ta₂O₅; and for b, 1 c.c. of water dissolves 0.00091Ta₂O₅.

Modifications of the process were used by E. S. Simpson, C. F. Rammelsberg, M. E. Pennington, A. Tighe, O. Ruff and E. Schiller, E. Meimberg, R. F. Weinland and L. Storz, W. Muthmann and co-workers, and W. E. von John. R. D. Hall and E. F. Smith thus described the process they used for the separation of the mixture of tantalum and columbium obtained from columbite:

The moist metallic acids, after having been washed with dil. sulphuric acid, were brought into a large platinum dish, and dissolved in fairly conc. hydrofluoric acid. This soln. was then filtered, through a hot water funnel, from undecomposed mineral, and from potassium silicofluoride (due to the presence of some potassium sulphate in the moist oxides). The hydrofluoric acid soln. were collected in large rubber dishes, and sufficient potassium hydroxide was introduced to convert the tantalura into potassium tantalum fluoride, most of which separated out and was removed by filtration. This precipitate was dried as far as possible by suction. It was washed once, and then allowed to dry in the air. It weighed 11 kilograms. The mother-liquor from the potassium tantalum fluoride was evaporated in stages, potassium hydrate being added. The columbium separated usually in hexagonal, hard, short crystals, such as separate from a strongly acid soln. containing an insufficient amount of potassium fluoride. The total residue obtained in this way amounted to about 8 to 10 kilograms. These residues were decomposed by treating them with twice their own weight of sulphuric acid, heating gently until the bulk of the hydrofluoric acid was expelled, and then evaporating until the mass fumes strongly, and maintaining the temp. until the excess of sulphuric acid had been almost completely driven out. Several hours were required for this. It is necessary in order to get rid of the hydrofluoric acid. The residual mass was boiled with water to extract the bases which dissolved as sulphates. The insoluble hydroxides were thoroughly washed and dissolved in hydrofluoric acid. The first crop of crystals, obtained by evaporation with potassium hydroxide, was removed, and the mother-liquor then evaporated to dryness with sufficient potassium hydroxide to change all of the metallic acids into double fluorides. A portion of these crystals (first crop) was dissolved in water, and the tantalum removed by adding dil. potassium hydroxide to the soln., which, after the formation of a permanent precipitate, was boiled for some time. The precipitate consisted mainly of potassium tantalum oxyfluoride. It was filtered out, and the filtrate evaporated to dryness. The residue was baked for some time at 200°. By this procedure some hydrofluoric acid was expelled, and, on taking up the residue with water and boiling, more potassium tantalum oxyfluoride separated. By repetition of the process all of the tantalum was removed from the soln. The only test relied upon for the detection of tantalum was the soln. of this precipitate in a drop of hydrofluoric acid and evaporation to crystallization. If needles separated, their solubility in water was used to ascertain whether they were potassium tantalum fluoride or potassium columbium oxyfluoride. It is true that this test consumes considerable time, yet it is the only satisfactory means of determining with which of the metals the chemist is dealing. The formation of a precipitate by protracted boiling of a dil. soln. of potassium

tantalum fluoride is not conclusive, for G. Krüss and L. F. Nilson have shown that potassium columbium oxyfluoride deposits under like conditions a small amount of a salt containing less fluorine. Further, the double fluoride must be re-crystallized several times, so that it will be sufficiently free from acid. Tantalum, if it is present in small amounts, may be precipitated by boiling.

H. Rose separated the mixture by fusing it with sodium hydroxide; dissolved the cake in water, and precipitated the two oxides by passing a current of carbon dioxide through the soln.; boiled the precipitate with soda-lye, and then with a dil. soln. of sodium carbonate until the filtrate scarcely shows any opalescence when treated with dil. sulphuric acid. The columbic acid passes into soln. and the tantalic acid remains as an insoluble sodium compound. W. B. Giles obtained a satisfactory separation by a repetition of the treatment; C. W. Blomstrand did not obtain good results. A. G. Ekeberg, R. Hermann, F. Oesten, C. W. Blomstrand, etc., tried modifications of this process. L. Weiss and M. Landecker said that columbic and tantalic acids are best separated from one another by fusing with sodium carbonate and nitrate, dissolving in warm water, cooling, and precipitating the tantalum with carbon dioxide. Slight variations in the conditions diminish the accuracy of the separation. A. R. Powell and W. R. Schoeller advocated the separation of these two elements by the fractional hydrolysis of the oxalates in the presence of tannin and a feebly acid soln.

The conversion of the salts into the pentoxides.—The complex fluosalts are heated with sulphuric acid at about 400° to drive off the fluorine. The product is then treated with a large excess of boiling water so as to form hydrated columbic or tantalic acid. This process was used by W. Muthmann and co-workers, and C. W. Balke. The sulphuric acid which contaminates the precipitate cannot be removed by prolonged washing, but F. Wöhler, H. Rose, and W. Muthmann and co-workers found that if the product be mixed with ammonium carbonate and heated, and the operation repeated a few times, the sulphuric acid is expelled—*vide infra*, columbium pentoxide. H. Rose recommended washing the hydrates with an ammoniacal soln. of ammonium chloride to eliminate the sulphuric acid. The ammonium chloride is used to prevent the peptization of the colloidal hydrates.

§ 4. Columbium

H. Rose¹ attempted to isolate columbium by reducing potassium oxy-penta-fluocolumbate with sodium, but he obtained only a lower oxide, not the element. J. C. G. de Marignac found that zinc does not reduce the boiling soln. to the metal; a mixture of zinc and sodium behaves like sodium; iron filings at a white-heat reduce the salt incompletely; there is an explosion with magnesium at a red-heat; aluminium gives an alloy; and when a molten mixture of potassium fluoride and fluocolumbate is electrolyzed, using platinum electrodes, the platinum is vigorously attacked but no columbium is formed. M. E. Pennington heated a mixture of 2 parts of columbium pentoxide, 10 of cryolite, and 10 of aluminium filings with an excess of sodium chloride in a graphite crucible for 8 hrs., and obtained a number of metallic buttons of an aluminium-columbium alloy. H. St. C. Deville also found that when columbium pentoxide is heated with carbon and sodium carbonate, a carbonitride is formed.

The preparation of columbium.—H. E. Roscoe obtained the metal as a bright, steel-grey, shining, metallic crust, by passing a mixture of the vapour of the pentachloride and hydrogen through a red-hot glass tube, and strongly igniting the crust in a current of hydrogen in a porcelain tube until no hydrogen chloride is evolved. Air must be excluded. C. W. Blomstrand obtained a similar product by reducing the same chloride with hydrogen. J. C. G. de Marignac regarded this product as a hydride—*vide infra*. H. Moissan obtained columbium by heating a mixture of columbium pentoxide and sugar-charcoal in an electrical tube furnace at a high temp. in the absence of air. The product contained 2.3–3.4 per cent. of carbon as carbide. H. Goldschmidt and C. Vautin reduced columbium pentoxide by powdered aluminium in the thermite process, and obtained an alloy of columbium and aluminium. L. Weiss and O. Aichel, and W. Muthmann and co-workers used mischmetall in place of aluminium as the reducing agent. W. von Bolton said that the product is a mixture of columbium and unreduced oxide, and he recommended the following process:

Purified columbium pentoxide was moulded into filaments (by mixing it with a little paraffin), and these were heated to whiteness for 4 or 5 hrs. in carbon powder. The filaments of tetroxide obtained in this way conduct electricity. When such a filament is heated to whiteness in a vacuum by a direct current it is but little changed, a small portion at the positive end only being reduced to metal. By using an alternating current, however, the filament is converted into the metal in a quarter of an hour. This method yields very small quantities of the metal. Larger quantities were prepared as follows: columbium pentoxide and powdered aluminium react together when the mixture is heated at one point, yielding a hard, metallic regulus of sp. gr. 7.5, and containing 2.8 per cent. to 3.2 per cent. of aluminium as well as some unchanged oxide. By heating this material in a vacuum (a current of 185 ampères at 40 volts for 15 hrs. is required for 20 grms. of metal) the whole of the impurities are vaporized, leaving columbium of a high degree of purity.

The preparation of columbium lamp-filaments has been described by the Wolfram-

Lampen A.G., and H. Kuzel. The last-named also prepared **colloidal solution** of columbium by the long-continued shaking of the finely divided metal with organic and inorganic acids, salts with an acidic reaction, phenols, alkali hydroxides, ammonia, organic bases, etc.

The physical properties of columbium.—H. E. Roscoe said that columbium has a steel-grey colour, and a bright metallic lustre. H. Moissan obtained columbium as a regulus; L. Weiss and O. Aichel, and W. Muthmann and co-workers described columbium as a white metal with a yellow tinge, and showing no sign of a crystalline structure; but W. von Bolton said that the metal is coarsely crystalline and consists of rhombic crystals. S. von Olshausen examined the **X-radiogram**, and inferred that it has four interpenetrating cubic lattices of side $a=4.191 \text{ \AA}$. The lustre is very stable, and W. Muthmann and co-workers found that it persists even after boiling the metal for a day with aqua regia. H. E. Roscoe gave 7.06 for the **specific gravity** of the metal at $15^\circ/15^\circ$; and J. C. G. de Marignac, 7.37; but these numbers are far too small. W. Muthmann and co-workers gave 8.4000 at $15^\circ/15^\circ$, and 8.431 at $19.8^\circ/19.8^\circ$. H. von Bolton gave for the highly purified metal 12.7, and after rolling into foil, 12.75. H. G. Grimm made observations on the ionic radius. H. Moissan described the metal he prepared as being somewhat hard, for it readily scratched glass and quartz; L. Weiss and O. Aichel said the metal is brittle and has a hardness of 7; while W. von Bolton found that the **hardness** is about the same as that of wrought iron; it can be hammered into foil 0.05 mm. thick; and it is possible, though difficult, to draw it into wire; it can be welded at a red-heat. W. Muthmann and co-workers gave 0.0617 for the **specific heat**, and 5.8 for the at. ht. W. von Bolton found the sp. ht. to be 0.071 between 21° and 100° , and the at. ht. 6.67. H. Moissan said that the **melting point** is over 1800° , and W. von Bolton found 1950° for the m.p. in vacuo. W. R. Mott gave 1950° for the m.p., and calculated 3700° for the **boiling point**. Columbium volatilizes to a considerable extent when heated in vacuo. W. Muthmann and co-workers found that the **heat of combustion** to the pentoxide is 44.133 Cals. per eq.

H. von Wartenberg² gave 1.80 for the **index of refraction**; 2.11 for the **absorption coefficient**, and 41.3 per cent. for the **reflecting power** with yellow light of wave-length $579\mu\mu$. R. Thalén found the lines in the **spark spectrum** of columbium were too feeble to measure; but measurements were made by E. Demarçay, W. M. Barr, G. Krüss and L. F. Nilson, F. Exner and E. Haschek, M. C. M. McDonald, and A. Hagenbach and H. Konen. The strongest lines in the visible spectrum are 4630 and 4573 in the blue; and 4165 and 4059 in the violet. The **arc spectrum** was examined by J. R. Capron, M. A. Catalan, J. H. Hildebrand, J. M. Eder and E. Valenta, F. Exner and E. Haschek, and A. Hagenbach and H. Konen. The **ultra-violet spectrum** was examined by F. Exner and E. Haschek, and C. C. Kiess and O. Laporte; the effect of **pressure** on the spectral lines by W. J. Humphreys; the influence of a **magnetic field**—the **Zeeman effect**—by R. Jack, and W. F. Meggers and C. C. Kiess; and the **ultimate rays**, by A. de Gramont. E. Paulson attempted to find **series spectra** in the lines of columbium represented by the existence of groups of lines showing a constant difference of frequency, but without success. H. E. White and R. C. Gibbs, and W. F. Meggers noted some regularities in the spark and arc spectrum of columbium. O. Laporte discussed this subject. J. Formanek observed no **absorption spectrum** with soln. of the salts when treated with alkanna. F. C. Blake and W. Duane,³ A. Leide, M. Siegbahn, B. B. Ray, J. Schrör, B. Walter, and M. Siegbahn and E. Friman gave for the **K-series of X-ray spectra**, $a_2\alpha' = 0.754$; $a_1\alpha = 0.749$; $\beta_1\beta = 0.669$, $\beta_2\gamma = 0.657$; and D. Coster, H. Hirata, D. Coster and E. P. Mulder, M. Druyvesteyn, E. Hjalmar, and M. Siegbahn, for the **L-series**, $a_2\alpha' = 5.717$; $a_1\alpha = 5.7113$; $a_3\alpha'' = 5.6886$; $\beta_1\beta = 5.4796$; and $\beta_2\gamma = 5.2951$; and D. Coster and F. P. Mulder, the **M-**, and **N-series**. S. J. M. Allen studied the absorption of the X-rays by columbium. M. Levin and R. Ruer found that ordinary columbic acid exhibits a feeble **radioactivity**, probably owing to the presence of radium or thorium impurities.

W. von Bolton⁴ found that the sp. **electrical resistance** is 0.0₃187 ohm. J. W. Marden and M. N. Rich gave 0.0₄18 ohm. per c.c. According to M. E. Pennington, when an aq. soln. of the complex fluoride, K₂CbOF₅·H₂O, is electrolyzed, for 8 hrs. with a current of one ampère, almost immediately the bottom of the platinum dish was covered with a blue deposit. This gradually spread over the whole surface exposed to the action of the current, and became in a short time iridescent. As the deposit increased, the deep blue tint changed to more of a grey and remained so until the current was broken. It was washed quickly with water, then with alcohol, and it was dried on the hand. The blue compound is a lower oxide of columbium. With a current of 2 ampères, a white hydroxide was formed, and a dark brown ring appeared about the anode. Soln. of sodium columbate behaved similarly. F. Ott studied the **electrolytic reduction** of columbic acid, using, in most cases, a lead cathode. He found that when columbium pentachloride is reduced in hydrochloric or sulphuric acid soln., or in an alcoholic soln. of hydrogen chloride, reddish-brown to black soln. are obtained, which contain tervalent columbium. Sodium columbate in hydrochloric acid soln. yields on reduction a green soln., which contains quadrivalent columbium; fused potassium fluoxyz-columbate, K₂CbOF₅, yields on electrolytic reduction a bluish-black product, which also contains quadrivalent columbium. When columbium pentafluoride is reduced in sulphuric acid soln. at a platinum cathode, a blue soln., which appears to contain a compound of quadrivalent and quinquevalent columbium (corresponding with the oxide, Cb₃O₇ = Cb₂O₅·CbP₂), is obtained. Assuming that the potential of the hydrogen electrode is zero, F. Ott found the results summarized in Table I.

TABLE I.—THE ELECTROLYTIC REDUCTION OF COLUMBIC ACID.

Oxide.	Colour.	Potential (volt).	Conditions of reduction.	Cathode potential (volt).
Cb ₂ O ₃	Blue or black	+0.125	CbCl ₅ in HCl-soln. and Pb or Pt cathode	0.5-0.59
	Reddish-brown	+0.125	CbCl ₅ in alcoholic HCl and Pb cathode	0.5-0.6
	Reddish-brown	+0.075	CbCl ₅ in H ₂ SO ₄ soln. and Pb cathode	0.5-0.6
CbO ₂	Green	+0.061	Na columbate in HCl soln. and Pb cathode	0.45-0.19
	Blue-black	+0.055	Molten K ₂ CbOF ₅	0.46-0.19
Cb ₂ O ₇	Blue	-0.032	CbCl ₅ in H ₂ SO ₄ soln. and Pt cathode	0.2-0.3
Cb ₂ O ₅	Colourless	-0.5		

W. Muthmann and F. Frauenberger found that the electromotive force of the cell Cb | H₂CrO₄, KOH | Cb is 2.4 volts. The electrode potential in 25 per cent. potash-lye rose from -0.433 to -0.197 volt in one min.; in 10 per cent. ammonia, from -0.403 to +0.322 in 3 mins.; and in conc. potash-lye, from -0.683 to -1.097 volts in 10 hrs. Again, in 40 per cent. nitric acid, the potential fall from -0.167 to -0.683 volt in 5 mins.; in conc. chromic acid, from +0.787 to -1.403 volts in 14 hrs.; in perchloric acid, from +0.987 to -0.063 volt in 1 hr.; in potassium permanganate, from +0.267 to -0.913 volt in 1 hr.; in ammonium ceric nitrate from +0.617 to -0.843 volt in 5 hrs.; in thiocyanic acid, from -0.033 to -0.493 volt in 10 mins.; and in 16 per cent. sulphuric acid, from +0.157 to -0.213 volt in 10 mins. The maximum value is +1.047 volts, and the minimum value -4.03 volts. The metal acquires a bluish film when it is in the **passive state**. W. von Bolton found that columbium electrodes in 10 per cent. sulphuric acid do not allow a current to pass even at 120 volts, but with one columbium cathode, one phase of an alternating current will pass. This was utilized by E. W. von Siemens and J. G. Halske in the construction of an electrolytic rectifier. A. Günther-Schulze studied the **electrolytic valve action** of columbium, and inferred that it is due to the formation of a porous non-conducting skin on the metal, the gas formed at the same time is retained in the pores of the skin,

and forming the non-conductor to which the valve action is due. U. Sborgi found differences in the behaviour of columbium in different electrolytes according to its compactness. The metal which is not very compact is used as the anode in O_2N- to $N-H_2SO_4$; there is a momentary current of 1-2 volts; the current then becomes almost zero, and if the voltage is increased up to 112 volts, each increase is attended by the passage of a current which is only momentary. Some bubbles of gas appear, and the electrode becomes covered with a greenish-yellow or blue iridescent film, which is insoluble in the common acids and alkalies, but dissolves in hydrofluoric acid. The same results are obtained with phosphoric acid, potassium hydroxide, sodium hydroxide, potassium carbonate, sodium sulphate, sodium oxalate, oxalic acid, and ammonium fluoride. In no case could a permanent passage of current be observed. In other electrolytes, however (hydrochloric acid, sodium chloride, nitric acid, sodium nitrate, acetic acid, potassium bromide and iodide), the metal dissolves with valency 5, columbic acid being precipitated; the electrode becomes disintegrated. The same occurs in hydrofluoric acid, but in this case columbic acid is not precipitated. An anode which has been used in sulphuric acid, and is covered with the film already mentioned, dissolves when made the anode in nitric acid; after a time the film disappears, and the electrode becomes grey from disintegration. When it is again placed in sulphuric acid no current passes. The columbium anode in all electrolytes (except hydrofluoric acid) becomes covered at the very beginning of electrolysis with a layer which hinders the passage of ions, although the degree of impermeability varies in different electrolytes. The behaviour of this metal differs from that of the ordinary passive metals in these respects, and also because soln. occurs when the current does pass. W. von Bolton observed that the **electrical spluttering** of columbium in vacuo makes it unsuited for incandescent filament lamps. K. Honda found columbium to be paramagnetic; and the **magnetic susceptibility** to be 1.3×10^{-6} units; M. Owen gave 1.75×10^{-6} units. K. Honda observed no change in the value between 0° and 400° . S. Meyer gave for the atomic magnetic susceptibility $+0.49 \times 10^{-6}$ per gram-atom, and for the magnetization number $+5.9 \times 10^{-6}$.

The chemical properties of columbium.—F. Fischer and F. Schrötter⁵ observed no reaction between **argon** and columbium when the metal is sparked in the liquefied gas. When columbium is heated in a current of **hydrogen**, a hydride is formed—*vide infra*. W. Muthmann and co-workers found that columbium does not change on exposure to **air**; and W. von Bolton showed that when it is gradually heated to redness, the metal acquires a yellow film which changes to blue, and finally brownish-blue. This film protects the metal from being rapidly attacked by **oxygen**. The metal is converted into the pentoxide by oxygen at a red-heat. H. Moissan added that the powdered metal burns to the pentoxide at about 400° in oxygen, and at a higher temp. in air. Some nitride is formed in air—*vide infra*. W. von Bolton observed that the red-hot metal in a current of the vapour of **water** reacts vigorously with the evolution of hydrogen. H. Moissan said that steam is not decomposed at 600° . H. Moissan observed that, at ordinary temp., columbium becomes incandescent in the presence of **fluorine**, and a volatile fluoride is formed. H. E. Roscoe said that the metal takes fire when gently heated in **chlorine**; and H. Moissan added that chlorine attacks the metal at about 205° , and **bromine** at a higher temp., while **iodine** acts at the softening temp. of glass. W. M. Barr observed no perceptible action with bromine at ordinary temp. H. Moissan showed that **hydrogen chloride** is decomposed by columbium at a dull red-heat, forming a white sublimate. The metal is slowly attacked by **hydrofluoric acid**; L. Weiss and O. Aichel added that the attack is rapid at the temp. of the water-bath, and W. von Bolton, that the attack is accelerated in the presence of platinum. H. E. Roscoe, H. Moissan, W. von Bolton, and L. Weiss and O. Aichel observed that hot or cold **hydrochloric acid** has no action on columbium. H. Moissan found that at a red-heat **iodic acid** is reduced by columbium. W. von Bolton said that **sulphur** reacts violently when heated with columbium; similarly with **selenium**. H. Moissan

found that the reaction with sulphur acts only superficially at about 600°, while selenium and **tellurium** have no action at this temp.; nor is **hydrogen sulphide** decomposed by columbium at 600°, but **sulphur dioxide** is reduced with incandescence at this temp. H. E. Roscoe, H. Moissan, and L. Weiss and O. Aichel found that cold **sulphuric acid** has no action on columbium, but the hot, conc. acid attacks the metal slowly. W. von Bolton said that the purified metal is not attacked by boiling sulphuric acid.

According to L. Weiss and O. Aichel, some nitride, as well as oxide, is formed when columbium is heated in air. H. Moissan said that **nitrogen** alone does not act perceptibly at 500°–600°, but at 1200°, it forms a yellow nitride; and W. Muthmann and co-workers added that at a bright red-heat, a black nitride is formed. H. Moissan found that at a red-heat **ammonia** is decomposed into its elements in the presence of finely divided columbium, which itself suffers no change in weight. W. von Bolton said that a strip of columbium heated to redness in ammonia acquires a brown film which gives off ammonia when treated with alkali-lye. H. Moissan showed that **nitrous oxide** is reduced by columbium at a dull red-heat; and similarly with **nitric oxide**—the reduction is attended by a vigorous combustion, and a grey powder is formed free from nitrogen. H. E. Roscoe, H. Moissan, L. Weiss and O. Aichel, and W. von Bolton observed that **nitric acid** does not dissolve columbium, nor is the metal attacked by aqua regia. H. Moissan said that **phosphorus** does not attack columbium at 500°–600°, but **phosphorus pentoxide** is reduced at a dull red-heat; **arsenic** and **antimony** do not act on columbium at 500°–600°, but **arsenic pentoxide** is reduced below this temp. The fused metal combines slowly with **carbon**, but even when the latter is in excess, a regulus containing graphite is not formed. At a red-heat, columbium reduces **carbon dioxide** to the monoxide.

According to H. Moissan, columbium does not form alloys with **sodium**, **potassium**, **magnesium**, or **zinc**; and these metals can be distilled from columbium without combination. W. von Bolton said that the metal does not dissolve in **mercury**. Alloys with **aluminium** can be formed as indicated above, and were made by J. C. G. de Marignac by reducing the heptafluocolumbate with aluminium; by M. E. Pennington, by reducing the pentoxide with aluminium; and by W. von Bolton, and H. Goldschmidt and C. Vautin, by the aluminio-thermite process. H. Moissan prepared **columbium trialuminide**, CbAl_3 . Columbium unites with small quantities of molten iron, but W. von Bolton said that the two elements form alloys with all possible proportions. H. Moissan observed that when heated with **chromic oxide** in the electric furnace, a brittle chromium-columbium alloy is formed. Columbium reacts vigorously when heated with **lead mono- or di-oxide**. W. von Bolton found that aq. soln. of **alkali hydroxide** have no action on columbium, but the fused alkali dissolves the metal, forming a columbate. L. Weiss and O. Aichel said that **alkali carbonate** behaves like the hydroxide. H. Moissan showed that molten **alkali sulphate** is reduced to sulphide by columbium, and blue crystals insoluble in water are formed; and that fused **oxidizing agents**—*e.g.* **potassium nitrate**—attack columbium. At a red-heat, columbium reduces **mercurous or mercuric chloride** to mercury and columbium chloride is formed.

Some reactions of analytical interest.—The reactions of tantalum and columbium present so many resemblances, that the two elements can be considered together. When **sulphuric acid** is added to a cold soln. of a dil. alkali tantalate or columbate, an amorphous precipitate of the hydrated pentoxide forms. The precipitate is soluble in hot, conc. sulphuric acid, and with columbium the cold soln. remains clear when diluted with water, whereas with tantalum, tantalic acid is re-precipitated. A conc. soln. of the alkali salt gives a precipitate of tantalic or columbic acid when treated with **hydrochloric acid**—the tantalic acid dissolves in an excess of the precipitant, but columbic acid dissolves only slightly. If the acid is poured off, the precipitate dissolves in water. The action of nitric acid resembles that of hydrochloric acid. If the hydrated pentoxide be dissolved in an

excess of hydrofluoric acid, and **potassium fluoride** be added, sparingly soluble potassium fluotantalate, and readily soluble fluocolumbate are formed. On boiling the aq. soln. of these salts sparingly soluble oxyfluotantalate is alone precipitated; the corresponding columbate is very soluble. Aq. **ammonia** or **ammonium sulphide** precipitates either the hydrated pentoxide or an ammonium salt from a soln. in hydrochloric acid, and the precipitate is soluble in hydrofluoric acid; and tartaric acid prevents the precipitation. Soln. of columbates, titanates, and cerium salts give a yellow coloration with **hydrogen dioxide**, but not so with soln. of tantalates. This is due to the formation of a yellow percolumbate (*q.v.*)—the corresponding pertantalate is colourless. Acid soln. of columbates or tantalates give a yellowish-white precipitate with **potassium ferrocyanide**—the precipitation is hindered in the presence of arsenic, oxalic, citric, or tartaric acid; **potassium ferricyanide** gives no precipitate, or a precipitate is formed very slowly; tincture of galls, or **tannic acid** in acid soln. of the tantalates gives a light brown precipitate; with columbates, the precipitate is orange-red. A mixture of **zinc** and hydrochloric acid gives a blue coloration with soln. of the columbates, but no coloration is observed with the tantalates. A. Stähler⁶ said that the indigo-blue soln., obtained when a sulphuric acid soln. of columbium pentoxide is reduced with zinc, reduces cupric sulphate to metallic copper, and is therefore more strongly reducing than one containing trivalent titanium. M. E. Pennington gave a comparison of the reactions of the salts indicated in Table II.

TABLE II.—COMPARISON OF SOME REACTIONS OF THE FLUOCOLUMBATES, FLUOTANTALATES, AND FLUOTITANATES.

Reagent.	$K_2CbOF_5 \cdot H_2O$	K_2TaF_7	K_2TiF_6

R. D. Hall found that a soln. of **potassium iodate** gave a complete precipitation with a soln. of potassium fluotitanate, but no precipitate with a soln. of the oxyfluocolumbate. R. D. Hall and E. F. Smith showed that no precipitation occurs with either except in acidic soln. when both are precipitated. No precipitation occurs with **potassium chlorate, bromate, or perchlorate**. L. Weiss and M. Landecker observed that when boiled with **perchloric acid** soln. of columbic and tantallic acids give a quantitative precipitate easily filtered; and **hydrofluosilicic acid** gives no precipitate. M. E. Pennington obtained white precipitates when both columbate and tantalates are treated with **sodium hydrosulphite, or thiosulphate**. R. D. Hall and E. F. Smith observed no precipitation when a soln. of

potassium fluotitanate, or oxyfluocolumbate is treated with *benzylaniline*, *diphenylamine*, *tribenzylamine*, β -*naphthylamine*, α -*naphthylamine*, *nitrophthalene*, *bromphenylhydrazine*, *nitrophenylhydrazine*, *benzidine*, *o-nitraniline*, *p-nitraniline*, *m-nitraniline*, *diphenyl*, *diphenyl carbonate*, *methyl carbonate*, *ethyl carbonate*, *piperine*, *monochlorhydrin*, *trichlorhydrin*, *dibromhydrin*, *nitrosodipropylene*, *nitrosodiethylene*, *nitrosodimethylene succinimide*, *methyl diphenylamine*, *tetranitromethylaniline*, *bromaniline*. No precipitation occurred with the fluotitanate and only a slight precipitation with the oxyfluocolumbate when treated with *m-bromaniline*, *o-chloraniline*, *dichloraniline*, *diethylaniline*, *p-chloraniline*, *dimethylaniline*, *p-xylidine*, *o-xylidine*, *m-xylidine*, *tetrahydroquinoline*. The precipitation was complete with soln. of the fluotitanate, and the pp. was soluble in excess with oxyfluocolumbate treated with *monomethylamine*, *dimethylamine*, *trimethylamine*, *tetramethylamine*, *monoethylamine*, *diethylamine*, *triethylamine*, *dipropylamine*, *amylamine*, *isobutylamine*, *allylamine*, *ethylenediamine*, *propylenediamine*, *secondary-butylenediamine*, *normal-butylenediamine*, *hexylamine*, *benzylamine*, *benzylmethylamine*, *piperidine*, *camphylamine*, *dibenzylamine*, *pyridine*, *di-isobutylamine*, *tripropylamine*, *diamylamine*, *heptylamine*. The precipitation was partial with the fluotitanate and incomplete with the oxyfluocolumbate when treated with *m-toluylenediamine*, *picoline*, *tri-isobutylamine*, *bornylamine*, *aniline*, *m-toluidine*, *monomethylaniline*, *mono-ethylaniline*, *isoquinoline*, *quinoline*, *hexamethylenetetramine*, *m-bromaniline*, *o-chloraniline*, as above. R. D. Hall and E. F. Smith also observed the reactions indicated in Table III. They added that strychnine, quinine, cinchonidine,

TABLE III.—REACTIONS OF TANTALUM, COLUMBIUM, TITANIUM, AND TUNGSTEN SALTS WITH SOME ORGANIC COMPOUNDS.

Reagent.	Ta	Cb	Ti	W
Codeine .	No colour	No colour	Faint pink, may be due to morphine	Light brown; on standing, trace purple
Morphine .	Faint yellow	—	Red to brown, very delicate	Grey-brown, becoming purple; H ₂ O ppt.
Resorcinol .	No colour	No colour	Red-brown, fairly delicate	No colour
Naphthol (β)	„	Faint yellow-brown	Coffee-brown, very delicate	Brown, becoming dark blue
Naphthol (α)	„	Faint brown	Green to dark greenish-brown	Deep blue, very delicate
Pyrogallol .	„	Yellow to light brown	Dull dark red	Deep red to brown to dirty blue
Salicylic acid	„	Very faint yellow	Deep red	Reddish-yellow
Cinchonidine	„	No colour	No colour	On standing a slight purple
Apomorphine	„	Yellow-brown	Light red-brown	Purple to brown to green and blue
Narceine .	„	Brownish-yellow	Brown	Dirty dark green
Bebeerine .	„	No colour	Clear brown	Dark brown to green
Narcotine .	„	Yellow	Brown	Light brown to green

and atropine gave no colour with any of the elements tested. Narceine and bebeerine alone in sulphuric acid gave a considerable colour, and with them the amount of reagent must be very small, or it will obscure any change produced by the addition of the double fluoride. In this connection it is of interest to note that L. Lévy studied the colours produced by the phenol-like bodies, dissolved in conc. sulphuric acid, when brought in contact with the oxides of titanium, tin, tantalum, columbium, and other elements, with the following results: Columbium could be tested for in the presence of all the others by using codeine, as it gave a pink colour, while titanium yielded no colour, and tantalum but a faint green. Titanium could be tested for by using morphine, with which it gave a carmine colour, columbium no colour, and tantalum a yellow colour passing into brown. Tantalum with resorcinol gave a dirty green colour, changing to amethyst and rose, while titanium yielded a flesh-red colour; going to chocolate-brown, and columbium a yellowish tint. None of the results was duplicated save the morphine test for titanium, which proved

exceedingly delicate, yet to have the colour show definitely in columbium the latter must contain 0.5 per cent. of TiO_2 . Codeine gave no colour with columbium, nor did resorcinol with tantalum, therefore L. Lévy could not have had pure material for his test. Morphine answered as a test for titanium. None answered for columbium in the presence of titanium, or for tantalum in the presence of columbium. Resorcinol proved to be fairly delicate test for titanium; it gave no colour with columbium, tantalum, or tungsten—*vide* Table III. J. H. de Boer observed a violet colour is produced by *alizarinsulphonic acid* with salts of zirconium, aluminium, thorium, cerium, yttrium, erbium, thallium, columbium, tungsten, molybdenum, uranium, and titanium. All disappear in the presence of conc. hydrochloric acid excepting with zirconium. F. Steidler found that various shades of brown are produced by tantalum or columbium salts with linen or artificial silk dyed with *turmeric*.

H. Geisow found that an alkaline soln. of formoxime precipitated zirconium and titanium but not columbium; and R. D. Hall and E. F. Smith added that the alkaline soln. of formoxime gave no precipitate when added to a soln. of titanium as double fluoride, zirconium as double fluoride, or to a soln. of columbium double fluoride. Further, after the addition of the formoxime soln., ammonium hydroxide failed to give a precipitate with any of the soln. noted above. It did, however, give a precipitate with tantalum double fluoride, but this was only partial. The statement of H. Geisow that titanium and zirconium can be separated from columbium by means of an alkaline formoxime soln. was not verified. The precipitation with tantalum is only partial, and not complete as stated by him. J. H. Muller observed that soln. of alkali columbate, tantalate, thorate, and zirconate give quantitative precipitates with **salicylic acid**, whereas titanates, molybdates, and tungstates are not so precipitated.

The atomic weight and valency of columbium.—Columbium behaves as a quinquevalent element as shown by the vapour density determinations of columbium pentachloride, CbCl_5 , and columbium oxytrichloride, CbOCl_3 , by H. St. C. Deville and L. Troost,⁷ and O. Ruff's observations on columbium pentafluoride, CbF_5 . In the percolombic acid, $\text{HCbO}_4 \cdot n\text{H}_2\text{O}$, of P. G. Melikoff and L. Pissarjewsky, there is probably an oxygen atom in a peroxide chain. Compounds of lower valency are illustrated by the tetroxide, Cb_2O_4 ; the trichloride, CbCl_3 ; the dioxide, Cb_2O_2 ; and the hydride, CbH . According to D. I. Mendeléeff, columbium and tantalum stand in close relationship with vanadium and phosphorus; while columbium is also related to molybdenum, and tantalum to tungsten. A. Piccini emphasized the relationship of the peroxides in the periodic table.

H. Rose analyzed a compound of columbium which he assumed to be a chloride, but which C. F. Rammelsberg showed was more likely to be an oxychloride. If the former, the at. wt. of columbium was near 122, and if an oxychloride near 94. The product, however, was probably contaminated with tantalum. R. Hermann's analyses are of little value in fixing the at. wt. of columbium because of the presence of impurities in his products. C. W. Blomstrand calculated from the ratio $2\text{CbCl}_5 : \text{Cb}_2\text{O}_5$, 96.1; from $\text{CbCl}_5 : 5\text{AgCl}$, 99.2; and from $5\text{AgCl} : \text{Cb}_2\text{O}_5$, 97.7. These numbers are not very concordant. J. C. G. de Marignac calculated 93.53 from the ratio $2(\text{CbOF}_3 \cdot 2\text{KF} \cdot \text{H}_2\text{O}) : \text{Cb}_2\text{O}_5$; 93.93 from $\text{CbOF}_3 \cdot 2\text{KF} \cdot 2\text{H}_2\text{O} : \text{K}_2\text{SO}_4$; 93.71 from $\text{Cb}_2\text{O}_4 : \text{K}_2\text{SO}_4$; 94.19 from $10\text{Cl} : \text{Cb}_2\text{O}_5$; 93.91 from $2\text{CbCl}_5 : \text{Cb}_2\text{O}_5$; and 94.48 from $\text{CbCl}_5 : 5\text{Cl}$. J. C. G. de Marignac, and B. Brauner assumed that 94 is the best representative value of these results. Subsequent observations make the values smaller than this. C. W. Balke and E. F. Smith calculated 93.5 from the ratio $2\text{CbCl}_5 : \text{Cb}_2\text{O}_5$; and F. W. Clarke estimated from these results that 93.528 is the best representative value. E. F. Smith and W. K. van Haagen calculated 93.13 from the ratio $\text{NaCbO}_3 : \text{NaCl}$. The International Table for 1925 gave 93.1 as the best representative value for the at. wt. of columbium.

The **atomic number** of columbium is 41. The **isotopes** have not been determined.⁸ The **electronic structure**, according to N. Bohr, will be (2) (4, 4) (6, 6, 6) (4, 4, 3) (2). C. D. Niven, H. Lessheim and R. Samuel, and M. L. Huggins studied the electronic structure of the atoms of columbium.

§ 5. Columbium Hydrides

According to J. C. G. de Marignac,¹ and W. von Bolton, the products obtained by C. W. Blomstrand, and H. E. Roscoe by reducing columbium oxytrichloride with hydrogen at a bright red-heat are hydrides. W. von Bolton also obtained a hard, brittle metal by charging a strip of columbium with hydrogen by making it the cathode in the electrolysis of dil. sulphuric acid. W. Muthmann and co-workers exposed finely powdered columbium at an elevated temp. to hydrogen, and obtained an alloy with 7.9 per cent. of hydrogen corresponding with **columbium hydride**, CbH. W. von Bolton obtained a dark grey product of a similar composition which neither gained nor lost hydrogen when reheated in that gas. According to J. C. G. de Marignac, this hydride is formed when a mixture of potassium fluocolumbate and sodium is heated while the mixture is protected by a layer of sodium chloride. G. Krüss and L. F. Nilson repeated the experiment, and washed the product first with water, then with alcohol, and finally with ether. After drying at 100°, analyses showed that the product contained 77.5 per cent. of CbH; 21.53 per cent. Cb₂O₅; and 0.97 per cent. of Fe₂O₃.

The product is a dark grey, or black glistening powder of sp. gr. 6.0–6.6. The sp. ht. and mol. ht. respectively between 0° and 100° are 0.0977 and 9.3; between 0° and 210.5°, 0.0925 and 8.8; between 0° and 301.5°, 0.0871 and 8.3; and between 0° and 440°, 0.0834 and 7.9. J. C. G. de Marignac said that the product does not alter when heated to dark redness in **hydrogen**, but at a white heat about 0.36 per cent. is lost, and the sp. gr. rises from 6.15 to 7.37—possibly by the formation of oxide from the presence of oxygen in the hydrogen. W. Muthmann and co-workers said that the hydride is stable in **air**; G. Krüss and L. F. Nilson found it to be hygroscopic. J. C. G. de Marignac, G. Krüss and L. F. Nilson, and W. von Bolton found that it burns with incandescence when heated below redness in air, forming columbium pentoxide and water. The blue flame of hydrogen can be seen burning on the surface of the hydride. When heated in dry **oxygen**, water is formed; when heated in **chlorine**, a volatile, yellow chloride is formed; it forms four different columbium chlorides when heated in **hydrogen chloride**. It is soluble in conc. **hydrofluoric acid** with the evolution of hydrogen, but is not attacked by hot or cold **hydrochloric acid**. It burns when heated with **sulphur**, forming a black columbium sulphide. It is not attacked by hot or cold dil. **sulphuric acid**, but it dissolves in the conc. acid. It is not attacked by hot or cold **nitric acid**, or by **aqua regia**. It dissolves in molten **potassium hydrosulphate**; while it is not attacked by boiling **alkali-lye**.

§ 6. The Lower Oxides of Columbium

The best defined oxide of columbium is the *pentoxide*, Cb_2O_5 , which is an acid anhydride furnishing a series of salts, the columbates. Above the pentoxides there are the percolumbates which are derivatives of *percolumbic acid*, HCbO_4 ; and below that the *tetroxide*, Cb_2O_4 ; *tritapentoxide*, Cb_3O_5 ; the *trioxide*, Cb_2O_3 ; and the *dioxide*, Cb_2O_2 , have been reported. The reduction of an alkali columbate with zinc and sulphuric or hydrochloric acid furnishes a blue soln. The reduction with zinc was examined by H. Rose,¹ A. E. Nordenskjöld, J. C. G. de Marignac, T. B. Osborne, F. Wöhler, etc. According to F. Ott, hydrofluoric acid hinders the reaction; and F. D. Metzger and C. E. Taylor said that the reduction proceeds nearly to the Cb_2O_3 stage. The reduction with tin was examined by H. Rose, and F. von Kobell; with copper, by H. Rose, and C. W. Blomstrand; and by electrolysis, by F. Ott, and M. E. Pennington—*vide supra*.

According to M. Delafontaine,² H. Rose, and R. Hermann prepared **columbium dioxide**, Cb_2O_2 , which they considered to be the metal. It was obtained by heating potassium oxyfluocolumbate with sodium under a layer of fused potassium chloride in a covered iron crucible; digesting the cold product with boiling water; and washing the black powder with dil. alcohol. M. Delafontaine represented the reaction: $2\text{K}_2\text{CbOF}_3 + 6\text{Na} = 4\text{KF} + 6\text{NaF} + \text{Cb}_2\text{O}_2$. H. Rose also made it from columbium chloride and sodium as well as by passing phosphorus vapour and hydrogen over heated sodium columbate; H. St. C. Deville and L. Troost, by passing the vapour of columbium oxytrichloride over heated magnesium: $2\text{CbOCl}_3 + 3\text{Mg} = 3\text{MgCl}_2 + \text{Cb}_2\text{O}_2$; and H. St. C. Deville, by heating to 1200° a mixture of potassium columbate with an excess of potassium carbonate in a graphite crucible along with a mixture of rutile and carbon to cut off the nitrogen of the air, and treating the cold mass with dil. hydrofluoric acid—the columbium dioxide remains undissolved. Columbium dioxide appears as a black powder, or, according to H. St. C. Deville and L. Troost, in black, cubic crystals. H. Rose gave 6.27 for the sp. gr., and said that it is a good electrical conductor. When heated in air, it oxidizes vigorously with incandescence, forming columbium pentoxide; when warmed in air-free chlorine it furnishes volatile columbium oxytrichloride. Warm hydrofluoric acid dissolves it with the evolution of hydrogen, and it is readily attacked in the cold by a mixture of hydrofluoric and sulphuric acids; but hydrochloric acid attacks it slowly with the evolution of hydrogen; aqua regia attacks it more slowly than hydrochloric acid; an excess of conc. sulphuric acid dissolves it slowly, forming a brown soln.; hot nitric acid does not dissolve it—L. Weiss and M. Landecker said that the pentoxide is formed; boiling alkali-lye converts it into alkali columbate, and a soln. of alkali carbonate acts similarly; and molten potassium hydrosulphate oxidizes it to columbium pentoxide. L. Weiss and M. Landecker found that when heated with potassium or ammonium nitrate it is oxidized to the pentoxide.

E. F. Smith and P. Maas reported a bluish-black powder of **columbium trioxide**, Cb_2O_3 , to be formed by heating columbium pentoxide with five times its weight of magnesium at a low temp. and dissolving out the magnesium and magnesium oxide with dil. hydrochloric acid. When the trioxide is heated in air it passes into the pentoxide. K. Friederich gave 860 ohms per sq. mm. for the electrical resistance of the trioxide. The trioxide is insoluble in acids with the exception of hydrofluoric acid. The evidence is not conclusive. According to T. B. Osborne, if a gram of hydrated pentoxide be dissolved in the smallest possible amount of hydrofluoric acid, and heated for 45 mins. at 80° with zinc and 50 c.c. of conc. hydrofluoric acid, pentoxide is reduced to the trioxide. E. Friederich and L. Sittig obtained the hemitrioxide by reducing the pentoxide with hydrogen; they said that it has a hardness of 6.5; a m.p. of 1780° ; and a sp. resistance of 800×10^4 ohms at 1100° .

J. C. G. de Marignac reported **columbium tritapentoxide**, Cb_3O_5 , to be formed by boiling the hydrated pentoxide with hydrochloric acid, and treating the filtrate with zinc. The brown soln. deposits this oxide as a brown precipitate, and the brown oxide is obtained when ammonia is added. This oxide was first obtained by F. Wöhler. J. C. G. de Marignac also found that when hydrated pentoxide is boiled with hydrochloric acid and filtered, the residue forms an almost clear soln. with water, and is coloured deep blue by zinc and, in time, a hydrated blue oxide is deposited. Both the blue and brown oxides yield the same columbate when melted with potassium hydrosulphate. If potassium oxyfluocolumbate be reduced with zinc and enough hydrochloric acid to dissolve all the zinc, and then titrated with permanganate soln., the pentoxide will be found to have lost about one-third of its oxygen. The evidence is therefore inconclusive.

According to H. Rose, columbium pentoxide is scarcely affected by hydrogen at a red-heat; but at a white-heat, F. Wöhler observed the formation of a bluish-black oxide, and M. Delafontaine found that at a white-heat, the pentoxide is reduced by dry hydrogen to **columbium tetroxide**, Cb_2O_4 . F. Ott electrolyzed 20 grms. of molten potassium oxypentafluocolumbate with the platinum dish as cathode, and a current of 2 amps. and 10 volts for 2 hrs. The cold product was leached with water and the residue, dried at 100° , was columbium tetroxide. V. M. Goldschmidt examined the crystals; and L. Pauling discussed the structure of the crystal lattice. The black powder has a pale blue lustre; it is stable in air at ordinary temp.; it burns at a dull red-heat, forming the white pentoxide. M. Delafontaine said that it is insoluble in hot and cold water, hydrochloric, sulphuric, and nitric acids, in aqua regia, and, according to F. Ott, in hydrofluoric acid. It is very little affected by boiling alkali-lye—*vide supra*, the electrical properties of columbium. F. Ott also obtained some evidence of the existence of a *columbium tritapentoxide*, Cb_3O_7 .

§ 7. Columbium Pentoxide, and Columbic Acid

The extraction of **columbium pentoxide**, Cb_2O_5 , from various minerals has been already described. When columbium is heated in oxygen; or columbium hydride or one of the lower oxides is heated in air; or ammonium oxyfluocolumbate, or columbium oxysulphide is roasted in air, columbium pentoxide is formed. The product from the oxysulphide should be heated with ammonium carbonate a few

times to remove sulphates. L. Weiss and M. Landecker¹ obtained it by calcining oxalatocolumbic acid. The same product is obtained when the compounds of columbium fluoride or oxyfluoride with the alkali fluorides are evaporated with sulphuric acid, washed with water and calcined; or when the chloride or oxychloride is treated with water or dil. ammonia, and the precipitate calcined. F. Wöhler obtained the pentoxide by melting a columbate with potassium hydrosulphate; washing the product with water, and calcining the product mixed with ammonium carbonate. According to J. C. G. de Marignac, the pentoxide is obtained by evaporating potassium oxyptafluocolumbate with sulphuric acid a few times, washing the product with water, and calcining it with ammonium carbonate to remove the sulphuric acid. A similar process was used by R. F. Weinland and L. Storz, G. Krüss and L. F. Nilson, R. D. Hall, G. Chesneau, and H. Biltz and L. Gonder. According to L. Weiss and M. Landecker, the calcination with ammonium carbonate does not remove all the sulphate; and they recommended treating the product with a small excess of ammonia, washing with dil. ammonia, and calcining the product. O. Ruff and F. Thomas said that columbium pentoxide is best purified by heating it in a bomb tube with carbon tetrachloride and fractionally subliming the resulting chlorides.

O. Hauser and A. Lewite found that a **colloidal solution** of hydrated columbium pentoxide is readily formed by fusing the pentoxide with alkali hydroxide, and dialyzing the aq. soln. so as to obtain a neutral liquid. The hydrosol is stable, and can be kept for weeks in a stoppered flask. By concentration over sulphuric acid, a liquid with 2.571 grms. of Cb_2O_5 per litre can be obtained. The disperse phase is negatively charged, and the various precipitation reactions are described. It is specially noteworthy that they are very sensitive to sulphate, chloride, sulphite, or nitrate ions, and that the hydrosol of tantalic acid is readily precipitated by a current of carbon dioxide, whereas that of columbic acid remains stable, at all events for 24 hrs. The sensitiveness towards the nitrate ion explains why H. W. Foote and R. W. Langley were unable to obtain good results in the separation of columbium and tantalum by L. Weiss and M. Landecker's process, since, according to this method, potassium nitrate is added to the sodium carbonate used in the fusion. Satisfactory results are obtained when sodium carbonate is used.

According to W. Muthmann and co-workers, and F. Ott, columbium pentoxide appears as a white, amorphous powder without taste or smell, and when heated it remains almost white. F. Wöhler, H. Rose, L. Weiss and M. Landecker said that the colour is yellow, and when heated it becomes lemon-yellow. When heated to a high temp., H. Rose said that it acquires a crystalline structure. J. J. Ebelmen obtained rhombic prismatic **crystals** by fusing the pentoxide with boric oxide. A. E. Nordenskjöld, A. Knop, and W. Florence obtained rhombic crystals by fusing the oxide with borax; but in that case, P. J. Holmquist said that the crystals retain a little sodium. A. Knop did not obtain crystals by fusing the pentoxide with microcosmic salt; but P. J. Holmquist prepared small colourless crystals by fusing the pentoxide with potassium or sodium hydrosulphate. According to E. Mallard, the rhombic prisms have the axial ratios $a:b:c=0.3557:1:-$. E. M. Bonshtedt described crystals of columbite from Lipovka, Urals, with $a:b:c=0.3936:1:0.35248$. The (100)- and (010)-**cleavages** are distinct; the optical character is positive. The **specific gravity** depends on the mode of preparation; C. W. Balke and E. F. Smith gave 4.48–4.51 for the pentoxide prepared by calcining the precipitate from the pentachloride and ammonia; and 4.88–5.05 for that made by calcining the product from the hydrolysis of the pentachloride in moist air; J. C. G. de Marignac gave 4.37–4.46 for that obtained by melting potassium oxyfluocolumbate with potassium hydrosulphate, and 4.51–4.53 for that obtained by calcining ammonium oxyfluocolumbate; F. Ott, 4.4849; H. Geisow, 4.00 when calcined over the colourless gas-burner, and 4.43 when calcined over the blast gas-flame; H. Rose likewise obtained numbers ranging from 4.601 to 5.262; and P. J. Holmquist, 4.568 for the crystals from the hydrosulphate fusion.

E. M. Bonshtedt gave 5.0 for the sp. gr. of crystals of columbite. D. Balareff, and C. del Fresno studied the mol. vol. G. Krüss, and L. F. Nilson found the **specific heat** and mol. heat respectively between 0° and 100°, to be 0.1184 and 31.7; between 0° and 210.5°, 0.1184 and 31.7; between 0° and 301.5°, 0.1243 and 33.8; and between 0° and 440°, 0.1349 and 30.1. J. J. Berzelius, and H. Rose observed the **calorescence** of the heated oxide, and J. Böhm showed, by X-radiograms, that the phenomenon is connected with the passage from the amorphous to the crystalline state. A. A. Read said that the pentoxide does not alter in weight when heated to 1750°. W. Muthmann and co-workers gave 44.133 Cals. per gram-eq. for the **heat of formation**.

C. Renz found that columbium pentoxide is **photosensitive**, for it is reduced when exposed to light in the presence of certain organic liquids and reducing soln.—*e.g.* glycerol. The process is affected by the presence of impurities. The lower oxide regenerates the pentoxide when exposed to air. E. L. Nichols and H. L. Howes found that columbium oxide mixed with a little tantalum oxide exhibits **flame luminescence**. E. L. Nichols said that when columbium oxide, Cb_2O_5 , is gradually introduced into a hydrogen flame, it glows with a pale greenish-blue colour when in the oxidizing portion, but in the reducing region the colour changes abruptly to deep red. The former phase is selective with luminescence bands superposed on the radiation due to temp., whilst the latter resembles that of a black body and is due to the formation of the oxide, Cb_2O_4 , which is black at the temp. of incandescence. The formation of similar black suboxides was observed in the cases of titanium and tantalum. A. Karl said that the oxide is **triboluminescent**. K. Friederich gave 11.4×10^6 ohms per sq. mm. for the **electrical resistance** of the pentoxide. S. J. Kiehl and D. Hart found that soln. of columbium pentoxide in 3 to 10M- H_2SO_4 can be completely reduced to the trivalent stage by a mercury cathode. S. Meyer gave for the magnetic susceptibility -0.08×10^{-6} , and S. Berkman and H. Zocher, -0.04×10^{-6} .

H. Rose said that columbium pentoxide is reduced and blackened when heated in **hydrogen**; and M. Delafontaine found that the tetroxide is formed. H. von Wartenberg and co-workers found that the oxide is reduced by hydrogen at 5 atm. press. at 2500°, and E. Newbery and J. N. Pring, that over 2000° and 150 atm. press., columbium monoxide is formed. For the action of **hydrogen dioxide**, *vide* tantalum pentoxide. W. K. van Haagen and E. F. Smith found that **hydrogen fluoride** converts the pentoxide into fluoride. When heated with dry **hydrogen chloride**, R. D. Hall and E. F. Smith found that a volatile chloride is formed. M. E. Pennington said that the thoroughly calcined pentoxide is slowly soluble in conc. **hydrofluoric acid**. On the other hand, R. F. Weinland and L. Storz found that calcined columbium pentoxide is insoluble in hydrofluoric acid; and F. Ott, that it is likewise insoluble in **hydrochloric acid**. H. Rose found that the red-hot pentoxide does not alter in weight when heated in a current of **sulphur dioxide**, and with **hydrogen sulphide**, the oxytrisulphide is formed. M. E. Pennington said that **hyposulphurous acid** colours the pentoxide yellow. H. Rose found that the uncalcined oxide dissolves in hot, conc. **sulphuric acid**, but the calcined oxide is scarcely soluble in that menstruum. S. J. Kiehl and D. Hart found that a sat. soln. contains 8.34 grms. of columbium pentoxide and 80.11 per cent. of anhydrous sulphuric acid in 100 grms. of soln. The soln. must be at least 3M- H_2SO_4 and contain not more than 0.038M- Cb_2O_5 to remain stable for 3 days. For higher conc. of the pentoxide, more conc. acid must be used. E. F. Smith and co-workers, and R. D. Hall observed that when heated with **sulphur monochloride** vapour, the oxytrichloride and then the pentachloride are formed; F. Bourion observed that the reaction with a mixture of sulphur monochloride and chlorine begins at about 300°. H. Rose found that at a white-heat, **ammonia** converts the pentoxide into nitride. H. Rose said that there is a small loss of weight when the pentoxide is mixed with **ammonium chloride** and calcined—presumably a trace of volatile oxychloride is formed. M. E. Pennington observed that **phosphorus pentachloride**, in a sealed tube at 180°–235°, forms

columbium pentachloride, and phosphoryl chloride. H. Rose showed that the vapour of **carbon disulphide** converts the white-hot pentoxide into the oxytrisulphide; and M. Delafontaine and C. E. Linebarger, and R. D. Hall and E. F. Smith found that **carbon tetrachloride** vapour, or a mixture of carbon dioxide and chlorine, converts the pentoxide into the pentachloride and the oxytrichloride—E. Demarçay said that the attack begins at 210°, and P. Cambouives, at 215°. O. Ruff and F. Thomas said that the chlorination occurs readily at 200°–225°, but not so with tantalum pentoxide. It is not possible to separate the two by this reaction because, in the presence of columbium pentoxide, tantalum also is converted into the pentachloride. F. Ott found that the calcined pentoxide is insoluble in **alkali-lye**; but it is converted into the alkali columbate by the fused hydroxide, or by fused **alkali carbonate**. L. Weiss and M. Landecker showed that it is soluble in a mixture of sodium carbonate and borax. As indicated above, it is dissolved by molten **boric oxide**, or **borax**, and most of the pentoxide crystallizes from the soln. on cooling. A. Knop found that it is dissolved by molten **glass**, but W. Muthmann and co-workers found that it is not affected by porcelain glazes at a red-heat. H. Rose, and L. Weiss and M. Landecker observed that the pentoxide dissolves in molten **potassium hydrosulphate**, and most of it crystallizes out on cooling. H. Rose said that when the pentoxide is fused with **ammonium hydrosulphate**, it forms a viscid mass soluble in water. H. Rose observed that when heated with **oxidizing agents**—molten potassium nitrate, a molten mixture of potassium chlorate and sodium carbonate, or a mixture of potassium chlorate and hydrochloric acid—no higher oxide is formed.

According to H. Rose, **hydrated columbium pentoxide**, $\text{Cb}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, or **columbic acid**, HCbO_3 , is formed when columbium oxytrichloride is hydrolyzed by water. If the oxytrichloride be treated with water, an amorphous, voluminous hydrate is formed which is difficult to wash, but if the oxytrichloride be exposed to air, water is gradually attracted from the atm. and a crystalline hydrate, easy to wash, is formed. B. Santesson treated a soln. of columbium oxyfluoride with dil. ammonia. C. W. Blomstrand boiled columbium pentachloride with water and obtained columbic acid; and J. C. G. de Marignac digested the product with aq. ammonia. C. W. Balke and E. F. Smith found it very difficult to wash out the last traces of chlorine, and they recommended treating the pentachloride with dil. ammonia, acidifying the liquid with nitric acid, filtering, and washing. H. Rose decomposed a boiling aq. soln. of an alkali columbate with hydrochloric acid, and obtained a hydrate which retained hydrochloric acid very tenaciously. R. F. Weinland and L. Storz used a modification of this process; and B. Santesson employed sulphuric in place of hydrochloric acid. H. Rose fused the pentoxide with potassium or ammonium hydrosulphate and treated the cold product with water. It retains sulphates very tenaciously, and the residue was therefore boiled with aq. ammonia or a soln. of sodium carbonate, and washed with dil. hydrochloric acid or a dil. soln. of ammonium chloride. L. Weiss and M. Landecker treated a soln. of columbium pentoxide in sulphuric acid with water or aq. ammonia. J. C. G. de Marignac, F. Wöhler, and R. F. Weinland and L. Storz obtained a **colloidal solution** of hydrated columbium pentoxide by boiling the precipitated pentoxide with hydrochloric acid.

Hydrated columbium pentoxide is a white, amorphous solid. H. Rose found the sp. gravity to be 4.3. When obtained by the hydrolysis of the halides, it shows the phenomenon of calorescence when heated—5.33, 10—but not so when obtained from the fused potassium hydrosulphate. When dried at 100°, it contains variable amounts of water; J. C. G. de Marignac found that it lost 4.47 per cent. at 150°; 5.75 per cent. at 200°; and 7.8 per cent. at 300°. B. Santesson observed that the hydrate prepared from the oxyfluoride contained 8.04–8.51 per cent. of water, and that prepared by treating alkali columbate with sulphuric acid, 13.79–14.00 per cent.—the theoretical value for $\text{Cb}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$ is 13.55 per cent. Hence the term “columbic acid” refers only to the acidic character of the hydrated pentoxide.

R. Robl observed no fluorescence when the so-called metacolumbic acid is exposed to ultra-violet light. H. Rose, and L. Weiss and M. Landecker found that the hydrated pentoxide is soluble in **hydrofluoric acid**; and that it is more soluble than tantalic acid in **hydrochloric acid**; but it is at the best only sparingly soluble in cold, conc. hydrochloric acid—R. F. Weinland and L. Storz found that only one per cent. Cb_2O_5 passes into soln. J. C. G. de Marignac, and F. Wöhler said that the hydrated pentoxide is only sparingly soluble in boiling hydrochloric acid, but the residue becomes soluble in water by this treatment. R. F. Weinland and L. Storz found that only 1.2 per cent. Cb_2O_5 dissolves in highly conc. **hydrobromic acid**; and only a trace dissolves in **hydriodic acid**, and at the same time a little pentoxide is reduced. L. Weiss and M. Landecker said that the hydrated pentoxide is insoluble in **perchloric acid**; and that it dissolves in **sulphuric acid** more easily than does tantalic acid. R. D. Hall and E. F. Smith said that it is insoluble in dil. sulphuric acid. The sulphuric acid soln. gives a precipitate when diluted with water, when treated with alkali sulphates, sulphur dioxide, etc. The properties of the sulphuric acid soln. were studied by H. Rose, J. C. G. de Marignac, and L. Weiss and M. Landecker. The last-named found that the solubility in acids is hastened if hydrogen dioxide be present. L. Weiss and M. Landecker found that the hydrated pentoxide dissolves in **nitric acid** more readily than does tantalic acid; and the solubility in aq. **ammonia** or **ammonium chloride** is hastened if hydrogen dioxide be present. M. E. Pennington found that up to 2 per cent. of the hydrated pentoxide dissolves in warm soln. of **ammonium sulphide** when digested therein for some time. L. Weiss and M. Landecker found that the hydrated pentoxide is insoluble in phosphoric acid, and that its solubility in a soln. of sodium hydrophosphate is favoured by the presence of hydrogen dioxide. Freshly precipitated hydrated pentoxide is soluble in **oxalic acid**, or **tartaric acid**—the soln. of columbium pentoxide in oxalic acid is not affected by many reagents which are active with soln. in other solvents. R. D. Hall found that a soln. of **potassium oxalate** dissolves the hydrated pentoxide. H. Lange found that with **ammonium salicylate** an insoluble, yellow adsorption compound is formed. H. Rose found that a soln. of an alkali columbate acidified with hydrochloric or sulphuric acid colours **turmeric** brown or reddish-brown. L. Weiss and M. Landecker found that the hydrated pentoxide is soluble in **hydrofluosilicic acid**. H. Rose, and F. Wöhler showed that the hydrated pentoxide is readily soluble in soln. of **alkali hydroxides** or **carbonates**. L. Weiss and M. Landecker showed that the presence of hydrogen dioxide hastens the process of dissolution. If the precipitate has aged a few hours, it dissolves with greater difficulty than the fresh precipitate. The hydrated pentoxide is insoluble in soln. of **sodium or ammonium hydrocarbonate**—*vide supra*, analytical reactions of columbium.

§ 8. Columbates or Niobates

According to A. Stähler,¹ the salt-forming properties of the lower oxides of columbium are more like the elements of the chromium family than are those of titanium and vanadium. Columbium pentoxide is an acid anhydride forming a number of salts. As an acid, said R. F. Weinland and L. Storz, columbic acid is about the same strength as silicic acid, and is stronger than titanitic acid. The alkali columbates were made by H. Rose by fusing a mixture of the alkali carbonate with what he called *Unterniobsaure*, Nb_2O_5 , but which J. C. G. de Marignac showed to be columbium pentoxide. C. F. Rammelsberg recalculated H. Rose's results for the acidic oxide Cb_2O_5 . A. F. Gehlen had previously obtained small, soluble crystals of alkali columbate by fusing columbite or tantalite with sodium or potassium carbonate. C. W. Balke and E. F. Smith, and M. H. Bedford showed that the nature of the product depends on the proportion of the component salts. F. Russ showed that the columbates readily form complex acid salts; and R. F. Weinland and L. Storz found that the oxygen can be partially displaced by chlorine or bromine. A potassium columbate of indefinite composition was obtained by A. F. Gehlen, W. von Bolton, H. Moissan, J. C. G. de Marignac, and W. Muthmann, by the action of molten alkali hydroxide, or a mixture of the alkali carbonate and nitrate on the metal. H. Rose also made potassium columbates by the action of fused potassium hydroxide or carbonate, or aq. soln. of these compounds on hydrated columbium pentoxide. F. Russ found that a mol of columbium pentoxide drives a mol of carbon dioxide from a mol of potassium carbonate, and 2.5 mols of carbon dioxide from 3 and 5 mols of potassium carbonate. In general, the alkali columbates can be obtained by fusing columbium pentoxide with the alkali carbonates, the product obtained depends on the relative proportions of pentoxide and carbonate employed; if too little carbonate be used, sparingly soluble acidic columbates are formed, while if large excess of carbonate is used, potassium, rubidium, and cesium carbonates give clear fusions, soluble in a relative small proportion of water, while with sodium carbonate, the fusion is not clear, and the resulting columbate is not soluble in the presence of an excess of the alkali carbonate, but it is completely soluble in water. A large number of columbates have been reported, but probably many of these are merely mixtures. H. Rose found that the aq. soln. of potassium columbates can be boiled without decomposition, and when the soln. is evaporated to dryness, it can be again dissolved in water. The aq. soln. are partly decomposed by carbon dioxide. The general properties of these salts have been considered in connection with the analytical reactions of columbium, and the properties of columbic acid. Complex columbates can be named by the system employed for the vanadates, etc.

The **ammonium columbates** have not been studied in detail; they are formed by double decomposition with the alkali columbates and ammonium salts. K. A. Hofmann and V. Kohlschütter reported **hydroxylamine columbate**, $3(\text{NH}_2\text{OH})\cdot\text{HCbO}_3$, to be formed by digesting a mixture of potassium deuterohexacolumbate with conc. aq. ammonia and hydroxylamine chloride; washing the product successively with dil. aq. ammonia, alcohol, and ether; and drying for an hour in vacuo over sulphuric acid. The white powder explodes when heated in a tube. It is sparingly soluble in water, and when digested with water at ordinary temp. it is decomposed. Another hydroxylamine columbate was obtained with similar properties; but with the composition $5\text{NH}_2\text{OH}\cdot\text{Cb}_2\text{O}_5\cdot 2\text{H}_2\text{O}$.

H. Rose did not make definite potassium columbates, but from the amount of carbon dioxide evolved when columbium pentoxide is fused with potassium carbonate, he inferred that **potassium orthocolumbate**, K_3CbO_4 , is formed; and F. Russ obtained this salt by calcining the oxalato-columbate, $3\text{K}_2\text{O}\cdot\text{Cb}_2\text{O}_5\cdot 6\text{C}_2\text{O}_3\cdot 4\text{H}_2\text{O}$. P. J. Holmquist reported the possible formation of acicular, or cubic and hexahedral crystals, or crystal aggregates of **sodium pyrocolumbate**, $\text{Na}_4\text{Cb}_2\text{O}_7$, by melting a mixture of 3.88 grms. of sodium carbonate, 4.94 grms. of columbium pentoxide, and 1.6 grms. of sodium fluoride; and washing out the fluoride with water. The salt is decomposed by water. A. Lottermoser placed a soln. of the normal columbate in the inner anode compartment, and 0.1N-NaOH in the outer cathode compartment, and on electrolysis with a platinum cylinder as anode, an acid columbate was formed in the inner cell. B. Santesson obtained **potassium pyrocolumbate**, $\text{K}_4\text{Cb}_2\text{O}_7$, by melting the tetracolumbate with an excess of potassium carbonate, and washing away the soluble matters with water.

Although J. C. G. de Marignac was unable to prepare definite sodium columbates, yet H. Rose described **sodium metacolumbate**, $\text{Na}_2\text{O}\cdot\text{Cb}_2\text{O}_5\cdot n\text{H}_2\text{O}$, or $\text{NaCbO}_3\cdot n\text{H}_2\text{O}$, as best crystallized and the most stable of all the columbates. A. Joly studied the substitution of columbic anhydride for carbonic anhydride in sodium carbonate, and P. J. Holmquist obtained the anhydrous salt by melting equimolar parts of sodium carbonate and columbium pentoxide with sodium fluoride as a flux. The cold mass was washed with water to remove the excess of sodium fluoride. The white, pseudo-cubic crystals consist of twinned plates. The sp. gr. of the finest powder at 18° is 4.512, and that of coarser powder is 4.559. The hydrated salt was obtained by H. Rose by fusing columbium pentoxide or hydroxide, or an acidic sodium columbate with sodium hydroxide in a silver crucible. The residue was insoluble in an excess of alkali-lye, but soluble in water. The same salt was formed by H. Rose, and B. Santesson by heating an aq. soln. of sodium hydroxide with columbium hydroxide in suspension; although the columbium pentoxide did not dissolve, on removing the excess of sodium hydroxide, the residue was soluble in water, and, on evaporation, the soln. gave crystals of the metacolumbate. H. Rose obtained the same salt by fusing sodium with columbium oxide; evaporating the clear liquid obtained by extracting the cold cake with water; and crystallizing the soln. C. W. Balke and E. F. Smith showed that the formulæ of H. Rose and C. F. Rammelsberg respectively— $\text{Na}_2\text{O}\cdot\text{Cb}_2\text{O}_5\cdot 6\text{H}_2\text{O}$ and $\text{Na}_2\text{O}\cdot\text{Cb}_2\text{O}_5\cdot 9\text{H}_2\text{O}$ —probably refer to impure products for the spontaneous evaporation of the aq. soln., yields triclinic crystals of the *heptahydrate*, $\text{Na}_2\text{O}\cdot\text{Cb}_2\text{O}_5\cdot 7\text{H}_2\text{O}$, with axial ratios $a : b : c = 0.9559 : 1 : 0.8394$, and $\alpha = 71^\circ 20'$; $\beta = 105^\circ 30'$; $\gamma = 54^\circ 7'$. T. Barth said that the crystals of sodium metacolumbate are pseudo-cubic and the X-radiogram shows that the space lattice has one mol in the parallelepiped; the edge of the pseudo-cube $a = 3.890$ Å. The salt is isomorphous with perowskite, CaTiO_3 , and mixed crystals occur as the mineral *dysanalyte* which has a pseudo-cubic lattice with edge 3.826 Å. The salt loses 22.93 per cent. of water at 100° ; and forms a clear soln. with water. A. Joly also reported **potassium metacolumbate**, KCbO_3 , to be formed by fusing equimolar parts of potassium carbonate and columbium pentoxide with calcium fluoride in a platinum crucible, and slowly cooling the molten mixture. The cold product was treated

with boiling dil. sulphuric acid for some days to remove the calcium fluoride, and there remained straw-yellow rectangular plates which did not belong to the cubic system.

J. C. G. de Marignac reported **potassium orthotetracolumbate**, $K_6Cb_4O_{13} \cdot 13H_2O$, to be formed by the slow evaporation of an aq. soln. of the dodeca- or tetradecacolumbate with an excess of potash-lye. The rhombic crystals have the axial ratios $a : b : c = 0.9770 : 1 : 1.1722$; and they rapidly effloresce in air; and lose 7 mols. of water at 100° . R. Hermann prepared two salts of nearly the same composition by evaporating in vacuo, over sulphuric acid, a soln. of columbic acid in boiling potash-lye. F. Russ obtained evidence of the formation of a more basic salt, $2K_2O \cdot K_6Cb_4O_{13}$, by measuring the amount of carbon dioxide expelled from potassium carbonate by columbium pentoxide. B. Santesson, and F. Russ obtained crystalline **potassium deutero-tetracolumbate**, $K_2Cb_4O_{12} \cdot 5\frac{1}{2}H_2O$, by melting equimolar parts of potassium carbonate and columbium pentoxide, and washing out the soluble matters with water.

J. C. G. de Marignac prepared **potassium orthohexacolumbate**, $K_8Cb_6O_{19} \cdot 16H_2O$, in well-defined crystals, by evaporating in vacuo an aq. soln. of a fused mixture of columbium pentoxide with 2 or 3 times its weight of potassium carbonate. W. E. von John also prepared this salt; C. W. Balke and E. F. Smith obtained it in monoclinic crystals with the axial ratios $a : b : c = 0.7120 : 1 : 0.5547$, and $\beta = 84^\circ 19'$. J. C. G. de Marignac said that the salt is isomorphous with the corresponding tantalate; it effloresces quickly in air; loses 12 mols. of water at 100° ; dissolves completely in water, and on evaporation, the aq. soln. yields the tetradecacolumbate. C. W. Balke and E. F. Smith likewise prepared **rubidium orthohexacolumbate**, $Rb_8Cb_6O_{19} \cdot 14H_2O$, in monoclinic crystals with the axial ratios $a : b : c = 0.8816 : 1 : 1.0491$; and $\beta = 84^\circ 7'$; and the corresponding **cæsium orthohexacolumbate**, $Cs_8Cb_6O_{19} \cdot 14H_2O$, in monoclinic crystals whose angular measurements coincide, within the limits of experimental error, with those of the rubidium salt. Both salts form an isomorphous group with the corresponding tantalates. A. Santesson reported small crystals of sodium deuterohexacolumbate, $Na_4Cb_6O_{17} \cdot 9H_2O$, to be formed from a boiling aq. soln. of a fused mixture of columbium pentoxide and potassium hydroxide; but M. H. Bedford could not confirm this. J. C. G. de Marignac obtained **potassium triterohexacolumbate**, $K_2Cb_6O_{16} \cdot 5H_2O$, as a white precipitate by boiling a soln. of potassium oxytrifluocolumbate and hydrocarbonate.

R. Hermann reported **sodium orthocolumbate**, $Na_{10}Cb_8O_{25} \cdot 21H_2O$, to be precipitated when sodium hydroxide is added to a hot soln. of potassium oxyfluocolumbate, but this has not been confirmed. W. R. Schoeller and C. Jahn studied the sodium columbates. A. Joly melted a mixture of columbium pentoxide with twice its weight of potassium sulphate in a platinum crucible at a red-heat, and after washing the cold mass with water, obtained thin tablets of **potassium deuteroctocolumbate**, $K_6Cb_8O_{23}$. C. W. Balke and E. F. Smith obtained crystalline needles of **rubidium deuteroctocolumbate**, $Rb_6Cb_8O_{23} \cdot 9\frac{1}{2}H_2O$, from a fused mixture of columbium pentoxide and rubidium carbonate, or by melting the orthohexacolumbate. H. Rose obtained a precipitate corresponding with **sodium tetroctocolumbate**, $Na_2Cb_8O_{21} \cdot 5H_2O$, as a gelatinous precipitate, by passing carbon dioxide into a soln. of sodium metacolumbate.

H. Rose reported **sodium orthodecacolumbate**, $Na_{12}Cb_{10}O_{29} \cdot 40H_2O$, to be obtained by washing with water the product obtained by melting a mixture of sodium carbonate and columbium pentoxide; C. W. Blomstrand's analyses corresponded with **sodium orthotetradecacolumbate**, $Na_{16}Cb_{14}O_{43} \cdot 30H_2O$. R. Hermann did not obtain the same results. C. W. Balke and E. F. Smith, and J. C. G. de Marignac obtained **potassium orthotetradecacolumbate**, $K_{16}Cb_{14}O_{43} \cdot 32H_2O$, by slowly evaporating an aq. soln. of the orthohexacolumbate. The rhombic bipyramidal crystals have the axial ratios $a : b : c = 0.9584 : 1 : 0.7083$. They can be recrystallized from water without change, and they lose 23 mols. of water at 100° . When the aq. soln. is treated with carbon dioxide a more acid salt separates

out. C. W. Balke and E. F. Smith said that this salt is probably the orthododecacobaltate.

C. W. Balke and E. F. Smith obtained crystalline **lithium orthododecacobaltate**, $\text{Li}_{14}\text{Cb}_{12}\text{O}_{37}\cdot 26\text{H}_2\text{O}$, by cooling a warm mixture of soln. of lithium nitrate made feebly alkaline with lithium carbonate and a conc. soln. of potassium triterohexacobaltate. M. H. Bedford recrystallized R. Hermann's sodium ortho-octocobaltate, and showed that it is probably the *dotricontahydrated sodium orthododecacobaltate*, $\text{Na}_{14}\text{Cb}_{12}\text{O}_{37}\cdot 32\text{H}_2\text{O}$. The same salt was made by recrystallizing the aq. extract of a fused mixture of sodium hydroxide and columbium pentoxide. This gives the *hexatrichontahydrate*; and if alcohol be added to the aq. soln., the *hemitrichontahydrate* is precipitated. This salt was also made by C. W. Balke and E. F. Smith. The prismatic crystals are fairly stable, and freely soluble in water. The aq. soln. gives precipitates with silver, barium, and zinc salts. W. E. von John said that the salt is insoluble in soda-lye. C. W. Balke and E. F. Smith obtained **potassium orthododecacobaltate**, $\text{K}_{14}\text{Cb}_{12}\text{O}_{37}\cdot 27\text{H}_2\text{O}$, by adding alcohol to an aq. soln. of the orthohexacobaltate; and by crystallization from aq. soln. of the same salt; and **cæsium orthododecacobaltate**, $\text{Cs}_{14}\text{Cb}_{12}\text{O}_{37}\cdot 30\text{H}_2\text{O}$, was obtained in an analogous way.

H. Rose obtained what he regarded as **ammonium sodium tetreroctocobaltate**, $\{(\text{NH}_4)_{0.833}\text{Na}_{0.167}\}_2\text{Cb}_8\text{O}_{21}\cdot 5\text{H}_2\text{O}$, by adding ammonium chloride or sulphate to a soln. of sodium metacobaltate; and J. C. G. de Marignac, **sodium potassium orthohexacobaltate**, $(\text{K}_3\text{Na})_2\text{Cb}_6\text{O}_{19}\cdot 9\text{H}_2\text{O}$, by adding sodium hydroxide to a soln. of potassium cobaltate.

A. Larsson prepared **copper metacobaltate**, $\text{Cu}(\text{CbO}_3)_2$, by melting with boric oxide the precipitate obtained by adding copper sulphate to a soln. of the sodium salt, and washing the product with dil. hydrochloric acid. The sp. gr. of the black crystal aggregates is 5.60. If the pale green precipitate be dried at 100° , C. F. Rammeisberg said that it is the *dihydrate*, and C. W. Balke and E. F. Smith, the *hemihydrate*; and C. W. Balke and E. F. Smith obtained **silver metacobaltate**, $\text{AgCbO}_3\cdot \text{H}_2\text{O}$, as a yellowish-white precipitate by adding silver nitrate to a soln. of sodium metacobaltate. The salt darkens by exposure to light. M. H. Bedford reported white, insoluble **silver orthododecacobaltate**, $\text{Ag}_{14}\text{Cb}_{12}\text{O}_{37}\cdot 5\text{H}_2\text{O}$, to be formed by adding a dil. soln. of silver nitrate to the sodium salt.

P. J. Holmquist obtained **calcium orthocobaltate**, $\text{Ca}_3(\text{CbO}_4)_2$, contaminated with sodium cobaltate, by treating a soln. of the sodium salt in molten sodium carbonate with calcium carbonate, and washing the precipitate with dil. hydrochloric acid. A. Joly obtained **calcium pyrocobaltate**, $\text{Ca}_2\text{Cb}_2\text{O}_7$, by heating to redness a mixture of columbium pentoxide with a great excess of calcium chloride, and washing the product with dil. hydrochloric acid; A. Larsson digested with a soln. of calcium chloride the precipitate obtained by treating a soln. of potassium cobaltate with calcium chloride; and P. J. Holmquist, by melting 1.83 grms. of columbium pentoxide, 20 grms. of calcium chloride, and 7 grms. of sodium fluoride; or by treating a soln. of columbium pentoxide in molten potassium hydrosulphate with calcium sulphate; or by adding calcium carbonate to a molten mixture of columbium pentoxide and calcium chloride. The colourless prismatic crystals, or rhombic needles or plates have a sp. gr. 4.4840 at 17° . P. J. Holmquist obtained what he regarded as isomorphous mixtures with sodium metacobaltate. A. Joly obtained **calcium metacobaltate**, $\text{Ca}(\text{CbO}_3)_2$, by heating a mixture of columbium pentoxide and calcium fluoride (2 : 1) with an excess of potassium chloride at a red-heat for 4-5 hrs., and extracting the product with water. A. Larsson said that the product is a mixture of the pyrocobaltate with columbium pentoxide; he also obtained the metacobaltate by melting the pyrocobaltate with boric oxide, and boiling the product with dil. hydrochloric acid. P. J. Holmquist said that the tabular crystals have a sp. gr. of 4.484 at 17° , and A. Larsson, 4.12. T. L. Walker and A. L. Parsons described a calcium cobaltate, $\text{CaO}\cdot \text{Cb}_2\text{O}_5\cdot 2\text{H}_2\text{O}$, or $\text{Ca}(\text{CbO}_3)_2\cdot 2\text{H}_2\text{O}$, occurring as a mineral in Monteaule, Ontario; and they called it

ellsworthite—after H. V. Ellsworth. The amber-yellow or dark chocolate-brown mineral occurs in masses with a conchoidal fracture. It is isotropic with a refractive index exceeding 1.74. The sp. gr. is 3.608–3.758; and the hardness 4. A. Larsson obtained **strontium and barium columbates** by treating a soln. of the potassium salt with strontium or barium chloride, and melting the product with boric oxide. He could not obtain satisfactory formulæ from the analyses. M. H. Bedford precipitated **barium orthododecacolumbate**, $\text{Ba}_7\text{Cb}_{12}\text{O}_{37}\cdot 18\text{H}_2\text{O}$, from a hot soln. of the sodium salt and a dil. soln. of barium chloride.

A. Larsson prepared **beryllium columbate**, in thin plates mixed with acicular crystals of columbium pentoxide, by treating a soln. of potassium columbate with beryllium chloride; melting the product with boric oxide; and washing with water. He likewise prepared magnesium metacolumbate, $\text{Mg}(\text{CbO}_3)_2$, in short, doubly refracting prisms. C. F. Rammelsberg represented the precipitate, before fusion with the boric oxide, as a *tetrahydrate*; and C. W. Balke and E. F. Smith as a *heptahydrate*. A. Joly reported **magnesium orthocolumbate**, $\text{Mg}_3(\text{CbO}_4)_2$, to be formed in colourless, prismatic crystals, along with those of a more basic salt, **magnesium oxyorthocolumbate**, $\text{MgO}\cdot\text{Mg}_3(\text{CbO}_4)_2$, by fusing in a platinum crucible a mixture of columbium pentoxide, or alkali columbate, and magnesium chloride covered with ammonium chloride. A. Larsson washed the product with boiling water, and with boiling hydrochloric acid; he could not prepare the ortho-salt. The colourless or pale yellow, hexagonal plates have a sp. gr. 4.43. The oxyorthocolumbate is not attacked by dil. acids, but hot conc. sulphuric acid, or a mixture of hydrofluoric and dil. sulphuric dissolves the salt. It is attacked by fused potassium hydrosulphate. A. Joly reported **magnesium pyrocolumbate**, $\text{Mg}_2\text{Cb}_2\text{O}_7$, to be formed in black rhombic prisms from a fused mixture of columbium pentoxide and magnesium chloride. According to A. Larsson, when the precipitate obtained by treating a soln. of potassium columbate with zinc chloride is fused with boric oxide, and the product washed with water, a brown aggregate of rhombic crystals of **zinc metacolumbate**, $\text{Zn}(\text{CbO}_3)_2$, is formed. The sp. gr. is 5.69 at 17°; **cadmium metacolumbate**, $\text{Cd}(\text{CbO}_3)_2$, was obtained in an analogous manner. The sp. gr. is 5.93 at 17°. C. W. Balke and E. F. Smith found that the precipitate obtained with the cadmium salt is the *hemiheptahydrate*. M. H. Bedford prepared **zinc orthododecacolumbate**, $\text{Zn}_7\text{Cb}_{12}\text{O}_{37}\cdot 25\text{H}_2\text{O}$, by adding zinc sulphate to a soln. of the sodium salt. H. Rose, and C. F. Rammelsberg obtained yellow **mercurous metacolumbate**, $\text{HgCbO}_3\cdot 1\frac{1}{2}\text{H}_2\text{O}$, by adding mercurous nitrate to a soln. of the sodium salt.

C. W. Balke and E. F. Smith prepared **aluminium metacolumbate**, $\text{Al}(\text{CbO}_3)_3\cdot 6\text{H}_2\text{O}$, by adding a soln. of alum to one of the sodium salt. A. Larsson obtained crystalline **yttrium orthocolumbate**, YCbO_4 , by treating a soln. of potassium columbate with yttrium chloride; melting the precipitate with anhydrous yttrium chloride; and washing the product with boiling hydrochloric acid. A. Joly also prepared the same salt in octahedral crystals. For tetragonal *fergusonite*, or, idealized, yttrium columbate, YCbO_4 , *vide* 5. 38, 3. T. Barth obtained it by fusing a mixture of yttria and columbium pentoxide. The X-radiograms of the crystals show that the tetragonal cell has $a=7.76$ A., and $c=1132$ A., or $a:c=1:1.46$. The mineral glows about 400°, and after fusion, the X-radiogram shows that the unit tetragonal cell has $a=77.4$ A., $c=11.31$ A., or $a:c=1:1.46$. Each cell contains eight molecules of YCbO_4 . A. Larsson obtained **yttrium metacolumbate**, $\text{Y}(\text{CbO}_3)_3$, by melting the precipitate just indicated with boric oxide instead of yttrium chloride. Y. Shibata and K. Kimuru described a rare earth at Ishikawa, Japan, and they called it **ishikawaite**. The black crystals have 8.40 per cent. of rare earths; 21.88 per cent. UO_2 ; 36 per cent. Cb_2O_5 , and 15 per cent. Ta_2O_5 . The axial ratios of the rhombic crystals are $a:b:c=0.9451:1:1.147$; the sp. gr. is 6.2 to 6.4; and the hardness 5 to 6.

R. D. Hall and E. F. Smith said that a **titanium columbate** is probably formed when different organic bases are added in excess to a mixed soln. of potassium

fluotitanate and oxyfluocolumbate. For the mineral **epistolite**—**sodium silicatotitanatocolumbate**, *vide* 6. 40, 47. A mineral from Vogtsburg, Baden, was regarded as cubic titanic oxide by F. A. Walchner, and *perovskite* by A. Breithaupt, but it was shown by A. Knop to be a **calcium iron titanatocolumbate**, approximating, according to the analyses of F. Seneca, A. Knop, F. W. Mar, O. Hauser, and F. Zambonini, $6\text{RTiO}_3 \cdot \text{RCb}_2\text{O}_6$, where $2\text{Cb}=3\text{R}$. The mineral was called **dysanalyte**—from *δυσανάλυτος*, difficult to undo—in allusion to the difficulty of the analysis. P. J. Holmquist obtained mixed crystals of $2\text{NaCbO}_3 \cdot \text{Ca}_2\text{Cb}_2\text{O}_7 \cdot \text{Ce}_6\text{Cb}_4\text{O}_{19}$. The iron-black, cubic crystals or cubo-octahedra were found by J. Söllner, and A. Ben Saude to be optically anomalous, and sections parallel to the (100)- and the (111)-faces show twinning analogous to perovskite. The hardness is 4–5, and the sp. gr. 4.02–4.18. G. A. König observed *hydrotitanite*—a mixture of ferric oxide and colloidal titanic oxide—to be a product of the weathering of dysanalyte. A. Larsson prepared **zirconium columbate**, $\text{ZrO}_2 \cdot 5\text{Cb}_2\text{O}_5$, by adding zirconium chloride to a soln. of potassium columbate; melting the precipitate with boric oxide; and boiling the product with dil. hydrochloric acid. The sp. gr. of the acicular crystals is 5.14 at 17°. P. J. Holmquist obtained a similar product by melting together zirconia, columbium pentoxide, and sodium fluoride. For **wöhlerite**, see **sodium calcium silicatzirconatocolumbate**, *vide* 6. 40, 48. A. Larsson made **thorium columbate**, $5\text{ThO}_2 \cdot 16\text{Cb}_2\text{O}_5$, by the method employed for zirconium columbate. The prismatic crystals are probably rhombic, and have a sp. gr. 5.21 at 17°. P. J. Holmquist also prepared a thorium columbate by melting together thoria, columbium pentoxide, and sodium fluoride. A pale yellow isotropic mineral called **lyndochite** was found by W. G. Miller in the pegmatite dyke of Lyndoch, Ontario. The composition approximates to an isomorphous mineral of the euxenite-polyserase family being a thorium calcium columbate of the euxenite type with uranium as a minor constituent. H. V. Ellsworth observed that the crystals are like those of euxenite, and have nearly the same axial ratio. There are parallel growths and twinning. There is no cleavage. The sp. gr. is 4.909 at 17.88; and the hardness 6.5.

C. W. Blomstrand obtained **chromium columbate**, as a yellow precipitate, by treating a soln. of columbium oxychloride with potassium dichromate; and E. F. Smith obtained **tungsten columbate** or rather complexes of columbium pentoxide and tungsten trioxide. The so-called *uranopyrochlore*, or *hatchettolite*—of 5. 38, 3—is a *calcium uranyl tantatocolumbate*; **sodium uranyl columbate**, $7\text{Na}_2\text{O} \cdot 4\text{UO}_2 \cdot 9\text{Cb}_2\text{O}_5$, was prepared by P. J. Holmquist by melting together 2.9 grms. of uranium tritoxide, 1.3 grms. of columbium pentoxide, and 5 grms. of sodium fluoride at a high temp. The orange-yellow tablets are isotropic; their sp. gr. is 5.156 at 20°, and 5.173 at 17°. H. V. Ellsworth described a uranium columbate from Sudbury, Ontario. He called it **toddite**. It contained 8.97 per cent. Ta_2O_5 ; 53.73 per cent. Cb_2O_5 ; 8.71 per cent. UO_2 ; and 2.37 per cent. UO_3 . It is pitch-black, isotropic, and brittle; it has no cleavage, and its hardness is 6½. A. Lacroix described a mineral from Ambalahazo and Ambolotora, Betafo, Madagascar; and he called it **betafite**. It is a hydrated yttrium uranyl columbate—the analysis is indicated below. The crystals are cubic octahedra, and the sp. gr. is 3.75–4.17; **samiresite** is from Samiresy, Madagascar, it is also a hydrated lead uranium columbate with the subjoined analysis; and it occurs in fragile octahedra resembling rubber in appearance; and **ampangabeite**, from Ampangabe, Madagascar, is a hydrated uranium columbate, containing some iron, whose analysis is indicated below:

	Cb_2O_5	Ta_2O_5	TiO_2	UO_2 or UO_3	$(\text{Ce}, \text{La}, \text{Di})_2\text{O}_3$	$(\text{Y}, \text{Er})_2\text{O}_3$	PbO	H_2O
Betafite	35.5	—	23.60	27.15	2.1	20.80	0.38	12.50
Samiresite	45.80	3.70	6.70	21.20	0.2	—	7.35	12.45
Ampangabeite	34.80	8.90	4.90	19.40	0.60	4.00	—	12.40

Betafite had also 0.37, SnO_2 ; 1.12, ThO_3 ; 1.50, Al_2O_3 ; 0.50, Fe_2O_3 ; 0.40, MgO ; 3.12, CaO . Samiresite had also 0.10, SnO_2 ; 0.74, Al_2O_3 ; 1.60, FeO ; and 0.30, K_2O . Ampangabeite had also 2.50, ThO_2 ; 2.10, Al_2O_3 ; 8.60, Fe_2O_3 ; and 1.50, CaO .

W. Vernadsky described a hydrated titanocolumbate containing 23.5 per cent. W_3O_8 , 15 per cent. CaO, and also lead, iron, and rare earths; it was called **menделееffite**—after D. I. Mendeléeff; and was found at Uluntui, near Slyudianka, Lake Baikal, Siberia. It resembles betafite, but whereas the yellowish or greenish colour of that mineral suggests the presence of uranium trioxide, the reddish-brown colour of menделееffite suggests uranium dioxide. The greyish-black, cubic crystals of menделееffite—rhombic dodecahedra with small octagonal faces—have a sp. gr. 4.76, and a hardness of 4.5.

A. Joly reported **manganese metacolumbate**, $Mn(CbO_3)_2$, to be formed in rose-red rhombic prisms when a mixture of equal weights of columbium pentoxide and manganese fluoride is melted with an excess of potassium chloride at a red-heat for an hour, and slowly cooled. The sp. gr. is 4.94 at 18°. A. Larsson added manganese sulphate to a soln. of potassium columbates, melted the precipitate with boric oxide, and treated the product with dil. hydrochloric acid. The dirty yellow crystalline powder of **manganese triterodecolumbate**, $Mn_3Cb_{10}O_{28}$, had a sp. gr. 4.97 at 17°. A. Joly made what was thought to be black prisms of **ferrous metacolumbate**, $Fe(CbO_3)_2$, by heating a mixture of 3 parts of columbium pentoxide, and 2 parts of ferrous fluoride with an excess of potassium chloride for 2 hrs. in a platinum crucible at a red-heat; and also by passing hydrogen chloride over a red-hot mixture of columbium pentoxide and ferric oxide. P. J. Holmquist thought that the crystals are possibly columbium pentoxide coloured with iron oxide; in the ideal case *columbite* or *niobite* is a ferrous manganese columbate, but in nature it is associated with more or less isomorphous *tantalite* so that both minerals are represented by $(Fe, Mn)\{(Ta, Cb)O_3\}_2$ —*vide* tantalates. P. J. Holmquist made a **ferric columbate** by melting columbium pentoxide with calcium chloride and ferric oxide—the product may be a calcium columbate coloured with ferric oxide. H. Rose, and C. F. Rammelsberg described **ferric hexacolumbate**, $Fe_4Cb_6O_{21} \cdot 8H_2O$, by adding ferric chloride to a soln. of an alkali columbate. A. Larsson treated a soln. of potassium columbate with cobalt nitrate, melted the precipitate with boric oxide; and obtained **cobalt metacolumbate**, $Co(CbO_3)_2$, as a dark blue crystalline powder of sp. gr. 5.56 at 17°. A. Larsson obtained **nickel columbate** in an analogous way.

§ 9. Percolumbic Oxide and the Percolumbates

P. G. Melikoff and L. Pissarjewsky¹ prepared what they called **percolumbic acid**, or **metapercolumbic acid**, $\text{HCbO}_4 \cdot n\text{H}_2\text{O}$, or, with quinquevalent columbium,

by heating columbium pentoxide with a 30 per cent. soln. of hydrogen dioxide; or by adding dil. sulphuric acid to potassium percolumbate, dialyzing out the sulphuric acid and potassium sulphate, concentrating the liquid on the water-bath, and drying the product over sulphuric acid. According to A. Piccini, some is formed by the action of hydrogen dioxide on potassium fluocolumbate. F. Ott obtained it by electrolyzing a soln. of columbium pentachloride in 80 per cent. sulphuric acid in a diaphragm cell. The columbium is oxidized by the ozone from the electrolysis of the dil. sulphuric acid in the anode compartment, forming an orange-yellow liquor. The dialyzed soln. just indicated is a **colloidal solution** of percolumbic acid; and the hydrosol is also formed by treating columbic acid with warm, 30 per cent. hydrogen dioxide when the yellow, gelatinous percolumbic acid first formed gradually passes into the hydrosol. The yellow, amorphous solid was found by P. G. Melikoff and L. Pissarjewsky to be more stable than pervanadic or pernitric acid. It decomposes at 100° with a change of colour; it is insoluble in water; and at ordinary temp. dil. sulphuric acid has no action, but when warmed the percolumbic acid is decomposed with the formation of hydrogen dioxide; with conc. sulphuric acid, ozonized oxygen is given off; and with hydrochloric acid, chlorine is formed. L. Weiss and M. Landecker found that the precipitation with hydroxylamine is not quantitative. According to R. D. Hall and E. F. Smith, when hydrogen dioxide is added to a hydrochloric acid soln. of columbic hydroxide, a yellow precipitate of **columbium perhydroxide**, $\text{Cb}_2\text{O}_5 \cdot \text{H}_2\text{O}_2 \cdot 5\text{H}_2\text{O}$, is formed.

C. W. Balke and E. F. Smith prepared the **percolumbates** by adding hydrogen dioxide to a soln. of the alkali columbate in the presence of an excess of the alkali carbonate or hydroxide. The salts are most readily obtained from such soln. by the addition of an equal vol. of alcohol, when the percolumbate separates as a white powder which can be filtered and washed with alcohol and ether. The percolumbates are stable in air; they dissolve in warm water without decomposition, but oxygen escapes when their soln. are boiled. C. W. Balke and E. F. Smith found **sodium perorthocolumbate**, Na_3CbO_8 , or, with quinquevalent columbium:

is difficult to prepare on account of the low solubility of sodium carbonate; they obtained it by adding hydrogen dioxide and sodium hydroxide to a soln. of sodium columbate, treating the soln. with an equal vol. of alcohol, and washing with alcohol and ether. They obtained **potassium perorthocolumbate**, K_3CbO_8 , as a white crystalline powder consisting of tetragonal crystals with the axial ratio $a : c = 1 : 0.844$. P. G. Melikoff and L. Pissarjewsky obtained **potassium permeta-columbate**, $\text{KCbO}_4 \cdot n\text{H}_2\text{O}$, as a white amorphous precipitate by warming or allowing a soln. of the pyro-salt to stand for some time. They obtained **potassium perpyro-columbate**, $\text{K}_4\text{Cb}_2\text{O}_{11} \cdot 3\text{H}_2\text{O}$,

by melting in a silver crucible a 1 : 8 mixture of columbium pentoxide and potassium hydroxide; treating the soln. in a little water with hydrogen dioxide; adding an

equal vol. of alcohol to the soln. warmed on a water-bath; washing the precipitate with alcohol and ether, and drying it on a porous tile. The product can be dissolved in water, mixed with hydrogen dioxide and potassium hydroxide, and again precipitated by alcohol. The properties of the salt resemble those of the perorthocolumbate, and C. W. Balke and E. F. Smith obtained the perorthocolumbate, not the perpyrocolumbate, when following P. G. Melikoff and L. Pissarjewsky's directions. O. Böhm obtained solid soln. of isomorphous mixtures of potassium or sodium percolumbate, pertantalate, and perchromate. According to C. W. Balke and E. F. Smith, **rubidium perorthocolumbate**, Rb_3CbO_8 , is produced by a method analogous to that employed for the sodium and potassium salts; and similarly also with **cæsius perorthocolumbate**, Cs_3CbO_8 .

C. W. Balke and E. F. Smith prepared acicular crystals of **sodium calcium perorthocolumbate**, $\text{NaCaCbO}_8 \cdot 4\text{H}_2\text{O}$, by adding a neutral or feebly alkaline soln. of calcium chloride to a soln. of potassium perorthocolumbate at 50° , and washing the precipitate successively with alcohol and ether; **potassium calcium perorthocolumbate**, $\text{KCaCbO}_8 \cdot 4\text{H}_2\text{O}$, was obtained in a similar way. Likewise also with **sodium magnesium perorthocolumbate**, $\text{NaMgCbO}_8 \cdot 8\text{H}_2\text{O}$; **potassium magnesium perorthocolumbate**, $\text{KMgCbO}_8 \cdot 7\text{H}_2\text{O}$; **rubidium magnesium perorthocolumbate**, $\text{RbMgCbO}_8 \cdot 7\frac{1}{2}\text{H}_2\text{O}$; and with **cæsius magnesium perorthocolumbate**, $\text{CsMgCbO}_8 \cdot \text{H}_2\text{O}$.

§ 10. Columbium Fluoride and Oxyfluorides

According to H. Rose,¹ hydrated columbium pentoxide dissolves easily in cold hydrofluoric acid—especially when the conc. or fuming acid is used—but no crystals are formed. If the soln. be evaporated to dryness, hydrogen fluoride is given off; and when the residue is heated, white fumes of fluoride or oxyfluoride are given off. Calcined columbium pentoxide does not dissolve in hydrofluoric acid, but if the mixture be evaporated to dryness, and heated, fumes of the fluoride are given off. If a mixture of calcined columbium pentoxide, and hydrofluoric and sulphuric acids be heated in a platinum vessel, white fumes of fluoride or oxyfluoride are given off. The action of fluorine on columbium has already been discussed. O. Ruff and J. Zedner prepared **columbium pentafluoride**, CbF_5 , by the action of fluorine on columbium containing about 3 per cent. of aluminium. The roughly-powdered metal contained in a boat is placed in a platinum tube 25 cms. long and 1.2 cms. diameter, the middle portion of which is inserted in an asbestos box; the constricted end of the tube is cooled by a lead worm, and connected to a receiver, from which moisture is carefully excluded. The fluorine when passed over the merely warmed columbium at once combined, and the reaction was finished when the tube began to cool. The box was next heated at 250° , when the pentafluoride distilled into the cooled portion of the tube, the aluminium fluoride remaining behind. On re-distillation in vacuo at 110° , it is obtained as colourless, strongly refractive, monoclinic prisms. O. Ruff and E. Schiller prepared the pentafluoride by mixing the pentachloride with anhydrous liquid hydrogen fluoride cooled by a freezing mixture and purifying the product by fractional distillation.

The pentafluoride forms colourless refracting prisms of **specific gravity** 3.2932 at 18° ; the m.p. is $72^\circ\text{--}73^\circ$. O. Ruff and E. Schiller gave 75.5° ; O. Ruff and

J. Zedner said that the **boiling point** of the pentafluoride is 236° at 760 mm.; and O. Ruff and E. Schiller gave 229·2°–229·5°. The **vapour pressure** p mm. is :

	184·5°	191 6°	194 5°	199 5°	204 5°	208 4°	212·5°	214·5°	216·5°
p	303·1	329·7	358·9	422·6	467·1	504·7	563·2	697·6	750·4

According to O. Ruff and co-workers, when the pentafluoride is heated above its b.p., in **hydrogen**, it forms a blue lower fluoride; below its b.p., it is not affected by **oxygen**. The pentafluoride is very hygroscopic in moist **air**. When the pentafluoride is treated with **water**, it hisses vigorously and dissolves with hydrolysis—hydrofluoric acid and an oxyfluoride are formed. The pentafluoride, above its m.p., reacts with **bromine**, and **iodine**; it dissolves in **hydrochloric acid** with the evolution of heat, and when the soln. is evaporated some hydrogen fluoride is given off. The pentafluoride above its m.p. reacts with **sulphur**; cold, conc. **sulphuric acid** dissolves a little pentafluoride, and when heated, hydrogen fluoride is given off. An excess of **ammonium sulphide** precipitates the hydroxide. Columbium pentafluoride is not so soluble in **sulphur monochloride** as is the tantalum salt; **sulphur dichloride** reacts vigorously in the cold with columbium pentafluoride; **sulphuryl chloride** dissolves it less easily than it does the tantalum salt; **nitrogen** is indifferent towards the pentafluoride below its b.p.; **ammonia** precipitates the hydroxide; cold fuming or conc. **nitric acid** dissolves the pentafluoride in the cold; yellow and red **phosphorus** have no action on the pentafluoride below its b.p.; **phosphorus trichloride** forms a yellow gelatinous mass which, when warmed, gives off phosphorus trifluoride; **phosphoryl chloride** readily dissolves the pentafluoride with the evolution of gas; **arsenic** and **antimony** have no action below the b.p. of the pentafluoride; **arsenic trichloride** dissolves no appreciable quantity of the pentafluoride, but when warmed a gelatinous mass is formed; **antimony pentachloride** behaves like arsenic trichloride; **toluene** dissolves the pentafluoride in the cold and the soln. becomes yellow and brown when heated; **paraffin** behaves similarly; **carbon disulphide**, and **chloroform** dissolve only a little pentafluoride when heated; **carbon tetrachloride** and **tetrachloroethane** react with the pentafluoride; **acetic acid** and **acetic anhydride** react with the pentafluoride when heated, and gas is evolved; **ether** and **alcohol** behave similarly; **silicon tetrachloride** has no action in the cold, but it has a solvent action when heated; warm **silico-chloroform** exerts a reducing action; **titanium tetrachloride** dissolves less columbium pentafluoride than the tantalum salt; **tin tetrachloride** dissolves very little pentafluoride when cold, but more is dissolved when the liquid is hot, and the solute crystallizes out on cooling; **gold**, **magnesium**, and **aluminium** are not changed by the pentafluoride boiling in an atm. of nitrogen; **copper**, and **silver** colour it blue; **iron**, dark blue; **lead**, bluish-grey; **zinc**, a deep blue; **tin** gives a grey powder. Cold soln. of **alkali hydroxide or carbonate** in excess give an insoluble, gelatinous precipitate; when hot, a columbate is formed; **potassium fluoride** forms only a trace of a complex fluoride; fused **potassium hydrofluoride** forms potassium oxyptafluocolumbate; and **potassium chloride** has no action on the pentafluoride.

According to J. C. G. de Marignac, if **metal fluorides** be added to a soln. of hydrated columbium pentoxide in hydrofluoric acid, complex salts with columbium oxyfluoride are formed; but if an excess of conc. hydrofluoric acid be present, complex fluorides are produced. B. Santesson obtained complex acid salts from a soln. of a metal carbonate and hydrated columbium pentoxide in conc. hydrofluoric acid. According to J. C. G. de Marignac, **potassium heptafluocolumbate**, K_2CbF_7 , is formed by cooling a warm soln. of potassium oxyfluocolumbate in hydrofluoric acid; and G. Krüss and L. F. Nilson evaporated a soln. of potassium oxyfluocolumbate and potassium hydrofluoride in a little hydrofluoric acid—*vide infra*, Table IV. J. C. G. de Marignac found that the rhombic crystals have the axial ratios $a : b : c = 0.6682 : 1 : 0.4699$, and are isomorphous with the corresponding tantalum salt; but, according to R. D. Hall, with potassium hexafluotitanate.

R. Hermann said that the crystals lose hydrogen fluoride at 80°; but J. C. G. de Marignac reported that they are stable at 100°, but decompose at a higher temp. In moist air, the crystals fume and gradually furnish the oxypentafluoride; the soln. in hot water yields the same salt when cooled. M. E. Pennington prepared **rubidium heptafluocolumbate**, Rb_2CbF_7 , by evaporating on a water-bath a soln. of columbium pentoxide in hydrofluoric acid mixed with rubidium fluoride. The white, microscopic prisms are soluble in water, and in dil. hydrofluoric acid, but not in alcohol. C. W. Balke and E. F. Smith said that this process furnishes the oxypentafluocolumbate, but if the salt be crystallized three times from its soln. in 35 per cent. hydrofluoric acid, **rubidium hexafluocolumbate**, RbCbF_6 , is formed in acicular crystals. M. E. Pennington prepared **caesium heptafluocolumbate**, Cs_2CbF_7 ; and C. W. Balke and E. F. Smith **caesium hexafluocolumbate**, CsCbF_6 , as in the case of the rubidium salts. R. D. Hall and E. F. Smith tried to make *potassium perfluocolumbate* by the action of hydrogen dioxide on a soln. of the peroxy-fluocolumbate in conc. hydrofluoric acid, but without success.

B. Santesson reported a series of acid salts to be formed from hydrofluoric acid soln. of eq. proportions of the metal fluoride and columbium pentoxide: **copper hydrofluocolumbate**, $\text{Cu}_2\text{CbF}_6 \cdot \text{HF} \cdot 9\text{H}_2\text{O}$, in dark blue tablets; **zinc hydrofluocolumbate**, $\text{Zn}_5\text{Cb}_3\text{F}_{25} \cdot 5\text{HF} \cdot 28\text{H}_2\text{O}$, is insoluble in water, and decomposed by heat; **cadmium hydrofluocolumbate**, $\text{Cd}_5\text{Cb}_3\text{F}_{25} \cdot 5\text{HF} \cdot 28\text{H}_2\text{O}$, in white, prismatic crystals; **mercuric hydrofluocolumbate**, $\text{Hg}_3\text{CbF}_{11} \cdot 8\text{H}_2\text{O}$, in spherical aggregates of white, prismatic crystals; **manganese hydrofluocolumbate**, $5\text{MnF}_2 \cdot 3\text{CbF}_5 \cdot 5\text{HF} \cdot 28\text{H}_2\text{O}$, in rose-coloured prisms; **ferrous hydrofluocolumbate**, $\text{Fe}_3\text{Cb}_2\text{F}_{16} \cdot 4\text{HF} \cdot 19\text{H}_2\text{O}$, in yellowish prisms; **cobalt hydrofluocolumbate**, $\text{Co}_5\text{CbF}_{19} \cdot 5\text{HF} \cdot 28\text{H}_2\text{O}$, in dark red prisms; and **nickel hydrofluocolumbate**, $\text{Ni}_3\text{Cb}_2\text{F}_{16} \cdot 4\text{HF} \cdot 19\text{H}_2\text{O}$, in green, acicular crystals, and $\text{Ni}_5\text{Cb}_3\text{F}_{25} \cdot 5\text{HF} \cdot 28\text{H}_2\text{O}$, in dark green prisms.

A. Joly² reported **columbium oxytrifluoride**, CbOF_3 , to be formed by keeping a molten, red-hot mixture of columbium pentoxide and calcium fluoride in an atm. of hydrogen fluoride for a long time. The crystals resemble those of the corresponding zirconium salt. *Columbium dioxyfluoride*, CbO_2F , is known only in combination with potassium fluoride—*vide infra*. J. C. G. de Marignac reported **ammonium trioxytetradecafluotricolumbate**, $(\text{NH}_4)_5\text{Cb}_3\text{O}_3\text{F}_{14} \cdot \text{H}_2\text{O}$, to be formed from a hydrofluoric acid soln. of potassium fluoride and an excess of columbium oxytrifluoride in hexagonal crystals with the axial ratio $a : c = 1 : 0.4575$. P. Groth added that, like the potassium salt, the crystals are probably pseudo-hexagonal and made up of monoclinic units. The salt loses water incompletely at 100°, and at the same time acid fumes are given off. The salt is decomposed when heated with calcium oxide. The mother-liquor remaining after the preparation of this salt with a very great excess of columbium oxytrifluoride, furnishes pseudo-tetragonal prisms of **ammonium oxytetrafluocolumbate**, $(\text{NH}_4)_2\text{CbOF}_4$, which are stable at 150°. J. C. G. de Marignac also obtained **ammonium oxypentafluocolumbate**, $(\text{NH}_4)_2\text{CbOF}_5$, from a soln. of ammonium fluoride and hydrated columbium pentoxide in hydrofluoric acid. A. Werner wrote the formula

The rhombic bipyramidal crystals have the axial ratios $a : b : c = 0.4184 : 1 : 1.0058$, and are isomorphous with ammonium dioxytetrafluotungstate. They are stable at 170°–180°, but if slowly heated, the whole of the columbium can be converted to the pentoxide; the reaction which occurs when heated with calcium oxide is symbolized: $5\text{CaO} + 2(\text{NH}_4)_2\text{CbOF}_5 = 4\text{NH}_3 + 2\text{H}_2\text{O} + 5\text{CaF}_2 + \text{Cb}_2\text{O}_5$. J. C. G. de Marignac prepared **ammonium oxyhexafluocolumbate**, $(\text{NH}_4)_3\text{CbOF}_6$, from hydrofluoric acid soln. containing an excess of ammonium fluoride. The octahedral or cubic crystals are isotropic, and do not lose weight at 100°. The salt was also made by H. Baker, and A. Piccini and G. Giorgis. J. C. G. de Marignac obtained

crystals of **ammonium oxyheptafluocolumbate**, $(\text{NH}_4)_3\text{CbF}_8 \cdot \text{CbOF}_3$, from a soln. of the oxyptafluocolumbate in warm hydrofluoric acid.

In his study of the complex fluorides of columbium, J. C. G. de Marignac reported that he obtained **sodium oxyfluocolumbates** as crystalline crusts of indefinite composition, and although no analyses are given, he assumed the existence of the two salts $2\text{NaF} \cdot \text{CbOF}_3 \cdot 2\text{H}_2\text{O}$ and $\text{NaF} \cdot \text{CbOF}_3 \cdot \text{H}_2\text{O}$. C. W. Balke and E. F. Smith could not confirm J. C. G. de Marignac's assumption, but they prepared **sodium oxyhexafluocolumbate**, $3\text{NaF} \cdot \text{CbOF}_3$, by evaporating a soln. of 30 grms. of columbium pentoxide and 24 grms. of sodium carbonate in hydrofluoric acid, and recrystallizing from hot water. J. C. G. de Marignac described and analyzed five potassium oxyfluocolumbates. O. Ruff and E. Schiller found the results indicated in Table IV for the percentage solubility of potassium oxyfluocolumbate

TABLE IV.—SOLUBILITY OF POTASSIUM OXYFLUOCOLUMBATE.

CbF_5	KF	HF	Solid phase.
5.19	2.98	0.35	$\text{K}_2\text{CbOF}_5 \cdot \text{H}_2\text{O}$
7.07	5.33	4.35	$\text{K}_2\text{CbOF}_5 \cdot \text{H}_2\text{O} + \text{K}_2\text{CbF}_7$
4.33	2.32	10.43	K_2CbF_7
1.16	5.54	-0.13	$\text{K}_2\text{CbOF}_5 \cdot \text{H}_2\text{O}$
2.67	6.04	5.39	$\text{K}_2\text{CbOF}_5 \cdot \text{H}_2\text{O} + \text{K}_2\text{CbF}_7$
30.39	14.68	0.35	$\text{K}_2\text{CbOF}_5 \cdot \text{H}_2\text{O}$
11.66	10.08	-1.53	$\text{K}_2\text{CbOF}_5 \cdot \text{H}_2\text{O}$

at 16° . (The negative sign is only apparent and is an effect of the mode of calculation.) J. C. G. de Marignac found that a soln. of potassium fluoride and columbium pentoxide in hydrofluoric acid furnishes **potassium oxyptafluocolumbate**, $\text{K}_2\text{CbOF}_5 \cdot \text{H}_2\text{O}$; and the same salt is produced when any of the other oxyfluocolumbates is crystallized from its aq. soln. The salt was analyzed by J. C. G. de Marignac, A. Piccini, and T. B. Osborne. G. Krüss and L. F. Nilson obtained the anhydrous salt by crystallizing an aq. soln. of potassium heptafluocolumbate, and drying the product at 100° . J. C. G. de Marignac added that the *monohydrate* loses almost all its water at 100° , and it can be heated to 180° – 200° without decomposition; and only a little hydrogen fluoride is lost when the salt is fused at a red-heat. The monohydrate crystallized from its aq. soln., or dil. hydrofluoric acid in thin monoclinic plates with the axial ratios $a : b : c = 0.992 : 1 : 0.980$, and $\beta = 103^\circ 46'$, isomorphous with potassium fluotitanate, and oxyfluotungstate. M. E. Pennington said that the electrical resistance of the aq. soln. is very high; and F. Ott found that no marked reduction occurs when the aq. or the hydrochloric acid soln. is electrolyzed, though hydrated columbium pentoxide separates on the anode; there is a reduction to columbium tetroxide at the cathode when the fused salt is electrolyzed. J. C. G. de Marignac said that at 17° – 21° , 100 parts of water dissolve 7.7–8.3 parts of the salt, but W. Muthmann added that the solubility is less than this. R. D. Hall and E. F. Smith found that the solubility is depressed by hydrogen dioxide, and raised by hydrofluoric acid; and R. D. Hall that it is depressed by potassium bromide and iodide. J. C. G. de Marignac, and M. E. Pennington said that the soln. is not changed by heat, and if any tantalum salt be present as impurity it is precipitated; G. Krüss and L. F. Nilson added that if the soln. is boiled, **potassium hexoxyptafluotricolumbate**, $\text{K}_2\text{Cb}_3\text{O}_6\text{F}_5$, is precipitated as a white, crystalline powder: $3\text{K}_2\text{CbOF}_5 + 3\text{H}_2\text{O} = \text{K}_2\text{Cb}_3\text{O}_6\text{F}_5 + 4\text{KHF}_2 + 2\text{HF}$, which is not altered at 110° , and is freely soluble in hydrofluoric acid.

J. C. G. de Marignac found that crystals of **potassium oxyhexafluocolumbate**, K_2CbOF_6 , can be obtained from soln. containing an excess of potassium fluoride; and C. W. Balke and E. F. Smith obtained it by crystallization from a soln. containing 40 grms. of the oxyptafluocolumbate and 30 grms. of potassium fluoride;

while H. Baker prepared it by melting columbium pentoxide with an excess of potassium hydrofluoride.

J. C. G. de Marignac said that although the crystals seem to be cubes, the optical properties do not correspond with the "cubic nor the square prismatic" systems; and he was unable to determine their crystal system. C. W. Balke and E. F. Smith observed the crystals are optically anomalous; but H. Baker obtained cubic crystals which were *isotropic*, and isomorphous with $3\text{NH}_4\text{F}\cdot\text{CbOF}_3$, $3\text{NH}_4\text{F}\cdot\text{ZrF}_4$, and $3\text{KF}\cdot\text{ZrF}_4$. The salt is stable at 100° , and only suffers a small loss when melted at a red-heat. J. C. G. de Marignac's acicular salt, **potassium hydro-oxyheptafluorocolumbate**, $\text{K}_3\text{CbOF}_6\cdot\text{HF}$, crystallizes in slender needles from soln. containing an excess of potassium fluoride and hydrofluoric acid. C. W. Balke and E. F. Smith obtained the best results with soln. containing potassium fluoride, hydrofluoric acid, and columbium pentafluoride in the proportions 1.8 : 1.2 : 1. J. C. G. de Marignac found that the axial ratios of the monoclinic crystals are $a : b : c = 0.6279 : 1 : 0.4900$, and $\beta = 93^\circ 14'$; and C. W. Balke and E. F. Smith added that the crystals are isomorphous with $\text{K}_3\text{SnF}_7\cdot\text{HF}$. J. C. G. de Marignac found that the salt is stable at 100° ; and loses hydrogen fluoride when melted at a red-heat. The "oblique, monosymmetrical" salt of J. C. G. de Marignac—**potassium trioxytridecafluotricolumbate**, $\text{K}_4\text{Cb}_3\text{O}_3\text{F}_{13}\cdot 2\text{H}_2\text{O}$ —was obtained from soln. containing an excess of columbium oxytrifluoride. C. W. Balke and E. F. Smith obtained the best results with potassium and columbium fluorides in the molar proportions 1 : 4. The triclinic crystals lose some water at 110° and all at 180° . J. C. G. de Marignac, and C. W. Balke and E. F. Smith found that soln. containing insufficient potassium fluoride to form the oxypentafluorocolumbate furnish monoclinic crystals of **potassium trioxytetradecafluotricolumbate**, $\text{K}_5\text{Cb}_3\text{O}_3\text{F}_{14}\cdot\text{H}_2\text{O}$, with the axial ratios $a : b : c = 0.596 : 1 : 0.400$, and $\beta = 104^\circ 28'$. Only part of the water is expelled at 100° . E. Petersen prepared **potassium decoxytrifluotetra-columbate**, $3\text{KF}\cdot 2\text{Cb}_2\text{O}_5\cdot 5\text{H}_2\text{O}$, by dissolving one part of columbium pentoxide in 3.25 parts of molten potassium fluoride, and extracting the soluble portion with water. A white crystalline powder remains. If the potassium fluoride be reduced to 1.3 parts, prismatic crystals of **potassium pentoxyfluodiu-columbate**, $\text{KF}\cdot\text{Cb}_2\text{O}_5\cdot 3\text{H}_2\text{O}$, are formed.

C. W. Balke and E. F. Smith obtained thin plates of **rubidium oxypentafluorocolumbate**, Rb_2CbOF_5 , from soln. containing 2 mols of rubidium fluoride, and one mol of columbium oxytrifluoride; while soln. with a mol of columbium pentafluoride and 4–10 mols of caesium fluoride furnished trigonal prisms of **caesium oxypentafluorocolumbate**, Cs_2CbOF_5 , with the axial ratio $a : c = 1 : 0.949$. According to J. C. G. de Marignac, a soln. of copper fluoride and columbium pentoxide in hydrofluoric acid furnishes blue monoclinic prisms of **copper oxypentafluorocolumbate**, $\text{CuCbOF}_5\cdot 4\text{H}_2\text{O}$, with the axial ratios $a : b : c = 0.7627 : 1 : 0.5629$, and $\beta = 103^\circ 20'$. They are sparingly soluble in water, and do not lose weight at 100° . P. J. Holmquist melted a mixture of 11.2 grms. of calcium oxide, 26.74 grms. of columbium pentoxide, and 9 grms. of sodium fluoride at a high temp. and obtained octahedral crystals of **sodium calcium octoxyfluodiu-columbate**, or *calcium-pyrochlore*, $\text{NaCaCb}_2\text{O}_6\text{F}$, of sp. gr. 4.196 at 19.5° ; the index of refraction for yellow light was 2.148–2.150, and for green light, 2.1795. He could not make the calcium salt without sodium. J. C. G. de Marignac obtained crystals of **zinc oxypentafluorocolumbate**, $\text{ZnCbOF}_5\cdot 6\text{H}_2\text{O}$, as in the case of the copper salt. The trigonal crystals have the axial ratio $a : c = 1 : 0.519$, and $\alpha = 112^\circ 6'$; they are isomorphous with zinc fluotitanate. C. W. Balke and E. F. Smith obtained rhombic crystals of **thallium oxypentafluorocolumbate**, Tl_2CbOF_5 , with the axial ratios $a : b : c = 0.4261 : 1 : 1.0129$, from hydrofluoric acid soln. of thallous fluoride and columbium pentafluoride.

A. Piccini mixed a warm aq. soln. of potassium oxypentafluorocolumbate with 3 per cent. hydrogen dioxide, and after crystallizing the product two or three times from its aq. soln., obtained white plates of **potassium peroxy-pentafluorocolumbate**, $\text{K}_2\text{CbO}_2\text{F}_5\cdot\text{H}_2\text{O}$. The same salt was made by C. W. Balke and E. F. Smith. The

salt is stable in air; it loses water at 100°, and oxygen at 150°. C. W. Balke and E. F. Smith also prepared **rubidium peroxyptafluocolumbate**, $\text{Rb}_2\text{CbO}_2\text{F}_5\cdot\text{H}_2\text{O}$, in thin yellow plates; and **sodium peroxyptafluocolumbate**, $\text{Na}_3\text{CbO}_2\text{F}_6\cdot\text{H}_2\text{O}$, in yellow crystals.

§ 11. Columbium Chlorides and Oxychlorides

H. St. C. Deville and L. Troost¹ obtained what was regarded as a violet-brown **columbium dichloride**, CbCl_2 , by passing the vapour of columbium oxytrichloride over magnesium ribbon—*vide supra*, columbium dioxide. H. E. Roscoe passed the vapour of columbium pentachloride through a red-hot tube and obtained a black crystalline deposit resembling iodine which was considered to be **columbium trichloride**, CbCl_3 . It is not decomposed by water, or aq. ammonia; it is oxidized by nitric acid to the pentoxide; and when heated in carbon dioxide: $\text{CbCl}_3 + \text{CO}_2 = \text{CO} + \text{CbOCl}_3$. F. Ott could not obtain the solid trichloride from aq. soln. He prepared the aq. soln. by electrolyzing a soln. of the pentachloride in cold, conc. hydrochloric acid with a lead or platinum cathode, and a platinum anode in a compartment cell using a current density of 0.1–2.0 amp. per sq. dm. The pentachloride is reduced to a reddish-violet or brown, or to a dark blue, almost black, liquid. When the liquid is exposed to air, or treated with hydrogen dioxide or potassium permanganate, it is oxidized through the stages: green tetroxide, blue heptatritoxide, and colourless pentoxide. It is very slowly oxidized by iodine; it reduces chromic acid to chromic oxide, and cupric to cuprous salts. Aq. ammonia gives a dark blue precipitate which is rapidly oxidized by air. According to A. Stähler, the electrolytic reduction of columbium pentachloride in hydrochloric acid soln. does not furnish a chloride of trivalent columbium. The brown soln. obtained by using an amalgamated lead cathode gives reactions like those of trivalent titanium; with a platinum cathode, a blue soln. is obtained of a colloidal character.

It gives a purple liquid with gold chloride, and on boiling, deposits a precipitate resembling purple of Cassius.

If the soln. of the trichloride in conc. hydrochloric acid be evaporated in a heated desiccator in an atm. of carbon dioxide, or in vacuo, black **columbium hydroxy-dichloride**, $\text{Cb}(\text{OH})\text{Cl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, is formed; the soln. in dil. hydrochloric acid, likewise treated, furnishes blue **columbium trihydroxytrichloride**, $\text{Cb}_2(\text{OH})_3\text{Cl}_3 \cdot 3\text{H}_2\text{O}$. The black compound is stable for a short time in an atm. of carbon dioxide; but in air, it absorbs water, and rapidly oxidizes to the pentoxide. The aq. soln. is green; and the alcoholic soln. is blue. It is insoluble in ether. The aq. soln. gives a brown voluminous precipitate with ammonia, which rapidly oxidizes. With sulphuric acid, a blue hydroxide is formed which quickly turns white; but hydrochloric acid is not changed. If a soln. of columbium pentachloride in dil. hydrochloric acid containing an excess of ammonium chloride be electrolyzed until all the solid is dissolved, and the soln. evaporated in a hot desiccator in an atm. of carbon dioxide, a blue solid, thought to be *ammonium chlorocolumbite*, is formed. When lithium chloride is treated in a similar manner, and the soln. evaporated in vacuo over phosphorus pentoxide, it furnishes a bluish-black mass, probably a mixture of lithium chloride and *lithium chlorocolumbite*; and similarly, what was probably impure *potassium chlorocolumbite* was formed.

The green liquid obtained by F. Ott by electrolyzing a hydrochloric acid soln. of sodium metacolumbate, was thought to contain **columbium tetrachloride**, CbCl_4 . It readily oxidizes in air. H. S. Harned obtained derivatives of what he regarded as bivalent *chlorocolumbium*, $[\text{Cb}_6\text{Cl}_{12}]\text{X}_2$, by reducing columbium pentachloride with sodium amalgam—*vide tantalum*. The salts appear to be derivatives of a *columbium tritahexptoxide*, Cb_3O_7 , evidence for the existence of which was obtained by F. Ott. The chief product of the reduction is **columbium tritahexptachloride**, $[\text{Cb}_3\text{Cl}_6]\text{Cl} \cdot 3\frac{1}{2}\text{H}_2\text{O}$, or $[\text{Cb}_6\text{Cl}_{12}]\text{Cl}_2 \cdot 7\text{H}_2\text{O}$, which appears as an olive-green powder, or in black crystals, insoluble in cold water but forming an olive-green soln. with hot water. The $[\text{Cb}_6\text{Cl}_{12}]$ radicle is cationic, when treated with an eq. proportion of sodium hydroxide, **columbium tritahexachlorohydroxide**, $[\text{Cb}_3\text{Cl}_6]\text{OH} \cdot 4\text{H}_2\text{O}$, or $[\text{Cb}_6\text{Cl}_{12}]\text{Cl}_2 \cdot 8\text{H}_2\text{O}$, is formed as a black microcrystalline precipitate, which when treated with hydrochloric acid precipitates a brown powder, $[\text{Cb}_6\text{Cl}_{12}]\text{Cl}_2 \cdot 9\text{H}_2\text{O}$, which is thought to have a constitution different from that of the olive-green chloride. If the hydroxide be treated with hydrobromic acid, **columbium tritahexachlorobromide**, $[\text{Cb}_3\text{Cl}_6]\text{Br} \cdot 3\frac{1}{2}\text{H}_2\text{O}$, or $[\text{Cb}_6\text{Cl}_{12}]\text{Br}_2 \cdot 7\text{H}_2\text{O}$, is formed as a black microcrystalline precipitate.

According to H. Moissan, **columbium pentachloride**, CbCl_5 , is formed by the direct union of the element at 205° when much heat is developed; W. von Bolton worked at a red-heat. H. Rose obtained the pentachloride by passing chlorine over an intimate mixture of the pentoxide and carbon at a high temp. H. Rose and R. Weber added that if the temp. be too high, the oxytrichloride is formed; if carbon monoxide be present, the pentachloride does not sublime. H. Rose freed the pentachloride from the oxytrichloride by subliming it in a current of chlorine; and C. W. Blomstrand, in a current of carbon dioxide. F. Ott described an apparatus for applying H. Rose's process. W. Biltz and A. Voigt obtained the pentachloride by passing chlorine over heated columbium sulphide, and after removing the sulphur chloride, distilling off the pentachloride. H. E. Roscoe obtained the pentachloride by passing the vapour of the oxytrichloride over red-hot carbon; H. Biltz and L. Gonder, by passing air-free chlorine over heated columbium sulphide; M. E. Pennington, by heating a mixture of the pentoxide and phosphorus pentachloride for 8 hrs. in a sealed tube at 210° ; E. Demarçay, P. Cambouliès, and O. Ruff and E. Schiller by passing a mixture of chlorine and the vapour of carbon tetrachloride over red-hot columbium pentoxide—the reaction begins at 280° , and proceeds rapidly at 440° ; F. Russ, by passing the vapour of carbon tetrachloride over red-hot potassium oxalatocolumbate; E. F. Smith, R. D. Hall, and C. W. Balke and E. F. Smith, by the action of the vapour of sulphur monochloride and chlorine

over columbium pentoxide at 200° in a sealed tube, and subsequently separating the pentachloride by fractional distillation, or else by passing the mixed gases over the heated pentoxide; and F. Bourion, by passing the vapour of sulphur dichloride and chlorine over the heated pentoxide.

In E. F. Smith and R. D. Hall's process for columbium chloride, a mixture of the vapour of sulphur monochloride from the flask *A*, Fig. 1, and dry chlorine coming along the tube

FIG. 1.—The Preparation of Columbium Pentachloride.

D, is passed over 10–20 grms. of strongly ignited columbium oxide in the combustion tube *E*. A voluminous oxychloride is first formed, and this is liable to choke the combustion tube containing the columbium oxide. The oxychloride is gradually converted into the volatile chloride which collects along with the sulphur chloride in the flask *F*. In 10–20 hrs. the stopcock connecting the system with the sulphur monochloride tube is closed, and the excess of sulphur monochloride is driven through the bulbs *H* and *I* and finally condensed in *K*. The columbium chloride is distilled from the bulb *F* to *H*, and finally from the bulb *H* to *I*, and the latter is finally sealed off. Tantalum pentachloride was prepared in a similar manner.

The sublimed pentachloride furnishes yellow, acicular crystals, which according to C. W. Balke and E. F. Smith, have a **specific gravity** 2.73–2.77 at 20°. Analyses were made by J. C. G. de Marignac, R. D. Hall, F. Bourion, and F. Ott. H. Rose's preparation was probably contaminated by much tantalum pentachloride. H. St. C. Deville and L. Troost found the **vapour density** to be 9.6 at 360° when the value calculated for CbCl_5 is 9.35. C. W. Balke and E. F. Smith obtained 9.45 between 280° and 300°. H. Rose gave 212° for the **melting point** and H. St. C. Deville and L. Troost, 194°. The molten salt is red. H. Biltz and L. Gonder said that it readily volatilizes, and F. Wöhler added that the vapour is yellow. C. W. Balke and E. F. Smith said that it volatilizes much below its **boiling point**, 241°; and H. St. C. Deville and L. Troost gave 240.5° for the b.p. R. Robl observed no fluorescence when columbium chloride is exposed to ultra-violet light. W. Biltz and A. Voigt found that when free from water, the **electrical conductivity** at 220°–235° is 0.000022, being about the same order as the best conductivity-water. The platinum electrodes were strongly attacked. W. Hampe had previously stated that the pentachloride is an insulator. C. W. Blomstrand, and H. E. Roscoe said that **hydrogen** at a red-heat reduces the pentachloride to the metal. F. Ott observed that the pentachloride fumes in moist air, and the surface was found by C. W. Balke and E. F. Smith to acquire a film of hydrated columbium pentoxide; the reaction is completed after a few days' exposure to moist air. H. Rose also observed that the pentachloride is hydrolyzed by **water** to form the pentoxide and hydrochloric acid. According to O. Ruff and E. Schiller, the pentachloride reacts with liquid **hydrogen fluoride**, forming columbium pentafluoride. H. Rose found that the salt is soluble in cold **hydrochloric acid**, which furnishes the hydrated pentoxide when boiled, or when diluted with water; the salt is soluble in conc. **sulphuric acid** with the liberation of hydrochloric acid—the soln. becomes turbid when heated, and on cooling forms a gelatinous mass. F. Ott showed that hydrolysis occurs when the sulphuric acid soln. is diluted with water. H. Rose observed that the pentachloride can be heated in the vapour of **carbon disulphide** without blackening. E. F. Smith and R. D. Hall observed that the pentachloride is soluble in **sulphur monochloride**, and the hot, sat. soln. gives crystals of the pentachloride on cooling. When **ammonia** is passed into the ethereal

soln., ammonium chloride and columbium pentatritantride are formed. C. W. Balke and E. F. Smith, and R. D. Hall and E. F. Smith regard **carbon tetrachloride** as one of the best solvents for columbium pentachloride, and the yellow, hot soln. yield crystals of the salt on cooling; **chloroform** rapidly dissolves the pentachloride, and the soln. decomposes when heated with the separation of a brown powder. H. Rose, and R. D. Hall and E. F. Smith found that when the soln. in **alcohol** is heated, alcohol, ethyl chloride, and hydrogen chloride are successively evolved; when the alcoholic soln. is boiled, the hydrated pentoxide is precipitated. The pentachloride is soluble in **ether**, forming a yellow soln. which on evaporation yields a viscid liquid. The pentachloride forms addition products with **aniline**, **pyridine**, **piperidine**, etc.; **benzene** reacts with the pentachloride, forming a gummy mass. H. Rose said that the pentachloride is soluble in a soln. of **potassium hydroxide** or **potassium carbonate**. O. Ruff and F. Thomas said that the pentachloride reacts with **tantalum pentoxide**: $Ta_2O_5 + 5CbCl_5 = 5CbO.Cl_3 + 2TaCl_5$.

R. D. Hall and E. F. Smith found that when columbium pentoxide is volatilized in dry hydrogen chloride, a white powder is formed approximating *columbium pentoxyhydrochloride*, $Cb_2O_5 \cdot nHCl$. It is insoluble in oxalic acid, and slowly dissolved by boiling, conc. sulphuric acid. E. F. Smith and P. Maas said that the white sublimate formed when columbium pentoxide is strongly heated in dry hydrogen chloride is *columbium tetroxyhydrochloride*, $Cb_2O_4 \cdot HCl \cdot 3H_2O$, but A. Larsson added that this is doubtful.

R. D. Hall and E. F. Smith said that the soln. of columbium pentachloride in carbon tetrachloride can be used for making complex salts with other **metal chlorides**, but no examples were indicated.

According to H. Rose and R. Weber, *columbyl chloride*, or **columbium oxytrichloride**, $CbOCl_3$, is produced at the same time as the pentachloride when an intimate mixture of the pentoxide and carbon is heated in a current of dry chlorine. The two compounds are easily separated owing to the greater volatility of the pentachloride. H. Rose separated them by fractional sublimation in chlorine; H. St. C. Deville and L. Troost, in hydrogen. R. D. Hall and E. F. Smith removed the pentachloride by sublimation in a current of chlorine over heated columbium pentoxide; and H. St. C. Deville and L. Troost made the oxytrichloride by passing the vapour of the pentachloride, in a current of carbon dioxide, over the red-hot pentoxide. M. Delafontaine and C. E. Lineberger, and R. D. Hall and E. F. Smith prepared this compound by heating the pentoxide in a current of carbon tetrachloride at 400° or a dull red-heat: $Cb_2O_5 + 3CCl_4 = 2CbOCl_3 + 3COCl_2$. The accompanying pentachloride is derived off by heating the product at as low a temp. as practicable in a current of carbon dioxide. R. D. Hall likewise obtained the oxytrichloride, mixed with the pentachloride, by the action of sulphur monochloride and chlorine over the pentoxide; and F. Bourion used sulphur dichloride. H. St. C. Deville and L. Troost made the oxytrichloride by the action of dry chlorine on hot columbium dioxide.

F. Wöhler, and F. Bourion described the oxytrichloride as a white, crystalline mass; and, according to R. D. Hall and E. F. Smith, when condensed on a hot surface, it forms a compact mass of acicular crystals. Analyses were made by H. Rose, C. W. Blomstrand, and H. St. C. Deville and L. Troost. The last-named found the **vapour density** to be 7.89 at 440° , and 7.87 at 860° in agreement with the theoretical value for $CbOCl_3$. The salt volatilizes at about 400° without melting. The vapour, said F. Wöhler, is colourless. C. W. Blomstrand found that the oxytrichloride is reduced to a blue product when heated in **hydrogen**; but if not too strongly heated, H. Rose and H. St. C. Deville and L. Troost found that it can be sublimed without decomposition. H. Rose, and R. Hermann observed that in moist **air**, the compound does not deliquesce, and it forms crystals of columbium pentoxide. It hisses in contact with **water**, and hydrolysis occurs with the separation of the hydrated pentoxide, and the evolution of much heat; C. W. Blomstrand added that if the temp. be kept low, the soln. which is formed furnishes, on spontaneous evaporation, a gum-like mass—the hydrogel of the pentoxide.

R. D. Hall and E. F. Smith sublimed the oxytrichloride in a current of **chlorine**. H. Rose found that cold **hydrochloric acid** does not dissolve the oxytrichloride, nor does it form a gelatinous mass; R. F. Weinland and L. Storz added that in hydrochloric acid, sat. at 0°, the eq. of about one per cent. Cb_2O_5 passes into soln. H. Rose found that boiling hydrochloric acid dissolves some oxytrichloride, and the soln. gives no turbidity with water, but it does so with sulphuric acid. C. W. Blomstrand said that dry **hydrogen sulphide** has no action in the cold; but when warmed, some oxysulphide, hydrogen chloride, and water are formed; **sulphur dioxide** has no action on the cold or hot oxytrichloride. H. Rose observed that conc. **sulphuric acid** slowly liberates hydrochloric acid, forming a turbid liquid, which becomes clear when heated and hydrogen chloride is evolved. C. W. Blomstrand said that when heated in **carbon disulphide** part of the oxytrichloride is blackened, and part volatilizes undecomposed. M. Delafontaine and C. E. Lineberger, and C. W. Blomstrand observed no reaction when the oxytrichloride is heated in a current of **carbon dioxide**; the salt is readily soluble in **alcohol**, and ether produces in this soln., a yellowish-white precipitate. H. Rose said that no precipitate is produced by heating the alcoholic soln. with sulphuric acid, and when the liquid is distilled, some hydrogen chloride and ether are formed, and the liquid clears in the retort; R. F. Weinland and L. Storz said that the oxytrichloride forms complex salts with **pyridine** and **quinoline**. A soln. of **potassium hydroxide** dissolves the oxytrichloride in the cold; but a soln. of **potassium carbonate** dissolves it only when boiling.

According to R. F. Weinland and L. Storz, the oxytrichloride forms complex salts with some **metal chlorides**. For instance, when a soln. of the hydrated pentoxide in conc. hydrochloric acid is mixed with an excess of ammonium chloride, crystals of unstable **ammonium oxypentachlorocolumbate**, probably $(\text{NH}_4)_2\text{CbOCl}_5$, are formed; with rubidium chloride, yellow, octahedral crystals of **rubidium oxypentachlorocolumbate**, $\text{Rb}_2\text{CbOCl}_5$, are formed—soluble in hydrochloric acid, and less stable than the caesium salt; similarly, pale yellow octahedral crystals of **caesium oxypentachlorocolumbate**, $\text{Cs}_2\text{CbOCl}_5$, were produced. R. F. Weinland and M. Fiederer said that the salt is isomorphous with the chromium salt, $\text{CrOCl}_3 \cdot 2\text{CsCl}$. The salts are stable in dry air.

§ 12. Columbium Bromides, Iodides, and Oxybromides

According to H. Rose,¹ **columbium pentabromide**, CbBr_5 , is formed along with the oxytribromide when bromine vapour is carried by a current of carbon dioxide over a red-hot mixture of columbium pentoxide and carbon. The two products are separated by fractional volatilization, the pentabromide being the more volatile. W. M. Barr also found that a little is produced when the oxytribromide is sublimed in an atm. of nitrogen or carbon dioxide. Columbium pentabromide is not produced when the vapour of sulphur monobromide is passed over the heated pentoxide, but it is formed when bromine vapour is passed over heated columbium metal obtained by the aluminothermite process. The crystalline product has the colour and appearance of red phosphorus; and when melted and cooled it yields garnet-red prisms. It melts at about 150° ; and distils undecomposed in a current of nitrogen or carbon dioxide at about 270° . It fumes strongly in air; is very hygroscopic, and forms first the oxytribromide, and then the pentoxide. It is hydrolyzed by water with the development of much heat. It is also readily dissolved by anhydrous ethyl bromide, or alcohol with the development of heat.

H. Rose, and W. M. Barr obtained **columbium oxytribromide**, CbOBr_3 , by passing the vapour of bromine over a red-hot mixture of columbium pentoxide and carbon, and removing the more volatile pentabromide by fractional distillation—*vide supra*. The pale yellow solid volatilizes without melting when heated in a current of bromine vapour. It is more difficult to sublime than the oxytrichloride; when heated in carbon dioxide, H. Rose said that it is transformed into the pentoxide. It fumes in moist air and forms the pentoxide; and it is hydrolyzed by water, forming the pentoxide and hydrobromic acid. It dissolves in conc. hydrochloric acid, and in hot conc. sulphuric acid. It dissolves with the development of heat in ethyl chloride, and in alcohol; R. F. Weinland and L. Storz found that the alcoholic soln. gradually forms hydrated columbium pentoxide and ethyl bromide. It forms a series of complex salts with pyridine, and quinoline. If columbic acid be suspended in conc. hydrobromic acid at 0° , and the soln. saturated with hydrogen bromide, and the soln. of the oxybromide be treated with the calculated quantity of a warm soln. of rubidium bromide and about 5 c.c. of 80 per cent. hydrobromic acid, dark red octahedral crystals of **rubidium oxypentabromocolumbate**, $\text{Rb}_2\text{CbOBr}_5$, are formed. The crystals are very sensitive to moisture. Brick-red, octahedral cubic crystals of **cæsium oxypentabromocolumbate**, $\text{Cs}_2\text{CbOBr}_5$, were obtained.

W. M. Barr said that an impure, stable **columbium iodide** was prepared from the pentabromide. R. F. Weinland and L. Storz were unable to prepare columbium iodide, and they said that the complex salt of columbium penta-iodide and pyridine iodide reported by C. Renz is really pyridine periodide. R. F. Weinland and L. Storz were also unable to prepare oxyiodocolumbates analogous to the oxychloro- and oxybromo-columbates.

§ 13. Columbium Sulphide, Oxysulphide, and Sulphates

According to W. von Bolton,¹ the direct union of heated columbium and sulphur furnishes **columbium sulphide**—according to R. Fittig, possibly CbS_2 . G. Krüss and L. F. Nilson obtained a sulphide by heating the hydride in sulphur vapour. H. Biltz and L. Gonder said that a brown product is obtained when the pentoxide

is heated in a current of hydrogen sulphide; and when the pentoxide is heated to bright redness in a mixture of the vapour of carbon disulphide and hydrogen sulphide—the product is washed with carbon disulphide, and dried over sulphuric acid in vacuo. The product was thought to be a mixture of Cb_2S_2 and Cb_2S_5 . Observations on this subject were made by H. Biltz and C. Kirchner. R. Robl observed no fluorescence when columbium sulphide is exposed to ultra-violet light. A. Karl said that the sulphide is triboluminescent.

According to H. Rose, columbium pentoxide at a white-heat is incompletely transformed by hydrogen sulphide into **columbium oxysulphide**—possibly Cb_2OS_3 , or $\text{Cb}_2\text{O}_2\text{S}_3$ —water, and sulphur; sodium columbate, or a mixture of columbium pentoxide and sodium carbonate, behaves similarly. The impure oxysulphide is also formed by passing the vapour of carbon disulphide for 4 hrs. over white-hot columbium pentoxide, and cooling the product in an atm. of carbon dioxide; and also by heating the oxytrichloride in dry hydrogen sulphide: $2\text{CbOCl}_3 + 4\text{H}_2\text{S} = \text{Cb}_2\text{OS}_3 + \text{H}_2\text{O} + 6\text{HCl} + \text{S}$. Analyses were made by R. Hermann, H. Rose, C. F. Rammelsberg, H. Biltz and L. Gonder, and M. Delafontaine, but without conclusive evidence as to the formula. F. Russ obtained an impure oxysulphide by the action of the vapour of carbon disulphide on heated potassium oxalato-columbate. The composition is $\text{K}_{15}\text{Cb}_4\text{O}_9\text{S}_{10}$, or $6\text{K}_2\text{S}_2\cdot\text{Cb}_4\text{O}_3\text{S}_7$; and since a little carbon was also present, it was thought that the $\text{Cb}_4\text{O}_3\text{S}_7$ would be better represented by $\text{Cb}_2\text{O}_2\text{S}_3$, or Cb_2OS_4 . It is also suggested that the product represents an intermediate stage in the sulphuration of columbium pentoxide, and that with the right conditions, *columbium pentasulphide*, Cb_2S_5 , as well as *potassium ortho-sulphocolumbate*, K_3SbS_4 , might be formed.

The black or bluish-black crystalline oxysulphide acquires a steel lustre, never a brassy lustre, when rubbed in an agate mortar; it is a good conductor of electricity. It loses about one-third of its sulphur when heated in a current of hydrogen; it burns when heated in air, forming columbium pentoxide and sulphur dioxide; chlorine converts it into the pentachloride—partially in the cold, completely when hot; iodine and boiling water do not attack it, and iodine can be sublimed from its admixture with the oxysulphide; boiling hydrofluoric acid attacks it slowly, but it is not attacked by boiling hydrochloric acid. Dil. sulphuric acid, hot or cold, has no action, but the conc. acid when heated forms a columbium sulphate; nitric acid slowly transforms it into the pentoxide, and aqua regia acts similarly; a boiling soln. of potassium sulphide has no action; molten potassium hydroxide converts it into potassium sulphide and columbate; and a mixture of sulphur and potassium carbonate acts similarly without forming a sulpho-salt.

The unsatisfactory nature of our knowledge of the columbium sulphides and oxysulphides applies also to the sulphates. F. Ott electrolyzed a soln. of columbium pentachloride in sulphuric acid and obtained liquids which may contain sulphates of trivalent and quadrivalent columbium. H. Rose obtained a soln. of **columbium sulphate** by dissolving the oxysulphide in aqua regia or in sulphuric acid, and by melting columbium pentoxide or a columbate with potassium hydrosulphate, and dissolving the cold product in water. C. W. Blomstrand obtained a white mass by treating an aq. soln. of columbium oxytrichloride with sodium sulphate. H. Geisow said that when the sulphuric acid soln. of the oxysulphide is evaporated, at 34° , **columbium tetroxysulphate**, $\text{Cb}_2\text{O}_5\cdot\text{SO}_3$, or $\text{Cb}_2\text{O}_4(\text{SO}_4)$, or $\text{O}_2\text{Cb}\cdot\text{SO}_4\cdot\text{CbO}_2$, is formed; and at 43° , $2\text{Cb}_2\text{O}_5\cdot\text{SO}_2$, or $\text{Cb}_2\text{O}_5\cdot\text{Cb}_2\text{O}_4(\text{SO}_4)$. F. Ott electrolyzed a soln. of 4.5 grms. of columbium pentachloride in 150 c.c. of hot conc. sulphuric acid with a lead cathode, in a compartment cell, and when the reduction had proceeded to trivalent columbium, added 10 grms. of ammonium sulphate, and continued the electrolysis until this salt had dissolved. The soln. was evaporated in vacuo, and the salt dried on a porous tile over phosphorus pentoxide. The resulting **ammonium hydropentasulphatocolumbite**, $(\text{NH}_4)_2\text{SO}_4\cdot\text{Cb}_2(\text{SO}_4)_3\cdot\text{H}_2\text{SO}_4\cdot 6\text{H}_2\text{O}$ appeared as a reddish-brown powder, which can be kept in dry air for some time. It forms a brown soln. with water, which by

oxidation becomes successively blue, green, and colourless; it is immediately coloured blue by ammonia, or hydrochloric acid; it is virtually insoluble in alcohol and ether. The solubility of potassium sulphate prevented the formation of **potassium hydropentasulphatocolumbite** in a similar way. A. Stähler could not obtain a sulphate of tervalent columbium, **columbous sulphate**, $\text{Cb}_2(\text{SO}_4)_3$, by the electrolytic reduction of a sulphuric acid soln. of columbium pentachloride; but S. J. Kiehl and D. Hart reduced a soln. of columbium oxide in 3 to 10M- H_2SO_4 completely to the tervalent stage by a mercury cathode.

§ 14. -Columbium Carbonate, Nitrate, and Phosphate

No *columbium carbonate* has been reported although F. Russ,¹ and L. Weiss and M. Landecker obtained a series of complex oxalates. No *columbium nitrate* has been described. C. W. Blomstrand obtained what may have been *columbium phosphate*, as an insoluble precipitate, by adding sodium phosphate to an aq. soln. of columbium oxytrichloride.

CHAPTER LVI

TANTALUM

§ 1. The Preparation of Tantalum

THE history and occurrence of the element tantalum have been described in connection with columbium. The metal of a high degree of purity has been obtained only in recent years. J. G. Children¹ obtained a reduction product of tantalum pentoxide as a reddish-yellow, brittle substance, which he obtained by strongly heating the pentoxide in an electric circuit. W. von Bolton obtained the element in the same way as he obtained columbium, namely, by electrically heating rods of the tetroxide in a vacuum furnace—*vide infra*, the action of oxygen on tantalum. J. J. Berzelius attempted to reduce tantalum pentoxide by heating it in a carbon crucible, but obtained a very poor result; and A. Joly heated a mixture of the pentoxide with carbon and sodium carbonate in a carbon crucible at a white heat, and obtained a mixture of tantalum carbide and nitride. H. Moissan obtained a better result by heating a mixture of a mol of tantalum pentoxide and 5 gram-atoms of carbon in a graphite crucible in an electric furnace. The product contained 0.5 per cent. of carbon alloyed with the tantalum probably as carbide. E. W. von Siemens and J. G. Halske recommended heating a theoretical mixture of oxide and carbon at a white-heat out of contact with air—say in an atm. of hydrogen—and removing the occluded hydrogen by heating the metal in vacuo.

H. Rose found that the passage of phosphorus vapour over sodium tantalate gave no metal; and E. F. Smith and P. Maas obtained none by the reducing action of magnesium or zinc on tantalum pentoxide. L. Weiss and O. Aichel ignited a mixture of the pentoxide and mischmetal as in the thermite process and obtained the metal. W. Muthmann and co-workers employed a similar process. W. von Bolton obtained a hard, brittle alloy by reducing the pentoxide with aluminium as in the thermite process; and W. K. van Haagen obtained a similar result. H. Rose obtained the metal by heating sodium with tantalum pentachloride in an iron crucible, but much chloride was lost by volatilization; if the pentachloride be heated with ammonia, tantalum nitride, not the metal, is formed.

J. J. Berzelius, H. Rose, and R. Hermann obtained the metal by heating sodium or potassium heptafluotantalate with the alkali metal under a layer of alkali chloride in an iron crucible; and leaching out the soluble products in the water. J. C. G. de Marignac considered that the product so obtained is tantalum hydride. The process was employed by A. Siemens, and M. E. Pennington. J. W. Marden reduced the chloride by sodium in a closed vessel. The black powder containing some oxide, and hydrogen, is purified by pressing it into small cylinders and melting it in vacuo by an electric current as in the patented process of E. W. von Siemens and J. G. Halske. A. S. Cachemaille reduced the oxide by heating it with calcium and an alkali or alkaline earth halide in an iron bomb lined with lime.

H. Kuzel prepared **colloidal tantalum** by the process employed for columbium; and T. Svedberg obtained the colloidal soln. by the spluttering of an arc of tantalum wires in isobutyl alcohol. The sol can be kept 2 or 3 weeks. It is brownish-black in transmitted light, and black in reflected light.

§ 2. The Physical Properties of Tantalum

W. Muthmann¹ and co-workers described tantalum as a white metal with a greyish tinge; the lustre is bright and is little affected by exposure to air. According to W. von Bolton the powder obtained by the sodium reduction when pressed and melted in vacuo furnishes a platinum-grey metal. When heated in vacuo over 1700°, the metal rapidly crystallizes. According to A. W. Hull, the **X-radio-gram** of tantalum agrees with a body centred cubic lattice with side of length 3.272 Å., and a distance between the nearest atoms of 2.833 Å. Observations were also made by E. C. Bain, and K. Becker and F. Ebert. Z. Jeffries and R. S. Archer estimated the lowest recrystallization temp. to be 1000°. J. A. M. van Liempt prepared single crystals by heating tantalum chloride vapour, and hydrogen by a glowing tantalum wire. H. Moissan gave 12.8 for the **specific gravity** of a metal with about half per cent. of carbon; W. Muthmann and co-workers found the sp. gr. at 16° to be 14.491; T. Barratt and R. M. Winter, 16.67; F. W. Hinrichsen and N. Sahlborn gave 16.5; and W. von Bolton, 16.64 for bars of the metal, and 16.5 for the wire. When heated electrically in vacuo for 12 hrs., the sp. gr. of the wires approaches that of the bars. W. von Bolton gave 14.08 for the sp. gr. of 96.8 per cent. tantalum obtained by reducing potassium heptafluotantalate. W. Muthmann and co-workers gave 12.61 for the **atomic volume**; H. G. Grimm made observations on the ionic radius. W. Muthmann and co-workers found that the **hardness** is between 6 and 6.5; and W. von Bolton, that the hardness of tantalum containing a little oxygen approaches that of hardened steel. E. W. Engle found that the hardness of tantalum on Brinell's scale is 46. According to E. W. von Siemens and J. G. Halske, the presence of carbon (carbide), hydrogen (hydride), oxygen (oxide), boron, aluminium, silicon, titanium, and tin hardens the metal. H. Moissan described the metal he obtained with half per cent. of carbon as being hard and brittle; W. von Bolton, and A. Siemens said that the purified metal is soft, tough, and **malleable**. It can be hammered out into thin sheets, or drawn into fine wire—filament wires, for instance, are only 0.03 mm. in diameter. The metal, indeed, is as elastic and tough as soft steel. The **elastic modulus** is nearly the same as that of steel, and approximates 19,000 kgrms. per sq. mm. for wires of 0.08 mm. diameter; wires 0.05 mm. thick have a **tensile strength** of 150–160 kgrms. per sq. mm.; and wires 1 mm. thick, a tensile strength of 93 kgrms. per sq. mm.—i.e. 57 tons per sq. inch. The elongation is one to two per cent. For the **compressibility**, T. W. Richards gave 5.4×10^{-7} megabars or 5.2×10^{-7} kgrms. per sq. cm. over a press. range of 500 kgrms. per sq. cm. at 20°; and P. W. Bridgman, working over the press. range of 12,000 kgrms. per sq. cm., found at 30°, $\delta v/v_0 = -10^{-7}(4.79 - 0.25 \times 10^{-5}p)p$; and at 75°,

$-10^{-7}(4.92-0.25 \times 10^{-5}p)p$, so that there is a close approach to constancy at the two temp. P. W. Bridgman also gave for the compressibility, β , at 30° , 0.0_6479 ; $\delta\beta/\beta\delta p=0.0_510$; $-\delta\alpha/\alpha\delta p=0.0_4126$; and $-\beta_0(\delta\alpha/\delta ap)=2.63$, where α denotes the coeff. of thermal expansion. T. W. Richards estimated 455,000 for the **internal pressure** in megabars. L. H. Adams gave 0.0_649 for the compressibility, and 0.01 for the change of the compressibility with press.—megabar unit. J. Laissus discussed the diffusion of tantalum in iron.

W. von Bolton found the coeff. of **thermal expansion**, with a rod of 3 mm. diam. and 15 cms. long, was 0.0000079 between 0° and 50° . A. G. Worthing found for the thermal expansion at T° K., $\delta l/l=0.0_5660(T-300)+0.0_552(T-300)^2$; in agreement with J. Disch's value $0.0_5646\theta+0.0_990\theta^2$. J. Dewar found the relative **thermal conductivity** to be about three-quarters that of iron, and about one-eighth that of copper. T. Barratt and R. M. Winter gave 0.130 cal. per cm. per degree per second for the heat conductivity of tantalum at 17° , and 0.129 cal. at 100° . W. Muthmann and co-workers gave 0.03017 for the **specific heat** of the metal with 0.5 per cent. of iron; and for the purified metal, 0.0346 ; W. von Bolton gave 0.0363 between 16° and 100° ; P. Nordmeyer and A. L. Bernoulli, 0.0326 between -185° and 20° ; and J. Dewar, 0.033 between 14° and 100° ; 0.032 between -78° and 14° ; and 0.028 between -78° and -183° . The influence of temp. is not very great, but, according to F. Streintz, it is sufficient to show that the metal does not follow the ordinary sp. ht. rule. W. Muthmann and co-workers gave 6.32 for the **atomic heat**; W. von Bolton, 6.57 ; and J. Dewar, 5.97 . F. Simon and M. Ruhemann gave for C_p and C_v respectively 3.56 and 3.55 at 71.11° K.; 3.81 and 3.80 at 77.55° K.; and 3.82 and 3.81 at 78.01° K. W. von Bolton gave $2250^\circ-2300^\circ$ for the **melting point**; A. G. Worthing, 3027° ; E. Tiede and E. Birnbräuer, 2475 ; M. von Pirani and A. R. Meyer, $2850^\circ \pm 40^\circ$; W. E. Forsythe, 2802° ; and W. R. Mott, 2850° . A tantalum lamp filament with the ordinary load was found by M. von Pirani to melt at 2000° . W. R. Mott calculated 5300° for the **boiling point** of tantalum. E. Tiede and E. Birnbräuer said that it begins to volatilize at 2200° . W. Muthmann and co-workers gave for the **heat of combustion**, 837.9 cals., or 30.8 Cals. per gram-equivalent; and J. E. Moose and S. W. Parr gave 1373 cals. for the heat of oxidation per gram.

H. von Wartenberg² found the **index of refraction** to be 2.05 ; the **absorption coefficient**, 2.31 ; and the **reflecting power**, R , 43.8 per cent. for yellow light with $\lambda=579\mu$. W. W. Coblentz gave for

λ	0.5	0.6	0.8	1.0	1.2	1.6	2.0	4.0	8.0	12.0
R	38.0	45.0	64.0	78.0	84.0	88.0	90.5	93.0	93.8	95.0

The spectral emissivity was studied by H. von Wartenburg, W. W. Coblentz, F. Henning, M. von Pirani, G. V. McCauley, and C. E. Mendenhall and W. E. Forsythe. A. G. Worthing gave:

T° K.				300°	1000°	1600°	2000°	2600°	3300°
Spectral emissivity	0.665μ			0.493	0.459	0.434	0.418	0.397	0.375
	0.463μ			0.56	0.52	0.49	0.47	0.44	—
Brightness temp. ($^\circ$ K.)				—	966°	1506°	1851°	2339°	2870°
Colour temp. ($^\circ$ K.)				—	—	1642°	2075°	2705°	—
Total emissivity				—	—	0.194	0.232	0.287	—
Radiation temp. ($^\circ$ K.)				—	—	1062°	1390°	1901°	—
Radiation intensity (watts per sq. cm.)				—	—	1.65	4.81	16.9	—

According to J. M. Eder and E. Valenta, the **spark spectrum** of tantalum is very poor in the visible region, and does not show any marked characteristics: The lines are feeble, or indistinct, and difficult to measure. Observations were reported by R. Thalén, E. Demarçay, F. Exner and E. Haschek. E. J. Allin and H. J. C. Ireton studied the spark spectrum under water. The **arc spectrum** of tantalum pentoxide between carbon electrodes was found by J. M. Eder and E. Valenta to be rich in lines in the extreme red region. The more intense lines are

6675-75, 6621-45, 6612-12, 5675-10, 6516-33, 6514-57, 6505-70, 6485-60, 6450-56, 6430-98, 6389-66, 6361-06, 6356-32, 6325-23, 6309-78, 6268-87, and 6256-81. Measurements were also reported by C. Rütten and H. Morsch, F. Exner and E. Haschek, and H. Morsch. W. J. Humphreys observed the effect of pressure on the spectral lines. H. Konen and H. Finger found that the spark spectrum between tantalum electrodes under liquids—especially water—is continuous. E. Paulson reported the existence of a **series spectra** represented by groups of lines showing a constant difference of frequency, but H. Josewsky could not verify this. W. W. Coblenz examined the **ultra-red emission spectrum** of tantalum. J. Formanek observed no **absorption spectrum** with soln. of tantalum salts, and no reaction with tincture of alkanna. A. L. Helfgott studied the radiation of tantalum. J. Lifschitz observed the spectrum of the **voltaluminescence**, *i.e.* the glow which occurs when an electric current is passed under certain circumstances through an electrolytic cell—with direct or alternating current, and tantalum electrodes.

M. Siegbahn³ gave for the K-series of the **X-ray spectrum**, $\beta_6=1.3267$; $\beta_7=1.2600$; $\gamma_5=1.1700$. B. R. Stephenson and J. M. Cork gave values for wave-lengths α' , α , β , and γ . J. Schrör, B. B. Ray, and A. Duvallier studied these rays. J. Schrör, P. Auger and A. Duvallier, G. Réchou, E. Hjalmar, Y. Nishina, M. J. Druyvesteyn, U. Dehlinger, M. Siegbahn, H. Hirata, I. Wennerlöf, D. Coster, A. Duvallier, and E. Hjalmar gave for the L-series, $\alpha_2\alpha_1=1.52933$; $\alpha_1\alpha=1.51824$; $\beta_1\beta=1.32351$; $\beta_2\gamma=1.28065$; $\gamma_1\alpha=1.13471$; $\eta=1.435$; $\gamma_2\theta=1.101$; $\beta_4\nu=1.341$; $\beta_3\phi=1.303$; and $\gamma_3\chi=1.094$. A. Duvallier, Y. Nishina, E. Hjalmar, J. H. van der Tuuk, and G. Wentzel reported for the M-series, $\alpha=7.237$, $\beta=7.0115$, etc.; Y. Nishina, J. Thibaud and A. Soltan, and J. C. Boyce studied the N-series; and Y. Nishina, the O-series. G. Hagen, and F. Kirchner studied the Compton effect with tantalum. G. von Hevesy and J. Böhm discussed the analysis of tantalum minerals by means of the X-ray spectrum. J. E. P. Wagstaff gave 4.75×10^{12} for the **vibration frequency**.

S. Dushman and co-workers⁴ studied the **emission of electrons** from tantalum at 200° K. O. W. Richardson, and S. Dushman and co-workers gave $i=60.2T^2e^{-b/T}$ for the general equation for the emission of electrons from a metal when i denotes the electronic current; T , the absolute temp.; e , the base of natural logarithms; and b , a constant of the emitting substance. The constant b is related to ϕ , the work done by an electron in escaping from the surface, by the equation $b=\phi/k$, where k is a constant. Electropositive elements with a low value of ϕ will give a higher electronic emission than substances with a high value of ϕ ; but metals with a high value of ϕ , and a high m.p. can be used at a higher temp. when the electronic emission is greater. Some values of ϕ in eq. volts are as follows:

	W	Pt	Ta	Mo	C	Cu	Fe	Th	K
ϕ	4.478	4.8	4.31	4.18	4.14	4.05	3.2	2.69	1.30

G. Hagen, and F. Kirchner studied the scattering of X-rays and the Compton effect. F. Rother found that the emission of electrons between tantalum electrodes occurs between 2×10^6 and 9×10^6 volts per cm.; S. C. Roy studied the photoelectric emission of electrons as a function of the temp.; and O. Rietschel, the effect of press. W. H. Rodebush estimated the rate of evaporations of electrons from a hot tantalum filament. N. Piltschikoff stated that the so-called **Moser's rays**—the rays emitted from metal surfaces—are emitted by tantalum; they restore silver bromide reduced by positive rays. M. Levin and R. Ruer observed that tantalum acid can affect a photographic plate probably owing to the presence of thorium or radium impurities. C. Renz found that while tantalum pentoxide is reduced with considerable difficulty by chemical means, it is markedly **photosensitive** in the presence of certain organic liquids—*e.g.* glycerol—and is reduced to a lower oxide. H. Klumb, and R. Shurmann investigated the influence of gases on the photoelectric emission of tantalum.

J. J. Berzelius⁵ said that the impure tantalum which he prepared had poor **electrical conductivity**; whilst H. Rose's sample was regarded as a good conductor, and H. Moissan's sample, with half per cent. of carbon, was called a non-conductor. W. W. Coblenz found the tantalum filament of an unused tantalum lamp had a diameter 0.048, and an **electrical resistance** of 0.85 ohm per cm. W. von Bolton said that the average sp. resistance is 0.165 with a temp. coeff. of about 3 per cent. between 0° and 100°. P. W. Bridgman found the coeff. for two different samples to be 0.00293 and 0.00335; L. Holborn gave 0.00347; and F. Streintz, 0.003. Observations were made by A. Schulze E. W. von Siemens and J. G. Halske found the conductivity to be 6.85 when that of mercury is unity. M. von Pirani found that wires of various thickness varied in their sp. resistance from 0.173 to 0.188 ohm, but after heating to 1900° in a high vacuum for from 100 to 200 hrs. they all possessed the same sp. resistance, namely, 0.146 ohm, and the temp. coeff. between 0° and 100° was 0.33 per cent. A. Siemens said that the temp. of tantalum filament consuming 1.5 watt per candle-power is about 1850°, and its resistance is about six times its resistance at 100° so that the temp. coeff. between 100° and 1850° may be taken as 0.29 per cent. The difference between these results is caused by alterations in the structure of the wires during their manufacture, and the heating in vacuo served a similar purpose to the annealing of steel. According to E. W. Engle, tantalum has a greater resistance but a smaller temp. coeff. than molybdenum or tungsten. J. W. Marden and M. N. Rich gave 0.0414 ohm per c.c. A. G. Worthing gave for the resistance, R ohms, in absolute temp.;

T	1600°	1800°	2000°	2200°	2400°	2600°	2800° K.
R	67.6	74.1	80.5	86.9	92.9	99.1	105.0 ohms

and for $(dR/dT)(T/R)$, 0.785. M. von Pirani found the following ratios for the resistance, R at θ° , between -180° to 2000° , to that at 20° , R_{20} :

	-180°	0°	100°	200°	600°	1000°	1400°	1600°	2000°
R/R_{20}	0.34	0.94	1.27	1.59	2.76	3.86	4.64	5.32	6.34

H. Pécheux found a tantalum wire, almost free from columbium, and 0.5 metre long, had $R=16.38(1+0.0025\theta+0.0000004\theta^2)$ microhm. P. W. Bridgman found for the effect of press., p , on the resistance, R , between 0 and 12,000 kgms. per sq. cm. to be:

	0°	25°	50°	75°	100°
R { $p=0$	0.01487	0.01497	0.01507	0.01518	0.01530
R { $p=12,000$	0.01373	0.01391	0.01409	0.01426	0.01442
R { Average	0.01430	0.01444	0.01458	0.01472	0.01486

A. G. Worthing observed that the ratio of the thermal and electrical conductivities, in C.G.S. units, is 27 at 1600° K.; 33 at 1800° K.; 46 at 2000° K.; and 56 at 2100° K. L. Grunmach and F. Weidert showed that the increase in the electrical resistance by transverse magnetization is less than is the case with many other metals—copper, silver, lead, zinc, tin, lead, bismuth, palladium, and platinum. R. Holm studied the contact resistance of two tantalum plates pressed together.

H. Pécheux found that the **thermoelectric force** of a *platinum-tantalum* couple with the tantalum almost free from columbium and platinum at a temp., θ° , between 0° and 400° , is $dE/d\theta=2.20+0.0246\theta$ microvolts. This value is increased by preheating the tantalum, and decreased when increasing proportions of columbium are present. Purified tantalum stands between palladium and platinum with 10 per cent. rhodium; if the tantalum be contaminated with columbium, it stands between platinum and palladium. A. G. Worthing found that the *tungsten-tantalum* couple at a high temp. is four times as sensitive as the platinum-Rd couple; the coeff. of Thomson's effect in microvolts per degree is -5 at 1600° K.; -6 at 1800° K.; -8 at 2000° K.; and -9 at 2100° K. S. Morugina also studied

this couple—*vide tungsten*. W. W. Coblentz found for the thermoelectric force of the *copper-tantalum* couple between -400° and 400° about 4.1 microvolt per degree, *i.e.*, nearly the same as that of the copper-constantin couple. R. L. Pearson's value was too low.

According to W. von Bolton, tantalum stands in the **electrochemical series**, in dil. nitric acid, between silver and platinum—rather closer to the former than to the latter. G. von Hevesy found the **potential difference** between tantalum and its pentoxide is 0.00 volt; W. Muthmann and F. Fraunberger gave -0.5 volt for the potential difference between tantalum and *N*-KCl; while G. von Hevesy found -0.04 volt with respect to the calomel electrode. G. von Hevesy showed that the metal readily assumes the **passive state**. G. C. Schmidt showed that tantalum gives a low potential after it has been polished, but the metal regains its normal potential in about 20 mins. G. von Hevesy and R. E. Slade showed that the potential difference between tantalum and a 0.006 mol soln. of tantalum pentafluoride is for the passive metal 1.537 volts, and for the active metal 0.165 volt—hydrogen zero. They added that in its most passive state, tantalum has *ein edleres Potential* than silver by about one volt, whilst an active metal has a potential close to that of copper. H. Kuessner found that a tantalum anode in 16*N*-KOH is converted into the pentoxide and the electrochemical valency is 5. The pentoxide forms a layer on the anode which permits a small current to pass. Increasing the applied voltage does not increase this current beyond 0.02–0.03 amp. per sq. cm. The tantalum anode in hydrofluoric acid acquires a coating of oxide which is broken at 220 volts.; and W. von Bolton found that in sulphuric acid, the tantalum anode acquires a film of oxide which stops the current. Hence, tantalum acts as a rectifier when used as an anode in an electrolyte, for it will allow of the passage of the positive current only in one direction. E. Müller measured the potential of a hypochlorite anode with a tantalum cathode of other metals. G. Osterheld showed that the **overvoltage** of the tantalum cathode in 2*N*-sulphuric acid is 1.14 volts. As a reducing electrode in the case of benzophenone, caffeine, and nitrobenzene, tantalum yields very poor results—*vide infra*, tantalum hydride. P. K. Frölich and G. L. Clark gave for the hydrogen overvoltage of the metals in increasing order: Pd, Pt, Ta, Ni, Co, Fe, Zn, Cu, Au, and Hg. The metal overvoltages decrease in the same order. A. Thiel and W. Hammerschmidt studied this subject. The **electrolytic valve action** was studied by A. Günther-Schulze, E. Newbery, E. W. Engle, E. M. Dunham, and E. H. Robinson said that the tantalum rectifier resembles the aluminium rectifier; dil. sulphuric acid is a satisfactory electrolyte, and lead as the other electrode. A current freely passes from the acid to the anode, but only to a small extent in the reverse direction unless the e.m.f. applied exceeds 40–200 volts, depending on the conditions. The addition of a small proportion of ferrous sulphate to the acid very much improves the rectification. Soda-lye, as electrolyte, corrodes the tantalum. N. A. de Bruyne and R. W. W. Sanderson studied the electrostatic capacity of tantalum anodes in dil. sulphuric acid of sp. gr. 1.285 at 18° . W. von Bolton found that the electrical spluttering of a tantalum filament in vacuo is very small; H. R. von Traubenberg studied the loss of weight of the tantalum electrode in the oscillatory spark discharge in oxygen and nitrogen; and H. Finger showed that the electrical spluttering of the tantalum under water is very slow. C. Zwickler studied the thermal emission of electrons. R. H. Fowler studied the electron theory of thermionic emission of tantalum.

E. W. Siemens and J. G. Halske⁶ found tantalum to be paramagnetic. M. Owen showed that the **magnetic susceptibility** of tantalum is 0.81×10^{-6} units, and it decreases with rise of temp. K. Honda gave 0.93×10^{-6} at 18° , and 0.8×10^{-6} at 800° . S. Meyer gave for the at. magnetic susceptibility 1.02×10^{-6} units; and the at. magnetization number, 58.0×19^{-6} . D. M. Bose and H. G. Bhar studied the susceptibility of tantalum salts.

§ 3. The Chemical Properties of Tantalum

The chemical reactions of tantalum are very similar to those of columbium; but it is not so strong a reducing agent. Tantalum readily absorbs hydrogen when heated to redness; thus, it forms a hydride (*q.v.*) with **hydrogen** and becomes very brittle. W. von Bolton¹ found that most of the absorbed hydrogen can be expelled by heating the product in vacuo. G. Oesterheld observed that, like palladium, a tantalum cathode easily absorbs hydrogen when used as cathode in the electrolysis of sulphuric acid. A. Sieverts and E. Bergner found that tantalum absorbs **argon** to a small extent, and a little more **helium** is absorbed than is the case with argon. F. Fischer and F. Schrötter observed no reaction when tantalum is sparked below liquid argon. J. J. Berzelius found that tantalum powder glows when heated to redness in **air**; and A. Siemens said that the black powder and thin wires can be ignited by applying to them the flame of a match. When the metal is heated in **air**, it shows at about 400° a yellow, and then a blue tint like steel, and when the heating is continued, it burns to the pentoxide. H. Moissan said that the ignition temp. in dry **oxygen** is 600°. A. Siemens, and W. von Bolton found that when a tantalum filament contaminated with oxide is heated in a high vacuo, the combined oxygen will be expelled; and it is possible to detect when a filament contains oxide by very gradually heating it up, when the parts containing the oxide will appear brighter than the other parts owing to the greater electrical resistance of the oxide. In a few minutes the glow of the filament becomes quite uniform owing to the expulsion of the oxygen. If the oxygen press. is below 20 mm., the tantalum does not form an oxide. Hence by electrically heating the oxide under reduced press., and pumping off the oxygen as it is given off, it is possible to isolate the metal. Red-hot tantalum decomposes **water**, and the escaping hydrogen inflames; below about 300°, tantalum is not affected by water; moisture has no action on the metal. W. Guertler and T. Liepus observed no action with sea-water, aerated sea-water, or aerated rain-water during 4 weeks' exposure; nor did a soln. of **hydrogen dioxide** in alkali-lye attack the metal in 48 hrs.

According to H. Moissan, **fluorine** unites with finely powdered and warm tantalum with incandescence; and J. J. Berzelius found that the hot metal burns vigorously in **chlorine**, and H. Moissan showed that the attack by chlorine is slow at 150°, faster at 200°, and rapid at 250°. W. Guertler and T. Liepus observed no action with sat. chlorine-water in 48 hrs. W. K. von Haagen showed that **bromine** scarcely attacks the hot metal, but if the temp. is high enough, the pentabromide sublimes; and, added H. Moissan, the action is fast at the softening temp. of glass, and much heat is developed. The vapour of **iodine** does not attack the metal; and when powdered tantalum is heated with **iodine pentoxide**, iodine vapours are copiously evolved. J. J. Berzelius, E. W. Engle, and H. Rose observed that tantalum dissolves slowly in warm **hydrofluoric acid**, and W. von Bolton noted that corrosion figures are produced; while if the metal in contact with platinum be dipped in this acid, it rapidly dissolves with the evolution of hydrogen. H. Kuessner found that tantalum goes anodically into soln., and at the same time becomes passive owing to the formation of a film of oxide, observed by G. von Hevesy and R. E. Slade—*vide supra*. H. Rose, and H. Moissan found that a warm mixture of hydrofluoric and nitric acids dissolves tantalum rapidly with the production of red fumes. H. Moissan observed that **hydrogen chloride** attacks the heated metal forming a white sublimate, which darkens as the temp. rises, and hydrogen is evolved. Boiling **hydrochloric acid** has no action on tantalum; W. Guertler and T. Liepus observed no action during 48 hrs.' exposure, to 10 and 36 per cent. acid; and A. Siemens, and W. von Bolton reported that since tantalum resists all acids, alkalies, and moisture at temp. below 300°, it is good for making chemical apparatus which do not require a high temp., and for instruments liable to rust if made of steel. H. Moissan observed that unlike columbium when tantalum is heated with an aq. soln. of **potassium chlorate** there is no action.

W. von Bolton showed that at 100° **sulphur** has no perceptible action on tantalum, but when heated to higher temp. union occurs; J. J. Berzelius found that his impure tantalum could be inflamed in sulphur vapour; and H. Moissan obtained a somewhat similar result. W. Guertler and T. Liepus observed that 10 and 50 per cent. soln. of **sodium sulphide**—with or without alkali-lye—do not attack tantalum during 48 hrs. H. Moissan added that **hydrogen sulphide** has no action at 600°; and **sulphur dioxide** is reduced at approximately 500°, forming sulphur and tantalum pentoxide. Boiling **sulphuric acid** does not attack the compact metal; but H. Moissan said that the boiling, conc. acid slowly attacked the tantalum he prepared, and was coloured brown. W. Guertler and T. Liepus observed that 10 per cent. sulphuric acid has no action during 48 hrs., and similarly also with 20 per cent. acid sat. with sodium sulphate. W. von Bolton observed that **selenium** behaves like sulphur towards tantalum. H. Moissan said that tellurium has no action at 700°; but W. von Bolton said that a greyish-black telluride is formed. W. Muthmann and co-workers said that **nitrogen** reacts with tantalum at a red-heat, forming a nitride; H. Moissan said that the attack is only slight at 1200°. On the other hand, W. von Bolton showed that at a dull red-heat, tantalum absorbs nitrogen greedily, and the metal becomes very brittle. H. Moissan showed that at a red-heat, **ammonia** is decomposed while the metal acquires a dark colour, without changing in weight. W. Guertler and T. Liepus observed no reaction with 10, 50, and 70 per cent. ammonia during 48 hrs. At 500°, tantalum reacts vigorously with **nitrogen trioxide and pentoxide**. Boiling **nitric acid**, or aqua regia was found by W. von Bolton to have no action on the metal. W. Guertler and T. Liepus also observed that 10 and 50 per cent. soln. of the acid have no action during 48 hrs., and similarly also with aqua regia. H. Moissan showed that molten **potassium nitrate** attacks tantalum more slowly than it does columbium. The vapour of **phosphorus** does not attack tantalum at the softening temp. of glass; and **phosphorus pentoxide** is reduced by the red-hot metal, forming phosphorus. The vapour of **arsenic** or **antimony** does not attack

tantalum at the softening temp. of glass, but **arsenic pentoxide** is reduced. W. von Bolton found that a trace of **boron** or **carbon** makes the metal hard without harming its ductility, but more carbon makes the metal brittle. A soln. of **carbon dioxide** in air was found by W. Guertler and T. Liepus to have no action on tantalum in 48 hrs.; and similarly also with soln. of **acetic, citric, and tartaric acids**. **Silicon** and **titanium**, like carbon, make the metal brittle. H. Moissan studied the carbide (*q.v.*), and O. Höningschmid, the silicide (*q.v.*).

H. Moissan found that molten **sodium** or **potassium** does not alloy with tantalum. W. von Bolton, L. Jordan and co-workers, and H. Moissan said that **silver** does not alloy with tantalum, and if molten tantalum be poured on a block of silver, the molten metal sinks into the silver without dissolving a trace; **magnesium** was found by E. F. Smith and P. Maas to form an alloy; W. von Bolton said that **zinc** forms no compound; and W. von Bolton, and G. Tammann and J. Hinnüber said that **mercury** forms no amalgam; and O. Brunck observed no alloying occurs when zinc is deposited electrolytically on tantalum; **cadmium** behaves similarly. E. F. Smith and P. Maas obtained an alloy by reducing the oxide with **aluminium** powder; and tantalum produced by the aluminothermite process contains some aluminium. J. C. G. de Marignac obtained **aluminium tritantalide**, Al_3Ta , by melting a mixture of potassium fluotantalate and aluminium filings (1 : 1.5) in a carbon crucible, and treating the regulus with cold hydrochloric acid. The black, crystalline powder has a sp. gr. 7.02. It is but slightly affected when warmed in air; it is attacked by cold hydrofluoric acid; and is slightly affected by boiling hydrochloric acid. Boiling, conc. sulphuric acid attacks it, but it resists cold dil. sulphuric or nitric acid, or aqua regia. It is attacked by molten potassium hydrofluoride. H. Schirmeister found that the mechanical properties of aluminium alloys, containing the following percentage proportions of tantalum, were:

Tantalum.	0.0	0.3	0.8	1.5	2.2	2.5 per cent.
Tenacity .	9.5	10.0	10.6	10.3	10.3	10.4
Elongation .	41	38	33	38	39	39
Hardness .	26	—	30	—	28	—

W. von Bolton found that **molybdenum** and **chromium** are readily soluble in molten tantalum. J. J. Berzelius heated **manganese** oxide with tantalum and found that when the product is treated with hydrochloric acid, manganese passes into soln., and the tantalum remains as a black powder. Five to 10 per cent. of **iron** forms a hard, ductile alloy. H. Moissan also obtained an alloy with iron. J. J. Berzelius obtained an alloy by heating tantalum with ferric oxide. L. Guillet studied the tantalum-steels, but found that they possessed no mechanical properties inviting special attention; he showed that the normal steels are all pearlitic in character; the quantity of pearlite is in proportion to the carbon content, but is better distributed as the percentage of tantalum increases. The mechanical properties show that the tantalum produces a slight increase in the breaking load, the limit of elasticity, and the resistance to shock, and a slight decrease in the elongation. The effect produced by 1 per cent. of tantalum can, however, be obtained by addition of other substances, particularly nickel. The transformation points between 600° and 675° are scarcely visible on the curve, but those between 770° and 790° on heating, and between 730° and 750° on cooling, are very clear; the last transformation, at about 900°, is rather slow. The quenched steels have the same structure as the ordinary steels. The influence of the tantalum on the mechanical properties is somewhat more evident with the quenched than with the ordinary steels. E. W. von Siemens and J. G. Halske found that **nickel** alloyed with 5–10 per cent. of tantalum is more ductile and acid-resisting than nickel alone; with 30 per cent. of tantalum, the alloy is tough, and easily worked, and is not attacked by aqua regia and other acids. A wire 0.5 mm. diameter breaks with a load of 2000 kgms. per sq. mm. W. von Bolton found that a boiling soln. of **alkali hydroxide** has no action on tantalum; but H. Moissan, and W. von Bolton

showed that the fused hydroxide decomposes the metal, forming hydrogen and a tantalate. A. L. Bernoulli found that tantalum dissolves anodically in conc. potash-lye, and, added F. W. Hinrichsen and N. Sahlbom, with a high anodic tension. W. Guertler and T. Liepus found that 10 and 50 per cent. soln. of sodium hydroxide have no action during 48 hrs. According to W. von Bolton, when tantalum powder is heated with **lead oxide** or **lead dioxide** metallic lead is formed; **manganese dioxide** at a red-heat is reduced by tantalum. For the action of tantalum on **manganese and iron oxides**, *vide supra*. H. Moissan showed that **mercurous or mercuric chloride** is reduced by tantalum. W. Guertler and T. Liepus observed no action with a soln. of mercuric chloride at 90°; nor with an aq. soln. of **magnesium chloride**. The reactions of tantalum of analytical interest have been indicated in connection with columbium.

The uses of tantalum.—Tantalum is used as a filament in the manufacture of incandescent lamps. The characteristic difference between carbon and tantalum filaments was illustrated by A. Siemens,² and W. von Bolton by representing the normal resistance of both filaments by 100 when they are giving a light of one candle for 1.5 watts. The resistance of tantalum alters directly and that of carbon inversely as the temp. so that the former is better able to resist over-heating. S. L. Malowan said that a tantalum lamp with a very thin filament burns with an efficiency of 1.5 watts per Hefner candle, and has a life of 1000 hrs.; at 2 watts per Hefner candle the temp. of the wire is 2201°. Tungsten filaments have largely replaced tantalum. A. Siemens, and M. von Pirani showed that tantalum can be used in making rustless instruments where great hardness and ductility are required—*e.g.* dental and surgical instruments; pen nibs; normal weights; clock springs; gramophone needles; etc. It can be used as cathode in electrolytic analysis, etc.; thus, according to C. W. Balke, it can be used for the deposition of zinc since it does not alloy with the metal, and if used for the electrodeposition of gold and silver, these metals can be dissolved from the cathode with aqua regia which does not attack the tantalum. It is also available as a rectifier, *e.g.* in charging accumulators from an alternating current supply since two tantalum electrodes in a single cell will convert an alternating current into a direct one. It has some advantages over platinum as an anticathode on account of its smaller tendency to splutter. In steels, S. L. Malowan said that tantalum raises the breaking and elasticity limits. O. Brunck discussed the application of tantalum as a substitute for platinum, where resistance to acids or aqua regia are required. Its sensitiveness towards hydrofluoric acid, and, when heated, towards oxygen limit its use. E. Groschuff and F. Mylius found that a tantalum crucible lost slightly in weight with hot nitric or hydrochloric acid; the loss was ten times greater when the crucible was heated with sulphuric acid at 200°; and it was completely destroyed by a conc. soln. of potash-lye at 130°.

The atomic weight and valency of tantalum.—In spite of a few more or less ill-founded reports to the contrary, tantalum almost uniformly behaves as a quinquevalent element. In the per-acids and per-salts also, as in the case of columbium, the element is quinquevalent. J. J. Berzelius³ at first regarded tantalum tetroxide as the metal, and he represented the pentoxide by the formula TaO_2 ; later, he measured what he regarded as the at. wt. by treating tantallic acid with baryta-water, and by the action of chlorine on the sulphide, and obtained 183.7–184.6 on the assumption that the at. wt. of oxygen is 16. The proximity of these numbers to the at. wts. employed at the present day is purely a coincidence since a different formula was employed— Ta_2O_3 for what is now known to be Ta_2O_5 . H. Rose obtained results similar to those of J. J. Berzelius; and likewise also C. W. Blomstrand. These numbers were afterwards recalculated for quinquevalent tantalum where the oxide becomes Ta_2O_5 .

From H. Rose's ratios $2TaCl_5 : Ta_2O_5 : 10AgCl$, it follows that the at. wt. of tantalum is 175.0; from C. W. Blomstrand's ratios, $2TaCl_5 : Ta_2O_5$, 173.7; $TaCl_3 : 5AgCl$, 178.4; and from $10AgCl : Ta_2O_5 : 2TaCl_5$, 176.2. J. C. G. de

Marignac's ratio $2K_2TaF_7 : Ta_2O_5$, the at. wt. of tantalum becomes 183.7; from $K_2TaF_7 : K_2SO_4$, 181.8; $K_2SO_4 : Ta_2O_5$, 132.76; $2(NH_4)_2TaF_7 : Ta_2O_5$, 182.76; $10AgCl : Ta_2O_5$, 182.26; and from $TaCl_5 : 5AgCl$, 181.00. F. W. Hinrichsen and N. Sahlbom calculated 181.0 from the ratio $2Ta : Ta_2O_5$. From these results, B. Brauner inferred that the at. wt. of tantalum is 181.4; and F. W. Clarke, 181.019. A. Joly obtained 182 by treating ammonium heptafluotantalate with sulphuric acid, and calcining the product for the pentoxide— $2(NH_4)_2TaF_7 : Ta_2O_5$. E. F. Smith added that the double salts are not suited for at. wt. determinations because of the uncertainty as to their composition after each crystallization. C. W. Balke calculated 181.52 from the ratio $2TaCl_5 : Ta_2O_5$; G. W. Sears and C. W. Balke obtained 180.90–181.36 from the ratios $2TaCl_5 : Ta_2O_5$ and $TaCl_5 : 5AgCl$; while W. H. Chapin and E. F. Smith obtained 181.68–181.91 from the ratio $2TaBr_5 : Ta_2O_5$. The International Table for 1926 gave 181.5 for the best representative value.

The **atomic number** of tantalum is 73. F. W. Aston ⁴ has not yet succeeded in determining the **isotopes** of tantalum. N. Bohr's **electronic structure** of the atom is (2) (4, 4) (6, 6, 6) (8, 8, 8, 8) (4, 4, 3) (2). The subject was discussed by L. A. Sommer, C. D. Niven, H. G. Grimm, and M. L. Huggins.

§ 4. Tantalum Hydride

J. C. G. de Marignac¹ said that when sodium heptafluotantalate is reduced with sodium under a layer of alkali chloride, **tantalum hydride** is the main product. According to W. von Bolton, if a strip of tantalum be used as cathode in the electrolysis of dil. sulphuric acid, there is an evolution of hydrogen, and about 0.3 per cent. is absorbed by the metal. At the same time, the metal becomes brittle. The hydrogen can be expelled only with difficulty, it is only partially removed by fusion. G. Oesterheld also observed that when tantalum is used as a reducing cathode it loses its elastic properties and becomes crystalline and brittle. M. von Pirani observed that tantalum at a red-heat occludes about 55 times its vol. of hydrogen—0.3 per cent.—and at a yellow heat about 740 vols. A crystalline hydride is formed, whose electrical resistance is about $2\frac{1}{2}$ times that of the metal. When the hydride is heated in vacuo, there remains 0.1 per cent. which is expelled only with long continued fusion in vacuo. A. Sieverts and E. Bergner showed that the solubility of hydrogen in tantalum from 1330° upwards is for the same hydrogen press. smaller with rise of temp., and is approximately proportional to the square root of the press. Below 500°, the gas-free metal is indifferent towards hydrogen. The saturation of the metal at the lower temp. is more quickly attained if the tantalum be first charged at a higher temp. W. Muthmann and co-workers observed that powdered tantalum in a stream of hydrogen takes up at 1000°, 1.0–1.5 per cent. in 2 hrs.; 2.1 per cent. in 12 hrs.; and at 1200°, the product corresponds with TaH_{12.5}. The black, pulverulent hydride has similar chemical properties to those of columbium hydride.

§ 5. The Lower Tantalum Oxides

R. Hermann¹ melted a mixture of potassium heptafluotantalate and potassium under a layer of fused sodium chloride in a well-closed iron crucible. The cold product is washed with water, and repeatedly boiled with potash-lye. The residual **tantalum dioxide**, Ta₂O₂, is readily removed from the admixed tantalum by levigation, and dried over sulphuric acid. There is a doubt about the chemical individuality of the product. The black powder has a sp. gr. 7.35; it burns like tinder when heated in air, forming the pentoxide; it dissolves in hydrofluoric acid with the evolution of hydrogen. K. Friederich and L. Sittig doubted the individuality of the dioxide Ta₂O₄. There are considerable doubts about *tantalum trioxide*, Ta₂O₃, which R. Hermann thought was present in the columbites, which when separated appears as the pentoxide, thus, according to W. K. van Haagen and E. F. Smith, the pentafluoride is produced when hydrogen fluoride is passed over a tantalate at a white-heat. K. Friederich gave 100 ohms per sq. mm. for the electrical resistance of the trioxide; but K. Friederich and L. Sittig doubted the chemical individuality of the trioxide.

According to O. Brunck, the film of oxide formed on a tantalum anode in the electrolysis of metal salt soln. is probably **tantalum tetroxide**, Ta₂O₄. J. J. Berzelius and J. G. Gahn obtained what was probably this oxide, in an impure state, by heating tantalum pentoxide for an hour in a closed carbon crucible;

W. von Bolton, by electrically heating to 1700° rods of tantalum pentoxide embedded in carbon; and E. F. Smith and P. Maas, by heating the pentoxide mixed with five parts by weight of magnesium, and treating the product with dil. hydrochloric acid to remove magnesium and magnesia, there remained a blue, dark grey, dark brown, or black mass, which, when rubbed in a mortar, does not give a metallic lustre. W. von Bolton said that it scratches glass, and is a good electrical conductor—J. J. Berzelius and J. G. Gahn said that it is a non-conductor and when heated in oxygen forms the pentoxide. It gives no carbon dioxide when fused with potassium nitrate; it forms a tantalate when fused with potassium hydroxide; and it is not attacked by acids, or by aqua regia.

§ 6. Tantalum Pentoxide and Tantallic Acid

According to J. J. Berzelius¹ powdered tantalum begins to glow when heated below redness in air, forming **tantalum pentoxide**, Ta_2O_5 ; and H. Moissan said that the metal begins to burn in dry oxygen below 600° . W. Muthmann and co-workers said that when the powdered metal is rapidly heated to redness in oxygen, it becomes incandescent, and the pentoxide is formed; the oxidation of the metal begins below redness but is not completed at that temp. The calcination of the hydroxide—*vide infra*—or one of the lower oxides (*q.v.*) furnishes the pentoxide. W. K. van Haagen obtained the pentoxide by roasting the sulphide, or treating it with nitric acid; by treating the pentafluoride or a fluotantalate with conc. sulphuric acid, washing with boiling water and calcining; hydrolyzing the pentachloride or pentabromide with water and calcining; or by treating these substances with oxidizing agents. The preparation of the pentoxide from the tantaliferous minerals has been described in connection with columbium. O. Ruff and F. Thomas said that tantalum pentoxide is best purified by converting it into potassium fluotantalate or sodium tantalate and treating the product repeatedly with conc. sulphuric acid.

According to W. Muthmann and co-workers, tantalum pentoxide is a white powder which remains white when hot, but then has a faint yellow tinge; if titanium oxide be present, the colour of the cold oxide may be yellow and when hot, orange. M. Delafontaine said that the yellow colour of H. Rose's product was due to the presence of some columbium pentoxide. H. Rose, and G. Tammann said that if the oxide be strongly heated it becomes crystalline; and H. Rose said that the oxide obtained from fused potassium hydrosulphate is a microcrystalline powder after it has been calcined with ammonium carbonate. J. J. Ebelmen found that prismatic **crystals** are produced by strongly heating the oxide with boric oxide; and E. Mallard obtained colourless, rhombic needles by heating it with microcosmic salt in a porcelain oven; the axial ratios were $a:b:c=0.8288:1:0.8239$. P. J. Holmquist prepared rhombic plates appearing like hexagonal plates owing to twinning, by heating the pentoxide with boric oxide in a porcelain oven. Observations on the crystals were also made by A. E. Nordenskjöld and J. J. Chydenius. According to H. Rose, the product obtained by calcining tantallic acid, precipitated from tantalum pentachloride by water, is amorphous, and has a **specific gravity** 7.28; that obtained from tantallic acid which has been slowly formed by exposure to a moist atm., is crystalline and has a sp. gr. 7.284; that obtained by fusion with

potassium hydrosulphate and calcination with ammonium carbonate is crystalline and has a sp. gr. 7.055-7.066, and after heating 45 mins. at a white-heat, it has a sp. gr. 7.986. After heating in a porcelain oven, at about 1600°, the sp. gr. is 8.257. Hence, the sp. gr. of the product depends on its mode of formation, or on the temp. at which it has been heated. W. K. van Haagen's product had a sp. gr. 7.58 when obtained by calcining the product from the hydrolysis of the pentabromide. J. C. G. de Marignac's product from fused potassium hydrosulphate had a sp. gr. 7.6; and that obtained by calcining the product of the action of sulphuric acid on ammonium fluotantalate, 8.01. F. W. Hinrichsen and N. Sahlbom gave 7.53 for the sp. gr.; W. Muthmann and co-workers, 7.5108-7.5867 at 20°; H. St. C. Deville and L. Troost, 7.35; C. W. Balke, 7.91-8.62; and P. J. Holmquist gave 7.7775 for the crystals obtained by calcination with boric oxide. D. Balareff, and C. del Fresno studied the mol. vol. O. Hahn and K. E. Pütter found that tantic acid is not volatile, and the loss observed when commercial tantic acid is heated, is due to the alkali which it contains. For the **flame luminescence**, *vide* columbium pentoxide. A. Karl said that the oxide is triboluminescent.

E. Tiede and E. Birnbräuer said that the pentoxide does not vaporize, and does not melt at 1650°. J. J. Berzelius observed the **calorescence** of the heated oxide, and J. Böhm showed by X-radiograms that the effect is due to the passage from an amorphous to the crystalline state. W. Muthmann found the **heat of formation** to be 837.9 cal., or 30.8 Cals. per gram-equivalent. J. E. Moose and S. W. Parr gave 1375 cal. per gram. H. Rose said that the **electrical conductivity** of the pentoxide is nil; but this statement does not apply to the heated oxide. K. Freiderich gave ∞ ohms per sq. mm. for the electrical resistance of the pentoxide. G. von Hevesy showed that the **electrode potential** Ta : Ta₂O₅ against the normal calomel electrode is 0.003 to 0.007 volt. S. Berkman and H. Zocher gave -0.07×10^{-6} for the **magnetic susceptibility**.

H. Rose said that tantalum pentoxide remains white after it has been heated to redness in **hydrogen**. H. von Wartenberg and co-workers did not reduce tantalum pentoxide by hydrogen at 2500° and 5 atm. press. E. F. Smith and P. Maas observed that the heated pentoxide is not attacked by **chlorine** unless it be mixed with carbon; similar remarks apply to the action of **bromine**. According to H. Rose, and W. K. van Haagen, **iodine** does not react with the pentoxide in a sealed tube at 280°; nor does the vapour react with a heated mixture of the pentoxide and carbon. Unlike columbium pentoxide, tantalum pentoxide is not attacked when strongly heated in **hydrogen chloride**, or in **hydrogen bromide**. W. K. van Haagen and E. F. Smith found that **hydrogen fluoride** converts the tantalum into volatile fluoride. J. J. Berzelius said that the pentoxide is insoluble in **acids**—**hydrochloric acid** and **hydrofluoric acid**—but M. E. Pennington found it soluble in conc. hydrofluoric acid. Although H. Rose stated that the pentoxide can be completely volatilized by heating it to redness with admixed **ammonium fluoride**. O. Ruff and E. Schiller said that no tantalum fluoride is formed, and no tantalum is lost by volatilization. In the absence of carbon, E. F. Smith and P. Maas found that the red-hot pentoxide is not affected by the vapour of **sulphur**; J. J. Berzelius noted that only a trace of sulphide is formed when **hydrogen sulphide** is heated in a current of hydrogen sulphide; H. Biltz and C. Kirchner agreed with this statement, and added that the pentoxide at 720° is coloured superficially grey by hydrogen sulphide. E. F. Smith observed that the **sulphur monochloride** dissolves tantalum oxide when the mixture is heated. J. J. Berzelius said that the pentoxide is not soluble in conc. **sulphuric acid**; and M. E. Pennington found that it is not coloured by **hyposulphurous acid**. H. Rose, and A. Joly observed that when the pentoxide is heated in **ammonia** gas, the nitride is formed. J. J. Berzelius said that the pentoxide is insoluble in nitric acid. M. E. Pennington observed that in a sealed tube at 180°-245°, **phosphorus pentachloride** converts the pentoxide into the pentachloride. J. J. Berzelius and J. G. Gahn found that **carbon** at a white-heat converts the pentoxide into tantalum and its tetroxide. H. Moissan observed the

formation of a carbide—*vide supra*—when the pentoxide is reduced at a high temp. by carbon. R. E. Slade and G. I. Higson found the equilibrium press. of the oxide mixed with carbon to be less than 0.1 mm. at 1270°. M. Delafontaine and E. C. Linebarger showed that the heated pentoxide is attacked by the vapour of **carbon tetrachloride**, and P. Cambouliès added that if air be excluded the formation of tantalum pentachloride begins at 250°. O. Ruff and F. Thomas said that tantalum pentoxide is not affected by carbon tetrachloride at 200°–225°. H. Rose observed that **carbon disulphide** reacts with red-hot tantalum pentoxide, forming the disulphide. E. F. Smith and P. Maas observed that a brownish-black mass with about 3.5 per cent. of **magnesium** is produced when the pentoxide is heated with magnesium in a current of hydrogen; they also tested the action of **aluminium**—*vide supra*, tantalum aluminide. According to L. Weiss and M. Landecker, molten **potassium hydroxide** dissolves the pentoxide, forming a mass which is soluble in water—*vide infra* for the action of the **alkali carbonates** and hydroxides. H. Rose also observed that the strongly calcined pentoxide dissolves with difficulty in fused **potassium hydrosulphate**, and a large excess of the latter—say 1 : 10—is required to open up the pentoxide. L. Weiss and M. Landecker opened up the oxide with this reagent, and also with a molten mixture of sodium carbonate and **borax**. H. Rose found that if the pentoxide is not too strongly calcined, it dissolves in molten **ammonium hydrosulphide**. J. A. Hedvall and N. von Zweigbergk studied the action of **barium dioxide** on the pentoxide. J. J. Berzelius and J. G. Gahn observed no reaction when the pentoxide is heated with **mercuric sulphide**. O. Ruff and F. Thomas found that tantalum pentoxide reacts with **columbium pentachloride**, forming tantalum pentachloride and columbium oxychloride.

According to H. Rose, in the hydrolysis of tantalum pentachloride by water, an amorphous precipitate is produced if water be mixed with the pentachloride, and if the pentachloride be exposed to a moist atm., the product is crystalline. It requires a prolonged washing with water to remove the hydrochloric acid; dil. aq. ammonia removes the acid much more quickly. When dried in air, the **tantalum hydroxide** contains over 20 per cent. water, *i.e.* $Ta_2O_5 \cdot 5H_2O$, and when dried at 100°, 6–8 per cent., thus approximating $Ta_2O_5 \cdot H_2O$, or **metatantallic acid**, $HTaO_3$. H. Rose also obtained tantallic acid by treating a soln. of sodium tantalate with sulphur dioxide, and washing the product with cold water—aq. ammonia extracts a little sulphuric acid; by fusing the pentoxide with potassium hydrosulphate, and washing the product with water, then with aq. ammonia to remove sulphates, and finally with water. The peptization of the precipitate during the washing is prevented by using $\frac{1}{2}$ per cent. aq. ammonia, or one per cent. acetic acid.

FIG. 1.—Vapour Pressures of Hydrated Tantalum Pentoxide.

G. Jander and H. Schulz showed that there is a continuous variation in the water content with varying vap. press., Fig. 1; and that the rehydration, and redrying curves resemble those obtained with hydrated silica. The hysteresis cycle at 100° is smaller than that at 0°, and is displaced more towards the side of lower

According to O. Hauser and A. Lewite, **colloidal tantalum hydroxide** is produced by melting a mixture of tantalum pentoxide and sodium hydroxide in a silver crucible; dissolving the cold mass in water; and dialyzing the soln. with parchment for about 10 days. The properties of the sol resemble those of the sol of columbium hydroxide, but unlike the latter, the hydroxide is completely precipitated by carbon dioxide; it is also precipitated by ammonium oxalate.

water content. The hydrated oxide remained white and chalky under all conditions.

Tantalum hydroxide appears as a white, amorphous, or crystalline powder. At a dull red-heat the water is expelled, and, as noted by J. J. Berzelius, a calorescence occurs, which H. Rose found to be less marked if the precipitate has been previously washed with hot water. L. Weiss and M. Landecker found that the hydroxide is less soluble in dil. acids than is the case with columbium hydroxide; H. Rose said that at the moment of formation it is soluble in different acids, the presence of **hydrogen dioxide** accelerates the speed of dissolution of the hydroxide in acids, aq. ammonia, in soln. of ammonium chloride, or sodium hydroxide, carbonate, hydrosulphate. The dissolved hydroxide is reprecipitated when the hydrogen dioxide is decomposed. A. A. Noyes found that tantalic acid is only slightly soluble in hydrogen dioxide; W. B. Giles, that it is completely dissolved when suspended in dil. sulphuric or hydrochloric acid and hydrogen dioxide; and O. Hahn and H. Gille, that when precipitated from hot soln. it is almost insoluble, but from cold soln. it is slightly soluble in acid hydrogen dioxide. As indicated by H. Rose, and C. W. Balke, it forms a clear soln. with **hydrofluoric acid**; R. F. Weinland and L. Storz found that only a trace dissolves in cold, highly conc. **hydrochloric acid**, so that dil. soln. of tantalates become opalescent when treated with the conc. acid; with dil. acids there is no precipitate on warming. The hydroxide is insoluble in **perchloric acid**. A little hydroxide dissolves in boiling, conc. sulphuric acid, and the soln. becomes turbid when poured into water, but the tantalum is not completely precipitated by the dilution even if the soln. be boiled. The action of **nitric acid** is like that of hydrochloric acid, but the solvent action is smaller. The hydroxide is insoluble in **phosphoric acid**; and also in **phosphorus, and hypophosphorus acids**. The freshly precipitated hydroxide is soluble in **oxalic and tartaric acids**; and, added J. J. Berzelius and J. G. Gahn, and R. D. Hall, in a soln. of **potassium oxalate**. Tantalic acid readily dissolves in **hydrofluosilicic acid**. Freshly precipitated tantalum hydroxide is easily soluble in aq. soln. of **alkali hydroxide**, and it dissolves in a soln. of **sodium carbonate** less easily than does columbium hydroxide; it is insoluble in soln. of sodium hydrocarbonate, or of ammonium carbonate. The solubility is perceptibly smaller if the hydroxide has been allowed to stand more than a few hours, at room temp., without being covered with an aq. soln., and disappears after warming the hydroxide to about 110°. H. Rose said that tantalic acid does not displace carbon dioxide from a soln. of the alkali carbonates. H. Lange found that a soln. of **ammonium salicylate** gives a flesh-coloured precipitate insoluble in hot water, and in a soln. of ammonium salicylate—*vide* Tables II and III, 9, 55, 4. E. Wedekind and H. Fischer found that colloidal tantalic acid does not adsorb prussian blue.

§ 7. The Tantalates

Tantallic acid forms a series of salts called **tantalates**. Many of these occur in nature; others can be prepared by first making an alkali tantalate, and treating a soln. of that salt with soln. of other metal salts. Some tantalates are also obtained by fusing the metal chloride with tantalum pentoxide. The alkali tantalate $R_2O : Ta_2O_5 = 4 : 3$ seems to be the most stable form. G. Jander and H. Schulz¹ said that this ratio should be 7 : 5 not 4 : 3. The tantalates, insoluble in water, can be dissolved in molten ammonium or potassium hydroxide, and, if they have not been calcined, in boiling sulphuric acid. The oxygen of the tantalates can be partially replaced by chlorine or bromine—*vide infra*, the oxyhalides.

According to H. Rose, tantalum hydroxide precipitated by ammonia from acid soln. always contains ammonia; and when a soln. of sodium tantalate is treated with ammonium chloride, and the precipitate washed with cold water, **ammonium triterohexatantalate**, $(NH_4)_2Ta_6O_{16} \cdot 5H_2O$, or $(NH_4)_2O \cdot 3Ta_2O_5 \cdot 5H_2O$, is formed. In the presence of alkali hydroxide or carbonate, the precipitation is slow in the cold, rapid when heated. The salt is a little soluble in water.

A. Joly observed that at a red-heat calcined tantalum pentoxide or tantallic acid unites with molten sodium hydroxide with incandescence; the resulting sodium tantalate does not dissolve in the matrix. H. Rose, and J. J. Berzelius observed that with potassium hydroxide the product is completely soluble in water. According to A. Joly, when the pentoxide is fused with sodium carbonate, carbon dioxide is expelled less readily than from potassium carbonate; and less readily, again, than is the case with columbium pentoxide. The amount of carbon dioxide expelled depends on the duration and temp. of fusion. In one case, A. Joly obtained a loss corresponding with the formation of *sodium orthotantalate*, $3Na_2O \cdot Ta_2O_5$, or Na_3TaO_4 ; and H. Rose, using potassium carbonate, obtained a loss eq. to the formation of $10K_2O \cdot 3Ta_2O_5$. F. Oesten reported an acid tantalate— Na_2O , 2.23 per cent.; Ta_2O_5 , 97.77 per cent.—or more probably a mixture of tantalates to be formed by melting tantallic acid with potassium hydrocarbonate (1 : 5), washing and drying the resulting sulphatotantallic acid; treating the product with cold soda-lye for a long time, and washing the mass with hot water. H. Rose also noticed that a tantalate with a low proportion of soda is produced by washing the metatantalate with water for a long time. All this means that the alkali tantalates are slowly hydrolyzed by water. A. Lottemoser obtained acid sodium tantalate by the method he used for the acid columbate.

H. Rose reported **sodium hexerotetradecatantalate**, $2Na_2O_5 \cdot 7Ta_2O_5 \cdot 10H_2O$, to be precipitated when carbon dioxide is passed into an aq. soln. of the orthohexatantalate, and drying the pale yellow product at 100°; hydrogen sulphide gives a similar result, but acts more quickly than carbon dioxide. W. R. Schoeller and C. Jahn studied the sodium tantalates. By repeatedly heating potassium orthohexatantalate with ammonium

chloride, and extracting the mass with water, H. Rose obtained what he regarded as **potassium penterotetradecatantalate**, $3K_5O \cdot 7Ta_2O_5$. By treating with carbon dioxide an aq. soln. of tantalum pentoxide in molten potassium hydroxide, H. Rose obtained **potassium deuterotetratantalate**, $K_2O \cdot 2Ta_2O_5 \cdot 3H_2O$, or **potassium deuterohexatantalate**, $2K_2O \cdot 3Ta_2O_5 \cdot 6H_2O$.

According to J. C. G. de Marignac, when sodium orthohexatantalate is heated alone, or, according to H. Rose, when it is heated with ammonium carbonate, and extracted with water, **sodium metatantalate**, $NaTaO_3 \cdot 2H_2O$, is formed. H. Rose obtained the same salt by mixing an aq. soln. of the orthohexatantalate with its own vol. of alcohol, washing the precipitate with conc. alcohol; calcining; and washing the product with a very dil. soln. of ammonium carbonate—if water alone be used, peptization occurs. The metatantalate is also produced by fusing tantic acid with twice its weight of sodium carbonate, extracting the excess of alkali with water; washing the residue with hot water; drying; and calcining the product. J. C. G. de Marignac reported **potassium metatantalate**, $KTaO_3$, to be formed by calcining the orthohexatantalate alone, or, according to H. Rose, with ammonium carbonate, and extracting the product with water. C. W. Balke and E. F. Smith obtained **cæsium orthododecatantalate**, $7Cs_2O \cdot 6Ta_2O_5 \cdot 38H_2O$, as a precipitate, by treating an aq. soln. of the orthohexatantalate with alcohol.

According to H. Rose, when tantalum pentoxide is fused with twice its weight of sodium hydroxide, and the excess of alkali removed from the cold mass with cold water, the residue containing all the tantalum dissolves in hot water, and on cooling this soln., small crystals of **sodium orthohexatantalate**, $4Na_2O \cdot 3Ta_2O_5 \cdot 25H_2O$, or $Na_3Ta_6O_{19} \cdot 25H_2O$, are formed. J. C. G. de Marignac also prepared this salt, but said that some acid salt is present, and added that the salt of a high degree of purity was produced by H. Rose by extracting the cold, fused mass, just indicated, with water; washing the residue until the wash-water no longer colours litmus blue, or silver nitrate brown; and drying in vacuo over sulphuric acid. The salt was analyzed by H. Rose, J. C. G. de Marignac, and R. Hermann. G. Jander and H. Schulz said that the ratio should be 7:5 not 4:3; and they represented the salts as derivatives of **hydropentatantalic acid**, $H_7[Ta(TaO_4)_4]$. The acid is probably a complex one in which the oxygen atoms of orthotantalic acid have been replaced by the TaO_4 -groups. The sodium salt is **sodium pentatantalate**, $7Na_2O \cdot 5Ta_2O_5 \cdot 24H_2O$, or $K_7[Ta(TaO_4)_4] \cdot 24H_2O$. They prepared the alkali tantalates by fusing the hydroxides with tantalum pentoxide and crystallizing from water; tantic acid is precipitated from the aq. soln. by acids, including carbonic acid, but the precipitate is soluble in excess of strong acid. Different proportions of potassium hydroxide and tantalum pentoxide always lead to the same crystalline tantalate; from highly conc. soln. crystals of different form were obtained, but these were readily converted into the first form, and probably differed only in water of crystallization. By the addition of sodium hydroxide to aq. potassium tantalate two sodium salts, also differing only in water of crystallization, were obtained, namely, the *heptahydrate*, $Na_7[Ta(TaO_4)_4] \cdot 11H_2O$, and the *icosihydrate* $Na_7[Ta(TaO_4)_4] \cdot 20H_2O$. The **lithium pentatantalate**, $Li_7[Ta(TaO_4)_4] \cdot 20H_2O$, was similarly prepared. According to J. C. G. de Marignac, the colourless, hexagonal plates of the sodium salt have the axial ratio $a : c = 1 : 1.0167$. H. Rose found that all but 2–4 per cent. of water is expelled at 100° , and E. Wedekind and W. Maas suggested that 4 or 5 mols. of water are constitutional. H. Rose suggested that when the salt is so heated, it is resolved into an acid salt and sodium hydroxide. The decomposition proceeds more readily in the presence of ammonium chloride, and the acid salt acts on the sodium carbonate and carbon dioxide is expelled. The moist product colours red litmus blue. If the salt be rapidly heated, the water is all expelled, and if heated with ammonium carbonate, it gives only a small loss in weight, and the moist product does not colour red litmus blue. E. Wedekind and W. Maas prepared a salt similar to that obtained by H. Rose. They added that 10.5 mols. of water are lost at 105° – 110° ; another mol. at 190° ; and the last mol.

requires a much higher temp. They therefore represented it by the formula $\text{Na}_4\text{HTa}_3\text{O}_{10}\cdot 12\cdot 32\text{H}_2\text{O}$, or, probably,

When dehydrated, the hexatantalate is formed. H. Rose found that 100 parts of water at $13\cdot 5^\circ$ dissolve 0.203 part of salt, and when boiling, 0.617 part. The salt suffers some hydrolysis, and colours red litmus blue. J. C. G. de Marignac found that when this compound is boiled with water a more acid salt is formed. H. Rose added that sulphur dioxide precipitates all the tantalum from the aq. soln., while hydrogen sulphide or carbon dioxide precipitated acid salts—*vide supra*. The salt is only sparingly soluble in alcohol; and when alcohol is added to the aq. soln., a precipitate is formed, which, when dried at 100° , has the composition: $\text{Na}_2\text{O}\cdot\text{Ta}_2\text{O}_5\cdot 2\text{H}_2\text{O}$. W. E. von John observed that the salt is insoluble in soda-lye. J. C. G. de Marignac, and H. Rose prepared **potassium orthohexatantalate**, $4\text{K}_2\text{O}\cdot 3\text{Ta}_2\text{O}_5\cdot 16\text{H}_2\text{O}$, from a molten mixture of tantalum pentoxide with potassium hydroxide or carbonate. Analyses of the salt were made by H. Rose, J. C. G. de Marignac, and R. Hermann. As indicated above, G. Jander and H. Schulz's analysis agrees with **potassium pentatantalate**, $\text{K}_7[\text{Ta}(\text{TaO}_4)_4]\cdot 12\text{H}_2\text{O}$, and its mode of preparation is there indicated. G. Jander and H. Schulz said that in the alkali tantalates the ratio $\text{M}_2\text{O} : \text{Ta}_2\text{O}_5$ is 7 : 5, and the basicity of the tantalic acid is at least six, according to the variation of the conductivity with the dilution. Potassium tantalate may be represented as $\text{K}_7[\text{Ta}(\text{TaO}_4)_4]$ with a mol. wt. of about 1440. 0.5*N*-soln. of potassium tantalate had a diffusion coeff. of 0.24 when dissolved in 0.1*N*-KOH, or 0.1*N*- KNO_3 , and a high value in water. The mol. wt. of potassium tantalate is therefore 1750. The crystals of the salt were found by J. C. G. de Marignac to be monoclinic prisms with the axial ratios $a : b : c = 0\cdot 7164 : 1 : 0\cdot 5475$, and $\beta = 95^\circ 19'$. The salt is partially decomposed at 100° into an acid salt and potassium hydroxide; and after the salt has been heated to redness, water abstracts one-fourth of the alkali and leaves the metatantalate behind. A similar result was obtained by H. Rose after heating the salt with ammonium carbonate. J. C. G. de Marignac found that the salt can be dissolved in warm water without decomposition, and it recrystallizes from the soln. on evaporation in vacuo—but not so readily as before. If the aq. soln. be boiled or evaporated in air, hydrolysis occurs, and an acidic salt is precipitated. H. Rose found that the longer the salt is boiled with water the greater the proportion of alkali extracted. W. E. von John said that the salt is soluble in potash-lye. According to J. Morgenroth and F. Rosenthal, potassium hexatantalate does not kill the trypanosomes of mice, though it seems to inhibit their transmission from one form to another, and it also inhibits the poisonous action of antimony compounds on the trypanosomes of mice, and on mice themselves. C. W. Balke and E. F. Smith obtained colourless, transparent, monoclinic pyramids of **rubidium orthohexatantalate**, $\text{Rb}_4\text{Ta}_6\text{O}_{19}\cdot 14\text{H}_2\text{O}$, by fusing a mixture of 15 grms. of tantalum pentoxide and 25 grms. of rubidium carbonate, extracting the cold mass with a little warm water, and cooling. The axial ratios are $a : b : c = 0\cdot 8822 : 1 : 1\cdot 0510$, and $\beta = 95^\circ 58'$; and the crystals are isomorphous with the corresponding columbium salt. Monoclinic prisms of **cæsium orthohexatantalate**, $\text{Cs}_4\text{Ta}_6\text{O}_{19}\cdot 14\text{H}_2\text{O}$, were produced in a similar way; they are isomorphous with the corresponding columbate. H. Rose treated a soln. of sodium orthohexatantalate with silver nitrate and obtained a white precipitate, which has a yellow tinge when dry; it is **silver orthohexatantalate**, $\text{Ag}_4\text{Ta}_6\text{O}_{19}$. At 100° , it becomes dark yellow, brown, and finally black; and loses 2.1–2.3 per cent. in weight when calcined. Hydrogen reduces the silver but not the tantalum pentoxide at a red-heat; ammonia dissolves the salt completely; and it is decomposed by nitric acid with the separation of tantalum pentoxide.

J. J. Berzelius² obtained a calcium tantalate of an undetermined composition

by digesting tantalic acid with calcium chloride. The mineral **pyrrhite** was described in connection with the rare earths—5. 38, 3. R. Brauns represented his incomplete analysis as if the mineral were **calcium orthotantalate**, $\text{Ca}_3(\text{TaO}_4)_2$, associated with some acid radicle. It forms yellowish- or brownish-red, isotropic octahedra; the sp. gr. is 4.13; the hardness, 5.5; and the index of refraction, over 1.83. The mineral **microlite** has been discussed from the point of view of the rare earths—5. 38, 3. W. C. Brögger, and E. S. Simpson reported a number of additional analyses; and the idealized formula is $\text{Ca}_2\text{Ta}_2\text{O}_7$, **calcium pyrotantalate**, where some tantalum is replaced by columbium. R. J. Strutt found that it also contained helium—0.5 c.c. per gram—radium— 3.7×10^{-8} per cent. RaBr_2 —thorium, and uranium—1.89 per cent. U_3O_8 . The radioactivity is 0.101 when that of U_3O_8 is unity; and the ratio $\text{Ra} : \text{U} = 1.96$. E. S. Larsen gave 1.930 for the index of refraction. A. Joly obtained the pyro-salt by heating the meta-salt with calcium chloride for 7–8 hrs.; and P. J. Holmquist, by melting a mixture of calcium chloride and tantalum pentoxide. The prismatic and acicular crystals belong to the cubic system, and they may have an abnormal double refraction. A. Joly said rhombic—if so, the salt is dimorphous. The crystals of microlite are cubic, and the sp. gr. is 5.17–5.65, and the hardness 6. The mineral **pyrochlore** has been discussed from the point of view of the rare earths—5. 38, 3—and, according to T. L. Walker and A. L. Parsons, it is also to be regarded as an impure **calcium metacolumbate**, $\text{Ca}(\text{CbO}_3)_2$, with part of the columbium replaced by tantalum—*vide infra*, fluotantalates. A. Joly synthesized calcium metatantalate by heating the pentoxide with calcium chloride for some hours at a bright red-heat, and obtained a crystalline mass of this salt on the bottom and walls of the crucible. The brown octahedral crystals of pyrochlore belong to the cubic system; the sp. gr. is 4.2–4.4; the hardness 5.0–5.5; and the m.p., 1340° —*vide* 5. 38, 3. E. S. Larsen gave $\mu = 1.96$ for the index of refraction; and S. Kreutz found for light of wave-length $\lambda \times 10^{-5}$ cm., the following values for the indices of refraction, μ :

λ	7.00	6.86	6.56 (C)	5.89 (D)	5.18 (b)	4.86 (F)
μ { I	1.9818	1.9831	1.9866	1.9995	2.0234	2.0363
II	2.0076	—	—	2.0248	—	2.0363

The differences between I and II are due to non-homogeneity of the material, a subject discussed by O. Mügge, and V. M. Goldschmidt as an example of what they call the *Isotropisierung* of mineral—a result of changes induced by the presence or proximity of radioactive minerals. The related minerals, *magnacite*, *loranscite*, and *wiikite*, were discussed in connection with the rare earths—5. 38, 3. E. S. Larsen gave 2.0 for the index of refraction of wiikite. T. L. Walker and A. L. Parsons described an amber-yellow or dark chocolate, massive mineral from Hybla, Ontario, which they called **ellsworthite**—after H. V. Ellsworth. The mineral is isotropic; the sp. gr. 3.608 (yellow), and 3.758 (brown); and the hardness, 4. The analyses are represented by the idealized formula of *dihydrated* calcium metacolumbate, $\text{Ca}(\text{CbCO}_3)_2 \cdot 2\text{H}_2\text{O}$, but considerable $(\text{UO}_2)''$, Fe'' , and traces of other elements replace Ca; much Ti; some Ta, Si, U'''' , and traces of other elements replace the Cb; and a little fluorine is present. E. T. Wherry applied the at. vol. replacement theory—*cf.* 6. 40, 44. J. J. Berzelius and J. G. Gahn obtained what was probably **barium orthohexatantalate**, $\text{Ba}_4\text{Ta}_6\text{O}_{19} \cdot 6\text{H}_2\text{O}$, by the action of a soln. of barium chloride on tantalic acid; and H. Rose, by the action of barium chloride on soln. of sodium orthohexatantalate, washing the precipitate with cold water, and drying at 100° . The salt is strongly calorescent when calcined. It is but slightly soluble in cold water. It is decomposed by fusion with potassium hydroxide.

H. Rose added magnesium sulphate to a soln. of sodium orthohexatantalate, and obtained a flocculent precipitate which became crystalline on standing for half an hour. It was washed with cold water and dried at 100° , when the analysis corresponded with **magnesium orthohexatantalate**, $\text{Mg}_4\text{Ta}_6\text{O}_{19} \cdot 9\text{H}_2\text{O}$. It showed no calorescence when heated. A. Joly made hexagonal crystals of what he regarded

as $4\text{MgO}\cdot\text{Ta}_2\text{O}_5$ —**magnesium dioxyorthotantalate**—by a method employed for the corresponding dioxyorthocolumbate. H. Rose prepared **mercurous ortho-hexatantalate**, $4\text{Hg}_2\cdot 0.3\text{Ta}_2\text{O}_5\cdot 5\text{H}_2\text{O}$, by adding a freshly prepared soln. of mercurous nitrate to one of sodium orthohexatantalate, washing with cold water, and drying at 100° . The yellow mass becomes brown at 100° ; it is decomposed by warm nitric acid. Mercuric nitrate gives a white precipitate of presumably **mercuric orthohexatantalate**, $4\text{HgO}\cdot 3\text{Ta}_2\text{O}_5\cdot n\text{H}_2\text{O}$, under similar conditions; mercuric chloride gives a precipitate very slowly, and if alkali hydroxide is present some mercury oxychloride is also formed.

J. J. Berzelius precipitated **aluminium tantalate** by adding an aluminium salt to a soln. of alkali tantalate. T. Barth³ obtained **yttrium tantalate**, YTaO_4 , as in the case of the columbate (*q.v.*). The X-radiogram shows that unit tetragonal cell has $a=7.75$ A.; $c=11.41$ A.; and $a:c=1:1.47$. The mineral **koppite** has been described from the point of view of the rare earths—5. 38, 3. It is a **calcium rare earth columbatotantalate**, but an approximate formula has not been derived from the analysis. It was examined by J. Soellner, and H. V. Ellsworth and J. F. Walker. E. S. Larsen gave 2.12–2.18 for the index of refraction, and the radioactivity was examined by G. Meyer. *Vide* 5. 38, 3, for **polycrase**, and **euxenite**. The neotantalite of 5. 38, 3, is a related mineral for which E. S. Larsen gave the refractive index 1.96. E. F. Smith said that complex **tantalotungstates** are obtained from soln. of tungstates and tantalates.

The mineral **hatchettolite** has been discussed from the point of view of the rare earths—5. 38, 3—and T. L. Walker and A. L. Parsons⁴ regard it as an impure **monohydrated calcium uranium metacolumbate**, $\text{R}(\text{CbO}_3)_2\cdot\text{H}_2\text{O}$. Varieties from Hybla, Ontario, had 9.27–13.58 per cent. of uranium, and 0.42–0.52 per cent. ThO_2 , and a radioactivity of 0.830–1.125 (euxenite unity).

The mineral **fergusonite** was previously described from the point of view of the rare earths—5. 38, 3. It is a **calcium rare earth orthocolumbatotantalate**, $(\text{Y}, \text{Er}, \text{Ce})(\text{Cb}, \text{Ta})\text{O}_4\cdot\text{Ca}_2\text{Cb}_2\text{O}_7$, or $12\text{R}(\text{Cb}, \text{Ta})\text{O}_4\cdot(\text{Th}, \text{U})(\text{Si}, \text{Sn})\text{O}_4$. Additional analyses were made by A. Lacroix,⁵ and Y. Shibata and K. Kimura. J. Schetelig, and A. Lacroix studied the radioactivity of the mineral; and E. S. Larsen gave 2.19 for the index of refraction. The related mineral **risorite**—5. 38, 3—is a complex uranium orthotantalate with admixed metatitanate; and it has also been described by J. Schetelig. E. S. Larsen gave 2.04–2.08 for the index of refraction. The related **rutherfordite**, and **kochelite** were also described 5. 38, 3. Similar remarks apply to **sippylite**, for which E. S. Larsen gave the refractive index 2.05–2.07. The mineral **euxenite** has been described from the point of view of the rare earths—5. 38, 3. T. L. Walker and A. L. Parsons⁶ represented the idealized mineral by the formula $\text{RO}\cdot 2\text{Cb}_2\text{O}_5\cdot\text{H}_2\text{O}$, **calcium yttrium uranyl deutero-tetracolumbate**—or, according to G. Tschermak, since the ratio $\text{Cb}_2\text{O}_5 : \text{TiO}_2$ is near 1 : 2, **calcium yttrium uranyl titanocolumbate**, $\text{Y}_2\text{Ti}_4\text{O}_{11}\cdot 2(\text{Ca}, \text{Fe})(\text{Cb}_2\text{O}_5)\cdot(\text{UO}_2)\text{Cb}_2\text{O}_5$. Part of the columbium is replaced by tantalum. Additional analyses were reported by R. C. Sabot, W. G. Miller and C. W. Knight, J. Schetelig, and A. Betim. P. Tschirwinsky and N. A. Orloff found 0.1 per cent. of scandium, L. F. Nilson, 0.003–0.01 per cent. A. Betim found some gallium. The crystals were examined by R. C. Sabot, H. Ungemach, J. Schetelig, and A. Betim. The radioactivity was examined by T. L. Walker and A. L. Parsons, A. Lacroix, and A. Betim; the spark spectrum by P. Tschirwinsky and N. A. Orloff, A. Betim, and L. F. Nilson. C. Grossmann examined the products of the weathering of euxenite. The related mineral **polycrase** was described in connection with the rare earths—5. 38, 3; and a similar remark applies to **blomstrandine**, and **priorite**. E. S. Larsen gave 1.70 for the index of refraction of polycrase. A. Lacroix examined the radioactivity of priorite, and J. Schetelig analyzed the mineral.

G. A. Goyder⁷ described a mineral occurring in the stanniferous sands of Greenbushes, West Australia. He called it **stibiotantalite** in allusion to its composition. Analyses by G. A. Goyder, and S. L. Penfield and W. E. Ford agree

with the formula **antimonyl metacolumbatotantalate**, $(\text{SbO})(\text{Ta,Cb})\text{O}_3$. The dark brown, hemimorphic crystals are rhombic with the axial ratios $a:b:c = 0.7995:1:0.8448$. There is polysynthetic twinning about the (100)-plane; the prismatic crystals may show vertical striations like columbite. The hemimorphism is in the direction of the a -axis. The (100)-cleavage is perfect; the (010)-cleavage is indistinct. The optical character is positive. The optical axial angle for Li-, Na-, and Tl-light is respectively $2V=73^\circ 40'$, $75^\circ 5'$, and $77^\circ 38'$ for material of sp. gr. 6.818, and $2V=70^\circ 0'$, $73^\circ 35'$, and $77^\circ 50'$ for material of sp. gr. 6.299. The sp. gr. of the mineral with 36.35 per cent. Ta_2O_5 and 18.98 per cent. Cb_2O_5 is 6.72; and with 11.16 per cent. Ta_2O_5 and 39.14 per cent. Cb_2O_5 , 5.98. The index of refraction and birefringence are:

Ray	Sp. gr. 6.818				Sp. gr. 6.299			
	α	β	γ	$\gamma-\alpha$	α	β	γ	$\gamma-\alpha$
Li .	2.3470	2.3750	2.4275	0.0805	2.3686	2.3876	2.4280	0.0594
Na .	2.3742	2.4039	2.4568	0.0826	2.3977	2.4190	2.4588	0.0691
Tl .	2.4014	2.4342	2.3876	0.0862	2.4261	2.4508	2.4903	0.0642

A. Joly⁸ prepared **manganese metatantalate**, $\text{Mn}(\text{TaO}_3)_2$, as in the case of the corresponding metacolumbate; and likewise, he prepared **ferrous metatantalate**, $\text{Fe}(\text{TaO}_3)_2$. The mineral **aeschynite** described in connection with the rare earths—5. 38, 3—is a calcium rare earth iron metacolumbate associated with thorium titanate, $2\text{R}(\text{CbO}_3)_3 \cdot 2\text{ThTiO}_4 \cdot \text{TiO}_2$. E. S. Larsen gave 2.205–2.26 for the index of refraction. F. Zambonini⁹ described a mineral from Craveggia, Piedmont, which he called **strüverite**—after G. Strüver. For a micaceous mineral of the same name, *vide* **sismondite**, 6. 40, 41. Analyses were reported by F. Zambonini and G. T. Prior, A. Lacroix, S. J. Johnstone, and R. C. Wells. The results agree with the assumption that the mineral is a **ferrous columbatotantalate**, associated with the titania— $\text{Fe}\{(\text{Ta,Cb})\text{O}_3\}_2 \cdot 4$ to 6TiO_2 . According to F. Zambonini, the iron-black crystals are tetragonal with the axial ratio $a:c=1:0.6456$. The sp. gr. is 5.54–5.56; and the hardness 6.0–6.5. This mineral may be taken to represent the tantalum-end of a series with **ilmenorutile** at the columbium end. Analyses of ilmenorutile were reported by W. C. Brögger, N. von Kokscharoff, and F. Zambonini and G. T. Prior. The sp. gr. is 5.074–5.133. A. Lacroix described a mineral from Ampangabe, Madagascar, which was called **ampangabeite**—5. 38, 3. Its composition corresponds with **uranium iron metacolumbate**, $\text{R}(\text{CbO}_3)_2 \cdot 3\text{H}_2\text{O}$, where RO represents oxides of uranium, thorium, rare earths, calcium, and iron. Analyses were reported by G. Tschernick,¹⁰ A. Lacroix, L. Duparc and co-workers, R. C. Sabot. The colour ranges from a pale yellowish-brown (sp. gr. 3.3484) to a brownish-black (sp. gr. 4.6441). The prismatic crystals are optically isotropic; the hardness is about 4. The crystals were examined by R. C. Sabot, A. Lacroix, and H. Ungemach. E. S. Larsen gave 2.13 for the index of refraction. The radioactivity is very marked. The mineral is soluble in hydrochloric acid.

The mineral **betafite** from Madagascar has been described from the point of view of the rare earths—5. 38, 3—a similar remark applies to **samiresite**. Both minerals were analyzed by A. Lacroix.¹¹ T. L. Walker and A. L. Parsons represented betafite by the formula $2\text{RO} \cdot 3\text{Cb}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, **calcium uranium iron deutero-hexacolumbate**. There is 16.2–18.3 per cent. of titania present, so that the mineral may be **calcium uranium iron titanocolumbate**. Up to about one per cent. of tantalum is present. The crystals were examined by H. Ungemach. E. S. Larsen gave 1.915–1.925 for the index of refraction of the isotropic crystals. A. Lacroix found the mineral to be radioactive. The sp. gr. is 4.17. T. L. Walker and A. L. Parsons represented samiresite by the formula $\text{RO} \cdot 2\text{Cb}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, **uranium iron deuterotetracolumbate**—about 6.70–8.76 per cent. of titania is present, and 3.7 per cent. of tantalum. A. Lacroix found the mineral to be radioactive. E. S. Larsen gave 1.92–1.96 for the index of refraction. The mineral **blomstrandite** was described in connection with the rare earths—5. 38, 3. T. L. Walker and

A. L. Parsons represented the idealized mineral by $\text{RO} \cdot 2\text{Cb}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, *i.e.* **uranium rare earth deuterotetracolumbate**. It is more likely to be a **uranium rare earth titanocolumbate**, since, from the analysis reported by A. Lacroix, 10.8 per cent. of titania is present.

W. J. Vernadsky¹² described a radioactive mineral from Ulunti, Lake Baikal, Siberia. It is related to betafite, and was called **mendeléeffite**—after D. I. Mendeléeff. The incomplete analysis corresponds with a **calcium uranium titanocolumbate**. The greyish-black cubic crystals appear in the form of rhombic dodecahedra with small octahedral faces. The sp. gr. is 4.46–4.76; and the hardness 4.5. The mineral **samarskite** has been described from the point of view of the rare earths—5. 38, 3. It is considered to be **calcium ferrous uranyl rare earth pyrocolumbatotantalate**, $(\text{Fe}, \text{Ca}, \text{UO}_2)\text{R}(\text{Cb}, \text{Ta})_6\text{O}_2$; additional analyses were given by Y. Shibata and K. Kimura, A. Lacroix, and L. M. Dennis and J. Papish. The rhombic crystals were described by Y. Shibata and K. Kimura, who gave for the axial ratios $a : b : c = 0.5456 : 1 : 0.5178$. E. S. Larsen gave 2.10–2.25 for the index of refraction. A. Lacroix examined the radioactivity of the mineral. The variety **yttrotantalite** has a refractive index, 2.15; and **hjelmitite** has $\alpha = 2.30$, and $\gamma = 2.40$ for Li-light or $\omega = 2.30$ and $\epsilon = 2.40$. **Nohlite**, **loranscite**, **rogersite**, **plumbonibobite**, **annerödite**, and **ishikawaite** were previously described—5. 38, 3.

The history of C. Hatchett's¹³ ore of columbium and A. G. Ekeberg's **tantalite** has been discussed in connection with columbium. R. Jameson called the ore of columbium, **columbite**; F. S. Beudant, **baierine**—from Bavaria; W. Haidinger, **niobite**; T. Thomson, **torrelite**—after J. Torrey; A. Breithaupt, **greenlandite**; C. U. Shepard, **hermannotite**—after R. Hermann; R. Hermann, **ferroilmenite**; F. von Kobell, **dianite**; A. E. Nordenskjöld, **mangantantalite**; A. Arzruni, **manganotantalite**; A. Lacroix, **manganocolumbite**; G. Rose, **mengite**; T. Thomson, **ferrotantalite**; J. F. L. Hausmann, **siderotantalite**; W. Haidinger, **ildeforsite**; and A. Breithaupt, **Harttantalierz**. The **paracolumbite** of C. U. Shepard was afterwards shown by him to be menaccanite. Numerous analyses have been reported.¹⁴ A selection of recent analyses is shown in Table I.

TABLE I.—ANALYSES OF COLUMBITES AND TANTALITES.

In Table I, No. 1 is from Ishikawa, Japan, by Y. Shibata and K. Kimura; Nos. 2 and 3, from Old Mike Mica Mine, Custer Co., by W. P. Headden; No. 4, from Hybla, Ontario, by T. L. Walker and A. L. Parsons; No. 5, from Ampangabe, Madagascar, by A. Lacroix; No. 6, as No. 3; No. 7, from Ambatofotsikely, Madagascar, by L. Duparc and co-workers,

and R. C. Sabot; No. 8, from Orust, Sweden, by G. K. Almström; No. 9, from Lyndoch, Ontario, by T. L. Walker and A. L. Parsons; No. 10, from S. Norway, by W. C. Brögger; Nos. 11 to 20 are by W. P. Headden—No. 11 is from Harney City, Pennington Co.; No. 12 is from Tin Mountain, Custer Co.; Nos. 13 to 20 are from Old Mike Mica Mine, Custer Co.; No. 20 is a tapiolite. No. 4 had 1.25 per cent. zirconia. SnO_2 is inclusive of WO_3 . No. 3 had 2.02 per cent. U_3O_8 . Rare earths, lime, silica, and water have been omitted.

When the proportion of columbium oxide predominates the mineral can be called *columbite*, and with tantalum oxide predominant, *tantalite*. In these analyses, the manganese oxide ranges from 1.14 to 19.86 per cent.; ferrous oxide, from 1.17 to 16.67 per cent.; columbium pentoxide, from 2.50 to 77.97 per cent.; and the tantalum pentoxide from 0.83 to 84.44 per cent. The compositions of the idealized manganese and ferrous tantalates and columbates are:

	FeO	MnO	Cb_2O_5	Ta_2O_5
$\text{Fe}(\text{CbO}_3)_2$	21.20	—	78.80	—
$\text{Fe}(\text{TaO}_3)_2$	13.96	—	—	86.04
$\text{Mn}(\text{CbO}_3)_2$	—	20.99	79.01	—
$\text{Mn}(\text{TaO}_3)_2$	—	13.80	—	86.20

Columbite and tantalite are therefore to be regarded as solid soln. of these four compounds, and they are symbolized $(\text{Ge}, \text{Mn})\{(\text{Cb}, \text{Ta})\text{O}_3\}_2$; ranging by insensible gradations from nearly pure **manganese ferrous metacolumbate** (columbite) to nearly pure **manganese ferrous metatantalate** (tantalite). In the manganocolumbite from Branchville, the iron is nearly all replaced by manganese, and also in the manganotantalite from Sanaska. H. V. Ellsworth described a mineral *toddite* from Sudbury, Canada. It appears to be a variety of columbite with some iron and manganese replaced by uranium. The amount of stannic oxide in these minerals ranges up to 5.38 per cent.; silica, up to 0.4 per cent.; titania, up to 6.20 per cent.; zirconia, up to 1.25 per cent.; tungstic oxide, up to 0.76 per cent.; uranic oxide, up to 2.02 per cent.; rare earths, up to 2.12 per cent.; alumina, up to 1.65 per cent.; magnesia, up to 0.42 per cent.; and calcium oxide, up to 0.56 per cent. T. L. Walker and A. L. Parsons found 3.34 per cent. of thoria in columbite from Hybla, Ontario—analysis No. 4, Table I. E. S. Simpson reported 0.02 per cent. nickel oxide in a sample from West Australia; A. E. Nordenskjöld, 0.14 per cent. of cupric oxide in a sample from Kimito, and A. Stelzner, 0.34 per cent. in a sample from Sierra de Cordoba, Argentine; C. W. Blomstrand, 0.12 per cent. of lead oxide in a sample from Greenland; and K. von Chrustschoff, 0.02 per cent. germania in a sample from Finland. G. Eberhard observed that special lines of scandium could be obtained with a columbite from South Dakota; Moss, Norway; and Orijarvi, Finland. W. Ramsay and co-workers found much hydrogen and no helium in a North American columbite; helium was obtained from other samples, and also from tantalite from Fahlun. H. Erdmann obtained over 0.0007 per cent. of ammonia from columbite from Fahlun.

Columbite and tantalite may be iron-black, greyish-black, brownish-black, or reddish-brown in **colour**, and they often show an iridescent surface. The minerals may occur massive; more usually in short prisms, or thin tablets. A. Schrauf¹⁵ in his *Monographie des Columbites* investigated the habit of the crystals; and observations on this subject were also made by H. W. Foote, and W. C. Brögger. The rhombic **crystals** were found by E. S. Dana to have the axial ratios $a : b : c = 0.82850 : 1 : 0.88976$; A. Schrauf obtained 0.40744 : 1 : 0.33467 with a different orientation of the crystals. W. C. Brögger found that as the proportion of tantalum in columbite increases, the *a*-axis increases, and the *c*-axis decreases; O. J. Lee and E. T. Wherry's observations are in agreement with this. The proportion of tantalum oxide increases with the sp. gr. as indicated below, and taking observations by A. des Cloizeaux, N. von Kokscharoff, E. S. Dana, J. D. Dana, and A. Arzruni in order,

Sp. gr.	5.39	5.37	5.65	5.95	7.3
Ta_2O_5	—	—	9.2	29.0	79.8 per cent.
$a : b : c$	0.829 : 1 : 0.878	0.830 : 1 : 0.882	0.829 : 1 : 0.890	0.829 : 1 : 0.878	0.830 : 1 : 0.873

G. Rose observed the **twinning** of the crystals. Contact twins about the (021)-plane are common; they are often heart-shaped, and show delicate, feathery striations on the (100)-face. Twinning about the (530)-, (051)-, or the (023)-plane is rare. There are also penetration twins. The **cleavage** on the (100)-face is distinct; that on the (010)-face is less clear. The **corrosion figures** of some columbites obtained by L. Michel, and O. Mügge are in agreement with the rhombic bipyramidal symmetry. Some variations show a feeble **pleochroism**, others a strong one. A manganotantalite from Amelia, Virginia, showed α to be pale red; β , blood-red; and γ , deep blood-red. The optic axial angle $2V$ is large; the optical character positive; and E. S. Larsen found for columbite from Canon City, Colorado, the **refractive index** 2.45 with the **birefringence** strong; a ferro-columbite from Haddon, Connecticut, also had a strong birefringence, and the index of refraction for Li-light, 2.40; a tantalite from Dakota had the indices of refraction $\alpha=2.26$, $\beta=2.32$, and $\gamma=2.43$; while a manganotantalite from Amelia, Virginia, had $\alpha=2.19$, $\beta=2.25$, and $\gamma=2.34$. Observations on the crystals were also made by W. P. Blake, O. B. Böggild, E. M. Bonshtedt, H. L. Bowman, A. Breithaupt, H. J. Brooke, A. des Cloizeaux, L. Duparc and co-workers, E. S. von Federoff, F. A. Genth, E. Hussak, P. Jereméeff, K. Jimbo, A. Lacroix, C. C. von Leonhard, H. C. Lewis, G. vom Rath, A. F. Rogers, R. C. Sabot, W. T. Schaller, C. U. Shepard, J. F. Smith, G. H. Tipper, H. Ungemach, T. Wada, and C. H. Warren. According to A. Breithaupt, G. Rose, and P. Jereméeff, columbite and wolframite are isomorphous; while P. Groth and A. Arzruni said that although the angles of the rhombic minerals are similar, the minerals are not isomorphous. W. C. Brögger showed that the minerals of the columbite and æschynite groups are related; and he discussed the relation between columbite, tantalite, brookite, rutile, tapiolite, wolframite, hübnerite, etc. G. T. Prior gave the following comparison of the topic parameters:

	Mol. vol.	χ	ψ	ω
Brookite, $Ti_3Ti_3O_{12}$	117.54	4.450	5.288	4.994
Tantalite, $Fe_2Ta_4O_{12}$	124.64	4.581	5.530	4.920
Hübnerite, $Mn_3W_3O_{12}$	126.40	4.647	5.599	4.859

Measurements of the **specific gravity** were recorded along with most of the analyses, and the results range from 5.15 to 8.2. The results depend on the proportion Cb : Ta. This is brought out by J. C. G. de Marignac's Table II; and

TABLE II.—RELATION BETWEEN THE SPECIFIC GRAVITY AND COMPOSITION OF COLUMBITES AND TANTALITES.

Origin of columbite.	Sp. gr.	Per cent. Ta_2O_5
Arksat fiord, Greenland	5.36	3.3
Acworth, New Hampshire	5.65	15.8
La Vilate, Limoges	5.70	13.8
Bodenmais	5.74	13.4
Haddam, Connecticut	5.85	(10.0)
Bodenmais	5.92	27.1
Haddam	6.05	30.4
Bodenmais	6.06	35.4
Haddam	6.13	31.5
Sweden (tantalite)	7.03	65.6

H. W. Foote and R. W. Langley proposed estimating the proportions of columbium and tantalum pentoxides from the sp. gr. of the mixture. The **hardness** is about 6. G. Spezia was able to **melt** columbite in the coal-gas flame fed by a blast of warm air. The **optical properties** were examined by A. Schrauf, O. Mügge, and J. Königsberger. T. W. Case said that the poor electrical conductivity of columbite is not appreciably affected by light. A. L. Fletcher found a sample from Arendal,

Norway, melted but did not flow freely at 1350°; a sample from Warwick, New Jersey, softened but did flow at 1500°, and another sample from Moss, Norway, melted at 1310° but did not flow freely; and at 1400°, the powder aggregated into drops. E. T. Wherry found columbite and tantalite to be good radio-detectors. F. Pisani showed that columbite from Bavaria had no effect on a photographic plate exposed for 24 hrs. D. Mawson and T. H. Laby found that columbite from Barrier Ranges, N.S.W., is not **radioactive**; but E. T. Wherry observed that a Pennsylvanian columbite was radioactive, and V. M. Goldschmidt obtained a similar result with a Norwegian columbite. T. L. Walker and A. L. Parsons found that columbite from Hybla, Ontario, had a radioactivity of 0.830 when that of euxenite was unity. A. Schrauf said that columbite has no **electrical conductivity**, and is **paramagnetic**. According to C. F. Plattner, tantalite and columbite dissolve slowly in molten borax, and in molten microcosmic salt. The minerals resist attack by the ordinary acids; they are decomposed by fused potassium hydro-sulphate. J. L. Smith opened up the mineral with hydrofluoric acid; W. K. van Haagen and E. F. Smith, with hydrogen fluoride at a white-heat; and E. F. Smith, with sulphur monochloride—*vide supra*, the extraction of columbium and tantalum pentoxides.

According to E. Mäkinen,¹⁶ the tantalite occurring in the pegmatite of Tammela and Kimito, Finland, was described by P. A. Gadd, in 1767, as a stanniferous garnet containing iron and manganese. In 1802, A. G. Ekeberg discovered the presence of tantalum, and named the mineral *tantalite*. The mineral was also analyzed by M. H. Klaproth in 1810, and L. N. Vauquelin in 1819. The mineral was also described by J. F. L. Hausmann, and by J. J. Berzelius. Some differences in colour, sp. gr., and composition were emphasized by N. Nordenskjöld, H. J. Holmberg, and A. E. Nordenskjöld. There was (i) the tantalite from Skogböle—*Tantalite mit zimtbraunen Pulver*; (ii) the tantalite from Kimito—*kimitotantalite*; (iii) the tantalite from Tammela or tammelatanalite—or the tantalite of A. G. Ekeberg. Some tantalite from Skogböle, in Kimito, was found by J. J. Berzelius to be stanniferous, and some was free from tin; and A. E. Nordenskjöld called the stanniferous tantalite from Skogböle *ixionite* or *ixiolite*—from Ixion, an associate of the mythological Tantalus. It is identical with the *cassiterotantalite* of J. F. L. Hausmann, and the *kimitotantalite* of N. Nordenskjöld. The other variety comparatively free from tin was called **skogbölite**, and it is what is ordinarily called tantalite; it is the tantalite of A. G. Ekeberg; the tantalite with the cinnamon-brown powder of A. G. Ekeberg, and J. J. Berzelius; and the *tammelatanalite* of N. Nordenskjöld. Both skogbölite and ixiolite furnish rhombic crystals. In 1861, A. E. Arppe described a tantalite from Sukula which had a composition very like that from Tammela, but furnishes tetragonal crystals, and A. E. Nordenskjöld called it **tapiolite**—after one of the gods of Finnish mythology. V. M. Goldschmidt discussed the X-radiogram of tapiolite. Analyses of skogbölite were reported by R. Hermann, and H. Rose; and of ixiolite by A. E. Nordenskjöld, R. Hermann, and C. F. Rammelsberg. P. Groth and K. Mieleitner regard ixiolite as a stanniferous columbite or tantalite; but the 13 per cent. SnO₂ reported by A. E. Nordenskjöld was not confirmed by C. F. Rammelsberg. E. S. Simpson described ixiolite from West Australia; and W. J. Vernadsky and A. E. Fersman, from the Ilmen mountains, Russia. Like columbite, therefore, ixiolite is ferrous manganous metacolumbatotantalate, $(\text{Fe}, \text{Mn})\{(\text{Ta}, \text{Cb})\text{O}_3\}_2$. Skogbölite may be represented by the same formula, although, according to the analysis of A. E. Nordenskjöld, it approximates closely to ferrous metantalate, $\text{Fe}(\text{TaO}_3)_2$. Analyses of tapiolite were reported by C. F. Rammelsberg, A. E. Nordenskjöld, W. C. Brögger, W. P. Headen, and E. S. Simpson. It too can be regarded as a ferrous manganous metacolumbatotantalate, approximating to ferrous metacolumbatotantalate. This remark applies also to the mineral **mossite** obtained in black crystals by W. C. Brögger from Moss, Norway. According to W. T. Schaller, mossite is only

a columbiferous tapiolite. V. M. Goldschmidt discussed the X-radiogram. E. S. Simpson described *Manganomossite* from Yinnietarra, Western Australia; it appears to be a *mangano-columbite*. N. Nordenskjöld reported *adelpholite*—5. 38, 3—as a tetragonal hydrated ferrous manganese columbatotantalate from Finland. It was also described by E. Mäkinen, and A. E. Nordenskjöld. The sp. gr. is 3.8; and the hardness, 3.5–4.5. P. Groth and K. Mieleitner regard it as a product of the weathering of columbite.

Skogbölite furnishes black, opaque, rhombic crystals which, according to N. Nordenskjöld, have the axial ratios $a : b : c = 0.81696 : 1 : 0.65106$. The cleavage of the prismatic crystals is indistinct. The sp. gr. is 7.8–8.0; and the hardness, 6.0–6.5. The greyish-black or steel-grey, rhombic crystals of ixiolite, have, according to A. E. Nordenskjöld, the axial ratios $a : b : c = 0.5508 : 1 : 1.2460$. W. J. Vernadsky and A. E. Fersman gave 0.545 : 1 : 0.201. The crystals are sometimes twinned about the (103)-plane. The sp. gr. is 6.87–7.1; and the hardness, 6.0–6.5. A. E. Nordenskjöld gave for the axial ratio of the black, tetragonal crystals of tapiolite $a : c = 1 : 0.6464$; E. Mäkinen gave 1 : 0.6499; and W. C. Brögger, 1 : 0.65251. The crystals sometimes appear to be monoclinic owing to distortion. The cleavage is not distinct; the sp. gr. is 7.36–7.496; and the hardness, 6. E. S. Larsen found the indices of refraction of tapiolite for Li-light to be $\omega = 2.27$, and $\epsilon = 2.42$; and the pleochroism is strong, ω being pale yellow or reddish-brown, and ϵ almost opaque. The black, prismatic crystals of mossite are tetragonal, and, according to W. C. Brögger, have the axial ratios $a : c = 1 : 0.6438$. Twinning occurs about the (101)-plane, and, in some cases, the twins simulate rhombic forms. There is no cleavage; the sp. gr. is 6.45. The relation between the axial ratios of the three rhombic minerals may be represented :

Columbite, $a : b : c$	Skogbölite, $a : b : c$	Ixiolite, $\frac{3}{2}a : b : \frac{3}{2}c$
0.8285 : 1 : 0.8898	0.8170 : 1 : 0.8681	0.8262 : 1 : 0.8307

P. Groth proposed A. Schrauf's relation for columbate while doubling the a - and c -axes, and gave the ratios $a : b : c = 0.8047 : 1 : 0.7159$ for columbite, and 0.8170 : 0.6511 for skogbölite; but, added E. S. Dana, the similarity is more apparent than real, because nearly all the prominent planes of each mineral are wanting on the other, and the habits are very different. Tantalite itself corresponds closely with the columbite in both habit and angle. E. S. Simpson discussed the relation between the sp. gr. and composition of tapiolite, mossite, strüverite, and ilemenorutile; and the subject was examined by T. Crook and S. J. Johnstone, and W. T. Schaller. W. C. Brögger suggested that ferrous metatantalate is dimorphous, forming tetragonal tapiolite, and rhombic tantalite.

J. A. Hedvall prepared **cobalt metatantalate**, $\text{Co}(\text{TaO}_3)_2$, by heating mixtures of cobalt oxide and tantalum pentoxide.

§ 8. Pertantallic Acid and the Pertantalates

According to P. G. Melikoff and L. Pissarjewsky,¹ when potassium metapertantalate is treated with dil. sulphuric acid, a white precipitate of **metapertantallic acid**, HTaO₄.nH₂O, is formed. It is more stable than percolumbic acid (*q.v.*), but its properties are otherwise similar. The constitution of HTaO₄.nH₂O is supposed to be:

P. G. Melikoff and L. Pissarjewsky evaporated to dryness on a water-bath a soln. of 1.5 grms. of sodium orthohexatantalate in 30 c.c. of 2 per cent. hydrogen dioxide; dissolved the residue in water; added a little hydrogen dioxide to the filtrate, and then an equal vol. of alcohol. The white amorphous precipitate appeared to be **sodium metapertantalate**—the analysis corresponded with NaTaO₄.NaTaO₅.13H₂O.

By treating sodium orthohexatantalate with the 2 per cent. hydrogen dioxide, and sodium hydroxide; mixing the filtrate with an excess of hydrogen dioxide; and, after cooling with ice-water, adding an equal vol. of alcohol, a precipitate **sodium orthopertantalate**, Na₃TaO₈.H₂O, is deposited. This was dried on a porous tile. The *monohydrate* is a white, amorphous powder sparingly soluble in water. When the aq. soln. is warmed, oxygen is given off; dil. sulphuric acid furnishes hydrogen dioxide, and the conc. acid, ozonized oxygen. C. W. Balke prepared the *tetradecahydrate*. G. Böhm modified E. H. Riesenfeld's formula for the perchromates to adopt it to P. G. Melikoff and L. Pissarjewsky's formula for the pertantalates:

Pertantalate.

Perchromate.

they found that potassium or sodium pertantalate, percolumbate, and perchromate are isomorphous. The subject was discussed by G. Böhm. P. G. Melikoff and L. Pissarjewsky prepared **potassium orthopertantalate**, K_3TaO_8 , by fusing tantalum pentoxide and potassium hydroxide (1 : 3) in a silver crucible, dissolving the cold cake in a little water, and proceeding with hydrogen dioxide as in the case of the sodium salt. The resulting *hemihydrate* has analogous properties. C. W. Balke obtained the anhydrous salt, and said that it is isomorphous with the corresponding perchromate. C. W. Balke and E. F. Smith added an excess of hydrogen dioxide to a soln. of 4 grms. of rubidium orthohexatantalate and 10 grms. of rubidium carbonate. The crystalline powder of **rubidium orthopertantalate**, Rb_3TaO_8 , was washed with alcohol and ether, and dried in air. It is less soluble than the corresponding percolumbate. In a similar manner, **caesium orthopertantalate**, Cs_3TaO_8 , was prepared. P. G. Melikoff and L. Pissarjewsky prepared what was probably **calcium, strontium, and barium orthopertantalates** by the method employed for the potassium salt; and when the potassium salt was treated with calcium chloride, **potassium calcium orthopertantalate**, $KCaTaO_8 \cdot 4\frac{1}{2}H_2O$, was formed in rhombic crystals; and C. W. Balke and E. F. Smith prepared acicular crystals of **sodium calcium orthopertantalate**, $NaCaTaO_8 \cdot 4\frac{1}{2}H_2O$, and also **sodium magnesium orthopertantalate**, $NaMgTaO_8 \cdot 8H_2O$; **potassium magnesium orthopertantalate**, $KMgTaO_8 \cdot 7H_2O$; and **rubidium magnesium orthopertantalate**, $RbMgTaO_8 \cdot 8H_2O$, in a similar manner. The needle-like crystals of the potassium salt are more soluble in water than the corresponding calcium salt.

§ 9. Tantalum Fluorides, Fluotantalates, and Oxyfluotantalates

H. Moissan¹ observed that warm tantalum powder burns in fluorine, forming fumes which condense on a cold surface. As previously indicated, J. J. Berzelius, H. Rose, W. von Bolton, and H. Kuessner obtained a soln. of the metal in hydrofluoric acid, and when evaporated, H. Rose said that tantalum fluoride is formed; while G. von Hevesy and R. E. Slade obtained the oxyfluoride. O. Hahn and K. E. Pütter found that soln. of tantalic acid in hydrofluoric acid are hydrolyzed during evaporation and the residue shows no volatility when heated. Dil. hydrofluoric acid was found by O. Ruff and E. Schiller slowly to dissolve tantalum pentoxide if the mixture is heated in a platinum flask provided with a reflex condenser. H. Rose said that no tantalum is volatilized if sulphuric acid be present, but in its absence, some tantalum is volatilized when the soln. is evaporated, and if tantalum pentoxide be heated with ammonium fluoride, it can be completely volatilized. These statements were contradicted by J. C. G. de Marignac, and by O. Ruff and E. Schiller. J. J. Berzelius, H. Rose, J. C. G. de Marignac, and O. Ruff and E. Schiller noticed that hydrofluoric acid forms a clear soln. with tantalum hydroxide, and if the soln. be evaporated alone, hydrolysis occurs, and an oxyfluoride is deposited; but if ammonium or alkali fluorides be present, complex fluotantalates are formed.

O. Ruff and E. Schiller prepared **tantalum pentafluoride**, TaF_5 , by the action of fluorine on tantalum containing about 3 per cent. of aluminium, as in the case of the corresponding columbium salt. The product was purified by distillation in vacuo at 90°–100°. The same salt was prepared by the action of dried hydrogen fluoride on tantalum pentachloride, cooled by a freezing mixture of ice and salt. When the evolution of hydrogen chloride has ceased, the hydrofluoric acid is distilled

off, and then the tantalum pentafluoride. Moisture must be excluded. O. Hahn and K. E. Pütter obtained the pentafluoride by heating barium fluotantalate. According to O. Ruff and E. Schiller, the tantalum pentafluoride product appears in tetragonal prisms with a strong double refraction. The **specific gravity** is 4.981 at 15°, and 4.744 at 19.5°. The **melting point** is 96.8°; and the **boiling point** at 760 mm. is 229.2°–229.5°. The **vapour pressure**, p mm., is :

	183°	198.5°	204°	212.5°	227.5°	228.9°
d	368.2	447.3	485.8	540.8	720.7	753.7

R. Lorenz and W. Herz discussed certain regularities in the relation $(T_2 - T_1)/(\theta_2 - \theta_1) = \text{constant}$, where T_1 and T_2 represent absolute temp. corresponding with vap. press., p_1 and p_2 , and θ_1 and θ_2 are the b.p. at the same two press.

The boiling pentafluoride is not affected by **hydrogen** or by **oxygen**. It is very hygroscopic in **air**, and it dissolves with a hissing noise in **water**. The boiling aq. soln. is clear, but on evaporation, an oxyfluoride is formed, which, when roasted in air, passes quantitatively into the pentoxide. G. von Hevesy and R. E. Slade found that it is less readily hydrolyzed by water than is the case with tantalum pentachloride, or the pentafluoride of columbium or vanadium. O. Ruff and E. Schiller showed that the boiling pentafluoride does not react with **bromine** or **iodine**. The pentafluoride dissolves in **hydrochloric acid** with the evolution of a little heat. The boiling pentafluoride does not react with **sulphur**; cold **sulphuric acid** dissolves only a little pentafluoride, but more dissolves in the hot acid, and hydrofluoric acid escapes; **sulphuryl chloride** dissolves the fluoride without any visible sign of chemical action, and when the soln. is evaporated, the residue contains sulphur, chlorine, fluorine, and tantalum. Cold **sulphur monochloride** dissolves only a little sulphofluoride; there is a vigorous reaction with **sulphur dichloride** in the cold—gas is evolved, and the liquid becomes warm; but no reaction occurs with **hydrogen sulphide**. The boiling pentafluoride is not attacked by **nitrogen**; **ammonium hydroxide**, or a soln. of **ammonium sulphide**, precipitates tantalum hydroxide. Cold fuming **nitric acid** does not dissolve the pentafluoride so readily as water—the soln. remains clear when diluted and when warmed, but on standing in a warm place, it slowly deposits a crystalline oxyfluoride. Boiling tantalum pentafluoride has no action on **phosphorus**; with **phosphorus trichloride**, in the cold, a jelly is formed, and when warmed, phosphorus trifluoride is produced; and with **phosphoryl chloride**, in the cold, there is a vigorous reaction, gas is evolved, and a colourless soln. is produced which, on evaporation, furnishes an oxychloride. The boiling pentafluoride does not act on **arsenic** or **antimony**. Cold **arsenic trichloride** dissolves very little when cold; and when warmed, a white jelly is formed; **antimony pentachloride** behaves similarly. The cold pentafluoride is indifferent towards many organic substances—*e.g.* **toluene**, and **paraffin**, but when heated, a brown decomposition product is formed; warm **carbon disulphide** dissolves a little pentafluoride; **carbon tetrachloride** gives a brown mass; **tetrachloroethane** gives a black mass; **chloroform** dissolves a little, without visible change; **acetic acid**, and **acetic anhydride**, readily dissolve the pentafluoride without visible reaction; absolute **alcohol** readily dissolves it with the generation of some heat; and **ether** reacts vigorously with the evolution of hydrogen fluoride. C. W. Balke obtained complex salts with **methylamine**, **ethylamine**, **triethylamine**, **pyridine**, and **quinoline fluorides**. O. Ruff and E. Schiller observed that at a high temp. **glass** decomposes the pentafluoride, forming tantalum pentoxide and silicon tetrafluoride. Very little pentafluoride is dissolved by **silicon tetrachloride**; while **titanium tetrachloride** reacts vigorously; and **tin tetrachloride** dissolves very little in the cold, but more is dissolved by the hot liquid, and crystals are deposited when the soln. is cooled.

The vapour of the pentafluoride does not attack **copper**, **silver**, **gold**, **magnesium**, **zinc**, **aluminium**, and **iron**; while a black powder is formed with **tin**, and **lead**. A cold conc. soln. of **alkali hydroxide** or **carbonate** reacts vigorously with the pentafluoride, forming an insoluble oxyfluoride; while cold,

dil. soln. precipitate a hydroxyfluoride, and if hot, the hydroxide. Molten **potassium hydrofluoride** forms a pentafluotantalate; hot **potassium fluoride** reacts very slowly with the pentafluoride; while **potassium chloride** reacts neither when cold nor when hot. C. W. Balke obtained a series of complex salts with the alkali fluorides.

H. O. Hahn and K. E. Pütter observed that with hydrofluoric acid, tantalum pentafluoride forms **hydrohexafluotantallic acid**, $\text{HTaF}_6 \cdot 6\text{H}_2\text{O}$. C. W. Balke prepared **lithium hexafluotantalate**, $\text{LiTaF}_6 \cdot 2\text{H}_2\text{O}$, by evaporating on a water-bath a soln. of 10 grms. of lithium carbonate in one of 40 grms. of tantalum pentoxide in conc. hydrofluoric acid, and cooling the soln. The colourless, monoclinic prisms can be crystallized from conc. hydrofluoric acid. The axial ratios of the crystals are $a : b : c = 0.5703 : 1 : 1.6235$, and $\beta = 92^\circ 14'$. The crystals gradually lose their lustre in air. The mother-liquor left after the preparation of sodium heptafluotantalate furnish cubic crystals of **sodium hexafluotantalate**, NaTaF_6 . C. W. Balke obtained crystals of **cesium hexafluotantalate**, CsTaF_6 , by mixing soln. of the constituent fluorides, and recrystallizing from hydrofluoric acid; and by recrystallizing the heptafluotantalate, 2 or 3 times from hydrofluoric acid. The trigonal crystals have the axial ratio $a : c = 1 : 1.0467$, and $\alpha = 95^\circ 40'$. By recrystallizing rubidium heptafluotantalate a number of times, C. W. Balke and E. F. Smith obtained impure **rubidium tridecafluoditantalate**, $\text{Rb}_3\text{Ta}_2\text{F}_{13}$, as a granular mass.

J. J. Berzelius prepared crystals of **ammonium heptafluotantalate**, $(\text{NH}_4)_2\text{TaF}_7$, by adding ammonia to a hydrofluoric acid soln. of tantallic acid, until a precipitate begins to form, and evaporating the clear liquid. J. C. G. de Marignac said that the tetragonal plates have the axial ratio $a : c = 1 : 1.804$. The crystals do not lose appreciably in weight when heated to 100° for an hour, but when kept for a longer time at that temp. they do lose weight. They decrepitate when rapidly heated. At a higher temp., J. C. G. de Marignac observed that ammonium fluoride is sublimed. J. C. G. de Marignac found the salt to be freely soluble in water, from which soln. it can be crystallized unchanged. If the aq. soln. be warmed for a short time, hydrolysis occurs, and tantalum hydroxide separates out. O. Hahn and K. E. Pütter also prepared the ammonium heptafluotantalate, $\text{NH}_4\text{F}_2 \cdot \text{TaF}_5$, or NH_4TaF_7 . If a soln. of sodium fluoride and a large excess of tantalum pentafluoride be evaporated and cooled, J. C. G. de Marignac, and C. W. Balke found that six-sided plates of **sodium heptafluotantalate**, $\text{Na}_2\text{TaF}_7 \cdot \text{H}_2\text{O}$, are formed. According to J. C. G. de Marignac, the rhombic bipyramids have the axial ratios $a : b : c = 0.838 : 1 : 1.274$. The crystals lose water at 100° , and suffer no other change at 130° – 150° . When recrystallized from water, the octofluotantalate is formed. J. J. Berzelius prepared **potassium hydroheptafluotantalate**, KHTaF_7 , by cooling a boiling sat. soln. of hydrofluoric acid and potassium tantalate; and from a hydrofluoric acid soln. of the heptafluotantalate. J. C. G. de Marignac said that this salt is not formed by recrystallizing a soln. of the heptafluotantalate and tantalum pentafluoride. J. J. Berzelius prepared **potassium heptafluotantalate**, K_2TaF_7 , by adding potassium hydroxide to a hot soln. of tantallic acid in hydrofluoric acid until a precipitate begins to form, and cooling the clear soln. W. H. Chapin obtained the salt from a soln. of potassium carbonate in a hydrofluoric soln. of tantalum hydroxide; H. Rose, by treating tantalum hydroxide with a soln. of potassium fluoride; and A. Piccini, from a soln. of potassium oxyfluotantalate in conc. hydrofluoric acid. Analyses were made by J. J. Berzelius, H. Rose, J. C. G. de Marignac, R. Hermann, A. Piccini, and W. H. Chapin. The small, acicular crystals were found by J. C. G. de Marignac to belong to the rhombic system, to have the axial ratios $a : b : c = 0.6682 : 1 : 0.4610$; and to be isomorphous with the corresponding heptafluocolumbate. H. Behrens said the birefringence is feeble. H. Topsøe gave 4.56 for the sp. gr., and F. W. Hinrichsen and N. Sahlbom, 5.24 . The salt decrepitates when heated and then fuses, and, according to H. Rose, and J. C. G. de Marignac, it does not decompose in a platinum crucible at a white-heat,

nor even when heated with potassium pyrosulphate. J. J. Berzelius said that the salt is freely soluble in cold water, more so in hot water; and C. W. Balke and E. F. Smith said that it is less soluble if hydrofluoric acid be present, and, added J. C. G. de Marignac, 100 parts of water containing a little hydrofluoric acid dissolve 0.5 part of salt at 15°; and with rather more hydrofluoric acid, 0.675–0.67 part. O. Ruff and E. Schiller represented the equilibrium conditions at 18°–18.5°, and at 85°–90° by

18°	Conc.	{ TaF ₅	0.25	0.10	0.09	1.33	1.24	5.35	0.036
		{ KF	0.12	4.79	6.73	0.56	0.52	2.25	21.93
		{ HF	0.029	0.074	0.015	4.47	4.2	24.3	10.44
	Solid phase	$K_wTa_2O_7F_2 + K_2TaF_7$				K_2TaF_7			
85°	Conc.	{ TaF ₅	2.18	0.9	5.73	6.00	10.91	1.18	
		{ KF	1.69	5.27	2.41	2.52	4.59	22.42	
		{ HF	0.85	1.17	4.47	4.2	24.3	10.44	
	Solid phase	$K_wTa_2O_7F_2 + K_2TaF_7$				K_2TaF_7			

The solubility is thus shown to increase with an increasing conc. of hydrofluoric acid, and afterwards to decrease. H. Rose said that the aq. soln. reddens blue-litmus; and decomposes when boiled with the separation of an oxyfluoride as shown by J. J. Berzelius, J. C. G. de Marignac, C. W. Balke and E. F. Smith, and M. E. Pennington. The electrolysis of the soln. was found by M. E. Pennington to yield some tantalum hydroxide. C. W. Balke, M. E. Pennington, and E. F. Smith prepared **rubidium heptafluotantalate**, Rb₂TaF₇, from a soln. of the component salts with a small excess of hydrofluoric acid. It can be recrystallized from water containing a little hydrofluoric acid. The white needles are more soluble than the potassium salt—100 parts of water dissolve 2.5 parts of salt. The aq. soln. is hydrolyzed when boiled. C. W. Balke found **caesium heptafluotantalate**, CsTaF₆, to be also more soluble than the potassium salt. It cannot be recrystallized from water without hydrolysis. J. C. G. de Marignac prepared **copper heptafluotantalate**, CuTaF₆.4H₂O, from a soln. of the component salts by evaporation over sulphuric acid. The blue, rhombic prisms are freely soluble in water; and lose some water and hydrofluoric acid at 100°. O. Hahn and K. E. Pütter prepared **barium fluotantalate**, 3BaF₂.2TaF₅. J. J. Berzelius prepared **calcium fluotantalate** by evaporating a soln. of calcium tantalate in hydrofluoric acid; likewise also **magnesium fluotantalate**. J. C. G. de Marignac also obtained the magnesium salt by evaporating a soln. of the component salts. Similarly with **zinc heptafluotantalate**, ZnTaF₇.7H₂O, which forms deliquescent, rhombic plates. F. Ephraim and L. Heymann obtained **thallium heptafluotantalate**, Tl₂TaF₇, from a soln. of the component salts in hydrofluoric acid. The rectangular plates do not form a clear soln. with water, and when boiled tantalum hydroxide is deposited. It is sparingly soluble in cold, readily soluble in hot hydrofluoric acid. It is decomposed by conc. sulphuric acid.

C. W. Balke obtained **ammonium octofluotantalate**, (NH₄)₃TaF₈, by concentrating a soln. of the component salts with ammonium fluoride in excess. J. C. G. de Marignac prepared **sodium octofluotantalate**, Na₃TaF₈, from a soln. of the orthohexatantalate in dil. hydrofluoric acid; and by crystallization from an aq. soln. of the heptafluotantalate. H. Rose obtained it from a soln. of the component salts, and C. W. Balke from a soln. with NaF : TaF₅ = 4 : 1. The needle-like crystals, according to C. W. Balke, are rhombic, and have the axial ratios $a : b : c = 0.6017 : 1 : 0.2799$. The crystals are stable in air; they fume but do not melt easily when heated in a platinum crucible. H. Rose added that the salt is freely soluble in water and the soln. reddens blue litmus. C. W. Balke found that

100 parts of water at 25° dissolve 4.83 parts of salt. When the aq. soln. is boiled, the oxyfluoride does not separate, but hydrofluoric acid passes off with the steam. The calcined residue blues a soln. of red litmus. M. E. Pennington said that white needles of **caesium icosifluotantalate**, $\text{Cs}_{15}\text{TaF}_{20}$, are formed from a soln. of the component salts. It is sparingly soluble in water, and the aq. soln. is not decomposed on the water-bath. J. D. M. Smith regards this compound as evidence of a co-valency of 20 in tantalum, but N. V. Sidgwick says that the compound may really be $\text{R}_3[\text{TaF}_8]_{12}\text{CsF}$.

J. C. G. de Marignac obtained an amorphous, white tantalum oxyfluoride by evaporating in vacuo a soln. of tantalum hydroxide in hydrofluoric acid. G. von Hevesy and R. E. Slade likewise obtained it by evaporating a soln. of tantalum in hydrofluoric acid. It is almost insoluble in water. The composition varies with the mode of preparation, but **tantalum oxytrifluoride**, TaOF_3 , appears in a number of complex salts. A. Joly obtained **ammonium oxyhexafluotantalate**, $3\text{NH}_4\text{F} \cdot \text{TaOF}_3$, from a hot soln. of tantalum hydroxide in conc., aq. ammonium fluoride. The octahedral crystals are freely soluble in water; and the aq. soln. becomes turbid when heated. If an excess of hydrofluoric acid be present in crystallizing the salt, **ammonium oxyhydroheptafluotantalate**, $3\text{NH}_4\text{F} \cdot \text{TaOF}_3 \cdot \text{HF}$, is formed. A. Joly obtained regular octahedra of **potassium oxyhexafluotantalate**, $3\text{KF} \cdot \text{TaOF}_3$, in a similar way. J. C. G. de Marignac, and C. W. Balke and and E. F. Smith obtained **potassium pentoxytetradecafluotetratantalate**, $4\text{KF} \cdot \text{Ta}_2\text{O}_5 \cdot 2\text{TaF}_5$, by boiling an aq. soln. of potassium heptafluotantalate. G. Krüss and L. F. Nilson represented its composition by $\text{KF} \cdot \text{TaOF}_3$. It is insoluble in boiling water; freely soluble in hydrofluoric acid.

A. Piccini prepared **potassium peroxyptafluotantalate**, $2\text{KF} \cdot \text{TaO}_2\text{F}_3 \cdot \text{H}_2\text{O}$, by cooling a warm soln. of potassium heptafluotantalate in 4 per cent. hydrogen dioxide, feebly acidified with hydrofluoric acid; and C. W. Balke and E. F. Smith, by dissolving the heptafluotantalate in hot, dil., aq. hydrofluoric acid, and mixing the soln. with an equal vol. of 3 per cent. hydrogen dioxide. The tabular crystals can be recrystallized from a hydrofluoric acid soln. of hydrogen dioxide. The salt gives off water at 100°, and oxygen at a higher temp.; it is freely soluble in water. Aq. ammonia does not precipitate tantalum hydroxide, but a precipitate is formed if alcohol be added. It is decomposed by hydrofluoric acid; and the sulphuric acid soln. decomposes potassium permanganate. In a similar way, C. W. Balke and E. F. Smith prepared **rubidium peroxyptafluotantalate**, $2\text{RbF} \cdot \text{TaO}_2\text{F}_3 \cdot \text{H}_2\text{O}$, in tabular crystals.

§ 10. Tantalum Chlorides and Oxychlorides

The normal chloride is tantalum pentachloride, $TaCl_5$. O. Ruff and F. Thomas¹ found that when tantalum pentachloride and aluminium are heated in an evacuated bomb-tube at 300° , complete reduction to tantalum does not occur even when the aluminium is in excess. If rather less than the calculated amount of aluminium be used for **tantalum tetrachloride**, $TaCl_4$, and the excess of the pentachloride and aluminium chloride be distilled off at 250° , the tetrachloride is formed, but whether it is a compound of quadrivalent tantalum, or a complex of the tri- and penta-chlorides is not clear. If the product be heated further, more pentachloride is given off, and the residue becomes richer in tantalum. Thus, at 350° – 400° , **tantalum trichloride**, $TaCl_3$, is formed; and at 600° , **tantalum dichloride**, $TaCl_2$. At 680° – 700° the product is richer in tantalum, and is pyrophoric. The dichloride dissolves in water with the evolution of hydrogen, and the formation of an oxychloride of tervalent tantalum. The trichloride dissolves without the evolution of gas. K. Lindner and H. Feit prepared the dichloride by heating the pentachloride with metallic lead at 600° in an atm. of hydrogen. The residue was extracted with hydrochloric acid in a reflux apparatus, and, after removing the lead with hydrogen sulphide, evaporating the soln. in vacuo. The green crystals were represented by the formula Ta_3Cl_6 , or $(TaCl_2)_3$. According to K. Lindner, E. Haller, and H. Helwig, tantalum pentachloride is reduced by powdered metals to the dichloride and, since the reaction proceeds less violently than with the molybdenum and tungsten compounds, the addition of powdered quartz may be omitted. Aluminium, zinc, and lead are efficient. The residues are extracted exhaustively with hydrochloric acid. The isolation of the compound $HTa_3Cl_7 \cdot 4H_2O$, a blackish-green, unusually stable, crystalline powder, from the extracts is a matter of some difficulty, since it only separates from very conc. soln. and its crystallization is greatly impeded by the presence of dissolved aluminium chloride. It is preferable, therefore, to use zinc which can be removed as sulphide after addition of sodium acetate to the solution; or else lead, the dissolved traces of which can be precipitated directly with hydrogen sulphide. Molten tantalum pentachloride cannot be reduced electrolytically between carbon poles, since the substance is an insulator. Electrolysis takes place after addition of alkali chlorides, and the dichloride is formed to some extent; but the method has no preparative value.

O. Ruff and F. Thomas said that the green soln. of tantalum trichloride in **hydrochloric or sulphuric acid** slowly oxidizes in air with the separation of tantalic acid. It is oxidized by **hydrogen dioxide**, by an aq. soln. of **chlorine**, by **nitric acid**, and by a soln. of **potassium permanganate**. An aq. soln. of **sodium hydroxide**, added in small quantities, gives a green flocculent precipitate soluble in excess, forming a fine green soln.; **sodium sulphide** produces a precipitate soluble in excess—when shaken in a test-tube the soln. is brown, but on standing, it becomes green—the precipitation is incomplete; aq. **ammonia** behaves like sodium hydroxide, but the precipitate is not soluble in excess, and the green precipitate rapidly oxidizes and becomes brown; **ammonium sulphide** gives a dark green precipitate which dissolves in conc. hydrochloric acid without giving off gas; a soln. of **sodium phosphate**, **potassium ferrocyanide**, **sodium borate**, or of **potassium fluoride** gives a gelatinous precipitate, the filtrate is green, and the precipitate is probably flocculated tantalic acid; **sodium carbonate**, and **hydrocarbonate** precipitate tantalous hydroxide incompletely; **sodium thiosulphate** gives a precipitate soluble in excess; **potassium oxalate** gives a dark olive-green precipitate—the precipitation is complete—soluble in conc. hydrochloric acid giving a pale green soln. of a complex salt; and **potassium cyanide** in small quantities precipitates a dark green cyanide which is soluble in more potassium cyanide and is decomposed by conc. hydrochloric acid giving off hydrogen cyanide. According to C. Chabrié, the *dihydrate* of tantalum dichloride, $TaCl_2 \cdot 2H_2O$, is formed when tantalum pentachloride is reduced with sodium amalgam. It is an emerald-green, microcrystalline

powder, with a spectrum like that of tantalum pentoxide. When freshly prepared, it is soluble in water. The pentoxide was moulded into filaments (by mixing it with a little paraffin), and these were heated to whiteness for 4 or 5 hrs. in carbon powder. The filaments of tetroxide obtained in this way conduct electricity. When such a filament is heated to whiteness in a vacuum by a direct current it is but little changed, a small portion at the positive end being reduced to metal. By using an alternating current, however, the filament is converted into the metal in a quarter of an hour. This method yields very small quantities of the metal. Larger quantities were prepared as follows: columbium pentoxide and powdered aluminium react together when the mixture is heated at one point, yielding a hard, metallic regulus of sp. gr. 7.5, and containing 2.8 per cent. to 3.2 per cent. of aluminium as well as some unchanged oxide. By heating this material in a vacuum (a current of 185 ampères at 40 volts for 15 hrs. is required for 20 grms. of metal) the whole of the impurities are vaporized, leaving columbium alone. According to W. H. Chapin, C. Chabrié used the at. wt. for tantalum 183 instead of 181, and so obtained a wrong formula. It can be represented as a **tantalum heptatritachloride**, $Ta_3Cl_7 \cdot 3\frac{1}{2}H_2O$, or $Ta_6Cl_{12}Cl_2 \cdot 7H_2O$. It furnishes a hydroxide: $[Ta_6Cl_{12}](OH)_2$, and is insoluble in hydrochloric acid. K. Lindner compared this salt with molybdous chloride, $(MoCl_2)_3$, and regarded it as a complex $H[Ta_3Cl_7(H_2O)]$, in which the water can be replaced by alcohol to form $H[Ta_3Cl_7(C_2H_5OH)]$. There is also **ammonium aminochlorotantalite**, $NH_4[Ta_3Cl_7(NH_3)]$ —*vide infra*.

J. J. Berzelius obtained **tantalum pentachloride**, $TaCl_5$, as a yellowish-white powder, by burning tantalum in chlorine; and H. Moissan said the attack begins at 150° , and at 250° is attended by incandescence, and the sublimation of the pentachloride. K. Lindner and H. Feit obtained it as a bright yellow powder by passing chlorine over tantalum at 600° . K. Lindner, E. Haller, and H. Helwig found that tantalum is converted into the pentachloride by carbonyl chloride vapour. H. Rose and R. Weber, and W. Biltz and A. Voigt made it by heating a mixture of the pentoxide and carbon in a current of dry chlorine. M. E. Pennington observed that it is formed when the pentoxide and phosphorus pentachloride are heated in a sealed tube at 210° – 245° , and the product fractionated by distillation under a reduced press. E. Demarçay, R. D. Hall and E. F. Smith, M. Delafontaine and C. E. Linebarger, and O. Ruff and E. Schiller obtained it by heating the pentoxide in a current of carbon tetrachloride; and F. Bourion, O. Ruff and E. Schiller, and R. D. Hall, by heating the pentoxide in a current of the vapour of sulphur monochloride and chlorine—*vide* columbium pentachloride. Tantalum pentachloride was analyzed by H. Rose, C. W. Blomstrand, R. D. Hall, H. St. C. Deville and L. Troost, M. E. Pennington, and F. Bourion. H. St. C. Deville and L. Troost found the **vapour density** to be 12.8 at 360° . The salt is a pale yellow solid—rather paler than columbium pentachloride. W. Biltz and A. Voigt obtained it as a snow-white mass of crystals. The sublimate appears in orange-yellow needles or prisms. H. Rose gave 221° for the **melting point**; and H. St. C. Deville and L. Troost, 211.3° . H. Rose said that it begins to volatilize at 144° , and, according to H. St. C. Deville and L. Troost, its **boiling point** is 241.6° , at 753 mm. press. K. Lindner and H. Feit gave 233° . W. Hampe found that molten tantalum pentachloride has a good **electrical conductivity**, but W. Biltz and A. Voigt found that at 230° – 240° , the conductivity is 0.30×10^{-6} mho. The platinum electrodes were strongly attacked. G. W. Sears said that the pentachloride is quite stable in dry air, but H. Rose found that it readily attracts moisture from **air**, and gives off the vapour of hydrogen chloride without becoming deliquescent. When freshly prepared, it hisses in contact with **water**, and is hydrolyzed into tantalum and hydrochloric acid. The hygroscopicity, and tendency to hydrolysis, are so great that G. W. Sears considers that the pentachloride is not suitable for use in at. wt. determinations. It does not occlude **chlorine**. O. Ruff and E. Schiller found that the pentachloride is converted by **hydrogen fluoride** into the pentafluoride (*q.v.*). H. Rose found that **hydrochloric acid** dissolves the pentachloride

in the cold, and after standing some time, it gives a gelatinous liquid; boiling hydrochloric acid dissolves it incompletely, but the soln. does not gelatinize on cooling. The addition of water makes the soln. opalescent. R. F. Weinland and L. Storz said that it is freely soluble in alcohol or acetic acid sat. with hydrogen chloride. O. Ruff and F. Thomas found that the pentachloride is not reduced when heated with **sulphur**. H. Rose showed that at a red-heat, **hydrogen sulphide** forms tantalum disulphide and hydrochloric acid; with conc. **sulphuric acid**, hydrogen chloride is given off, and the salt passes into soln. which becomes very turbid when heated. The pentachloride is stable in dry **nitrogen**; with aq. **ammonia** in the cold, the tantalum is completely precipitated as hydroxide. K. Lindner and H. Feit found that when ammonia is passed into a sat. soln. of the tetrachloride in carbon disulphide, a yellow **tantalum amminopentachloride** is formed; and a yellow product is produced when ammonia is passed into a boiling soln. of tantalum pentachloride in carbon tetrachloride; and when alcoholic soln. of ammonia and tantalum pentachloride are mixed, a crystalline substance is formed. These three products were too unstable for analysis. O. Ruff and F. Thomas said that the pentachloride is reduced to a lower chloride when heated with red **phosphorus**, but not so with **arsenic, antimony, or bismuth**. H. Rose observed no reaction with the vapour of **carbon disulphide** and the heated pentachloride. The pentachloride is soluble in absolute **alcohol**, and the boiling soln. gives a precipitate with sulphuric acid. When the alcoholic soln. is distilled, alcohol and hydrogen chloride are evolved at 83°–85°, but no tantalum is volatilized. K. Lindner and H. Feit found that it is soluble in **chloroform, ethyl bromide, carbon tetrachloride**, and particularly **carbon disulphide**. It forms complex salts with **pyridine**. O. Ruff and F. Thomas found that the pentachloride is reduced to a lower chloride when heated with **magnesium, zinc, tin, or aluminium**, but not so with **mercury**. H. Rose found that a boiling soln. of **potassium hydroxide** dissolves a little pentachloride, but not so with a soln. of **potassium carbonate**. No complex salts have been obtained with the **alkali chlorides**.

H. St. C. Deville and L. Troost observed the formation of no oxychloride when the vapour of tantalum pentachloride is passed over the heated pentoxide; but when the pentachloride, prepared from the pentoxide, is sublimed in *vacuo*, at 500°, O. Ruff and F. Thomas observed the formation of **tantalum dioxychloride**, TaO₂Cl. According to F. R. Weinland and L. Storz, colourless crystals of complex salts of **tantalum oxytrichloride**, TaOCl₃, with pyridine and with quinoline can be prepared by the action of the base on tantalum pentachloride dissolved in alcohol, and containing some hydrochloric acid. They also obtained a complex with pyridine and **tantalum trioxytetrachloride**, Ta₂O₃Cl₄.

K. Lindner and H. Feit saturated an aq. soln. of the dichloride with hydrogen chloride, and on evaporation obtained dark green, six-sided crystals of what they regarded as H[Ta''₃Cl₇.H₂O].3H₂O, analogous to the corresponding molybdenum compound. O. Ruff and F. Thomas said that when a hydrochloric soln. of tantalum trichloride is evaporated under reduces press., a crystalline compound of trivalent tantalum is formed, *viz.*, **tantalum oxyheptachloride**, Ta''₃Cl₇O.3H₂O. It is the same as that obtained by K. Lindner and H. Feit, who were mistaken in assuming that it contained bivalent tantalum from its reducing action on potassium permanganate, and silver salts. Only 3 mols. of water are lost when it is heated, and the evolution of a little hydrogen chloride on further heating, is ascribed to traces of water having been retained by the salt. K. Lindner and H. Feit found that the oxychloride forms complexes with alcohol, and with pyridine. When treated with dil. potash-lye, and afterwards with acetic acid, a dark brown amorphous precipitate of **tantalum oxydihydroxypentachloride**, [Ta₃Cl₅(H₂O)₅]OH.Aq., or, according to O. Ruff and F. Thomas, [Ta₃Cl₅O(OH)₂.3H₂O].3H₂O, is formed. K. Lindner added: *das letzte Wort in dieser Wertigkeitsfrage est wohl noch nicht gesprochen.*

§ 11. Tantalum Bromides and Oxybromides

W. H. Chapin¹ reduced tantalum pentabromide with sodium amalgam as in C. Chabrie's method for tantalum dichloride, and obtained a product whose composition corresponded with **tantalum heptatritabromide**, $Ta_3Br_7 \cdot 3\frac{1}{2}H_2O$, which he represented by the formula $[Ta_6Br_{12}]Br_2 \cdot 7H_2O$. The green powder, under the microscope, consists of hexagonal crystals; at 100°, only a little hygroscopic moisture is given off; at 120°, the compound decomposes, forming an insoluble compound which is anhydrous after being heated to 150°–250°. The salt is freely soluble in water, forming a green soln. which is stable in air, and colours silk, and paper. The rise of the b.p. in propyl alcohol corresponds with a mol. wt. of 2275 when the theoretical value for $[Ta_6Br_{12}]Br_2$ is 2332; while the lowering of the f.p. of water corresponds with a mol. wt. of 720, which is only one-third of the theoretical. Bromine-water decolorizes the liquid, and sulphur dioxide restores the colour; and hydrochloric acid forms $[Ta_6Br_{12}]Cl_2 \cdot 7H_2O$. In the cold, aq. ammonia changes the colour of the liquid, and when heated, yields a brown precipitate of tantalum hydroxide. The salt is freely soluble in alcohol, and in pyridine, and these soln. are decomposed when heated. With sodium hydroxide, $[Ta_6Br_{12}](OH)_2 \cdot 5H_2O$ is formed; silver nitrate precipitates only one-seventh of the bromine so that 2 mols. of bromine are supposed to be bound in the mol. different to the other twelve. K. Lindner represented the bromide as an acid, $H[Ta_3Br_7(H_2O)]$; and the chlorobromide, $H[Ta_3Cl_6Br(H_2O)]$.

W. K. van Haagen reduced tantalum pentabromide by passing the vapour mixed with hydrogen through a red-hot glass tube, and obtained a small yield of a green compound, with marked tinctorial properties when dissolved in water. He thought that it is *tantalum tribromide*, $TaBr_3$, but W. H. Chapin showed that it is more probably the pentatritabromide.

W. K. van Haagen said that when bromine vapour is passed over tantalum at ordinary temp., the metal is not attacked; but at an elevated temp., a pale yellow sublimate of **tantalum pentabromide**, $TaBr_5$, is formed. This compound was made by H. Rose, by passing bromine vapour over a red-hot mixture of tantalum pentoxide and carbon—taking care that moisture and air are excluded. W. H. Chapin and E. F. Smith employed a similar process. W. K. van Haagen resublimed the product three times in an atm. of purified and dried carbon dioxide. According to W. K. van Haagen, the yellow tabular crystals have a **specific gravity** 4.67; the **melting point** is about 240°, and they form a transparent red-liquid; the **boiling point** is about 320°, but volatilization begins below the m.p. The

yellow vapour looks like chlorine. The compound can be sublimed in **hydrogen** without decomposition, but at a higher temp., there is a partial reduction to a lower chloride. The compound fumes strongly in **air**. H. Rose found that the salt is hydrolyzed by **water**, forming **tantalum hydroxide** and **hydrobromic acid**. When distilled with **hydrogen iodide**, some pentaiodide is formed; and with **potassium iodate** some iodine is set free. The pentafluoride is freely soluble in methyl or ethyl **alcohol** with the development of so much heat that the alcohol may boil. The soln. is pale yellow—water decolorizes the soln. but gives no precipitate. The salt is freely soluble in **ethyl bromide**, and the soln. becomes warm—the red soln. deposits golden-yellow crystals when cooled or evaporated in vacuo. The pentabromide is not reduced by **silver** to a lower bromide; and it reacts vigorously when mixed with **silver fluoride**, but tantalum fluoride is not produced—possibly a complex salt is formed.

W. K. van Haagen observed that no tantalum oxybromide is formed during the sublimation of tantalum pentabromide, but W. H. Chapin and E. F. Smith said that **tantalum oxytribromide**, TaOBr_3 , is possibly formed by heating tantalum pentoxide in an atm. of hydrogen bromide, and in the distillation of the pentabromide. W. H. Chapin found that when the tritahptabromide is treated with 0.1*N*-NaOH, in the cold, and the precipitate washed with ether, and dried in vacuo, dark green, hexagonal plates of **tantalum hydroxyhexabromide**, $\text{Ta}_3(\text{OH})\text{Br}_6 \cdot 5\text{H}_2\text{O}$, or $[\text{Ta}_6\text{Br}_{12}](\text{OH})_2 \cdot 10\text{H}_2\text{O}$, are formed. They are stable in air below 100°; but on a water-bath at 100°, part becomes insoluble, and some tritahptabromide is formed; at 250°, the water is all expelled; and at 500°, the hydroxyl-group is driven off. The salt is sparingly soluble in water, soluble in alcohol, and insoluble in ether; it dissolves in acids, and with hydriodic acid forms $[\text{Ta}_6\text{Br}_{12}]\text{I}_2 \cdot 7\text{H}_2\text{O}$. R. F. Weinland and L. Storz could not prepare complex salts with tantalum oxytribromide owing to the insolubility of tantalum pentabromide in hydrobromic acid. W. H. Chapin said that the lower chloride he prepared furnishes complex salts.

W. H. Chapin obtained a mixed salt, **tantalum hexabromochloride**, $\text{Ta}_3\text{ClBr}_6 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, or $[\text{Ta}_6\text{Br}_{12}]\text{Cl}_2 \cdot 7\text{H}_2\text{O}$, by evaporating a hydrochloric acid soln. of the hydroxide or of the tritahptabromide. According to K. Lindner and H. Feit, if tantalum pentachloride be reduced with lead, at 600°, in an atm. of hydrogen, and the product dissolved in hydrobromic acid, the soln. furnishes green crystals of **tantalum oxybromohexachloride**, $\text{H}[\text{Ta}_3\text{Cl}_6\text{Br} \cdot \text{H}_2\text{O}] \cdot 3\text{H}_2\text{O}$ —or better, according to O. Ruff and F. Thomas, $[\text{Ta}_3\text{Cl}_6\text{Br} \cdot \text{O}] \cdot 3\text{H}_2\text{O}$ —when evaporated in vacuo. This compound forms a complex salt with pyridine and in the presence of an excess of hydrobromic acid, a complex salt of pyridine with **tantalum tribromohexachloride**, $(\text{Ta}_3\text{Cl}_6\text{Br}_3)(\text{C}_5\text{H}_5\text{N})$.

§ 12. Tantalum Iodides and Oxyiodides

¹ W. K. van Haagen¹ observed no reaction occurs when iodine and tantalum are heated in a sealed tube at 280° for 8 hrs.; and H. Rose said that no tantalum iodide is formed when iodine vapour acts on a red-hot mixture of tantalum pentoxide and carbon. H. Moissan was unable to prepare this iodide; W. K. van Haagen found that by distilling tantalum bromide over granular silver iodide, iodine is set free, but if silver iodate be present, **tantalum pentaiodide**, TaI_5 , is formed:

$7\text{TaBr}_5 + 5\text{AgIO}_3 = \text{TaI}_5 + 3\text{Ta}_2\text{O}_5 + 5\text{AgBr} + 15\text{Br}_2$. The liberated bromine reacts on the penta iodide, reforming the pentabromide. The penta iodide is best made by slowly distilling the pentabromide in a current of dried hydrogen iodide, when it appears as a brownish-black sublimate consisting of lamellar crystals resembling those of iodine. The crystals melt to a brown liquid; the vapour looks like bromine vapour. The salt resembles the pentabromide in its relations to moist air and water, but it reacts more slowly. W. H. Chapin did not succeed in reducing the penta iodide to a lower iodide by means of sodium-amalgam. No *tantalum oxyiodide* was observed by W. K. van Haagen when the penta iodide was heated in a current of dry air.

W. H. Chapin made hexagonal prisms of **tantalum hexabromiodide**, $\text{Ta}_3\text{Br}_6\text{I}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, or $[\text{Ta}_6\text{Br}_{12}\text{I}_2]_2 \cdot 7\text{H}_2\text{O}$, by dissolving the hydroxyhexabromide in hydriodic acid, and crystallizing the soln.

§ 13. Tantalum Sulphides and Sulphates

J. J. Berzelius¹ said that tantalum at a red-heat burns with great vigour in sulphur vapour, forming **tantalum disulphide**, TaS_2 ; and W. von Bolton heated a mixture of the two elements under a layer of potassium chloride and observed that the elements unite vigorously. J. J. Berzelius and J. G. Gahn observed no sulphide is formed by heating a mixture of tantalum pentoxide with sulphur, with mercuric sulphide, or potassium sulphide; or by heating the pentoxide in a current of hydrogen sulphide. H. Rose obtained the sulphide by passing hydrogen and the vapour of carbon disulphide over the white-hot pentoxide; but not by heating tantalum pentachloride in the vapour of carbon disulphide. H. Rose made the sulphide by passing a slow current of dry hydrogen sulphide over heated tantalum pentachloride; H. Biltz and C. Kirchner prepared the disulphide by passing a dry mixture of hydrogen sulphide and carbon disulphide over heated tantalum pentoxide. The pentoxide is attacked at 650° , but the pure sulphide is best obtained at temp. higher than 900° . It is stable at all temp. up to 1300° , and above 1200° it begins to change from the amorphous to the crystalline condition. Analyses were made by J. J. Berzelius, H. Rose, R. Hermann, and H. Biltz and C. Kirchner. Tantalum disulphide appears as a dark grey or black, crystalline mass. R. Robl observed no fluorescence when the disulphide is exposed to ultra-violet light. A. Karl found the sulphide to be triboluminescent. H. Rose found that the trisulphide loses very little sulphur when heated in **hydrogen**. It burns to the pentoxide when heated in **air**, but the last traces of sulphur dioxide can be removed only by calcination with admixed ammonium carbonate. Hot or cold **water** has no action. The disulphide absorbs moisture very readily, and holds it very tenaciously, and when heated in water vapour forms hydrogen sulphide and tantalum pentoxide. In the cold, **chlorine** has no action, but when heated, it forms sulphur monochloride and tantalum pentachloride; **iodine** can be sublimed from the disulphide without change; and when heated with iodine and water no reaction occurs; **hydrofluoric acid** decomposes it so slowly that no smell of hydrogen sulphide can be detected; and **hydrochloric acid** has no action. Boiling, conc. **sulphuric acid** slowly decomposes the sulphide; boiling **nitric acid** decomposes it slowly, forming, according to W. von Bolton, tantalum pentoxide; **aqua regia** is not much faster than nitric acid in its action of the sulphide. Molten **potassium hydroxide** forms potassium

sulphide and tantalate; and analogous products are obtained when the sulphide is fused with a mixture of sulphur and **sodium carbonate**; and a conc. soln. of **potassium polysulphide** does not dissolve tantalum disulphide.

O. Ruff and E. Schiller obtained a complex product, thought to be *tantalum sulpho-fluoride*, from a soln. of tantalum pentafluoride in sulphur monochloride; and a *tantalum fluochlorosulphide* from a soln. of the pentafluoride in sulphuryl chloride.

J. J. Berzelius² said that tantalum sulphate remains when tantalum sulphide is roasted in air; and when tantalum hydroxide is treated with conc. sulphuric acid. R. Hermann reported **tantalum oxysulphate**, $3\text{Ta}_2\text{O}_5 \cdot \text{SO}_3 \cdot 9\text{H}_2\text{O}$, or $2\text{Ta}_2\text{O}_5 \cdot \text{Ta}_2\text{O}_4(\text{SO}_4) \cdot 9\text{H}_2\text{O}$, to remain as a residue when the product of fusing tantalum pentoxide with potassium hydrosulphate is extracted with water. W. Muthmann and co-workers said that this compound does not lose its sulphate-radicle when roasted at a red-heat for a long time. It is soluble in hydrochloric acid, but separates when the dil. soln. is boiled.

W. H. Chapin said that crystalline **tantalum bromosulphate**, $[\text{Ta}_6\text{Br}_{12}]\text{SO}_4 \cdot n\text{H}_2\text{O}$, is formed when the corresponding bromide is treated with silver nitrate. If the product obtained by reducing tantalum pentachloride with lead at 600° be treated with dil. sulphuric acid, K. Lindner and H. Feit said that the soln. furnishes crystals of **tantalum chlorosulphate**, $\text{H}_2[\text{Ta}_3\text{Cl}_6\text{SO}_4]$, or, as represented by O. Ruff and F. Thomas, $\text{Ta}_3\text{Cl}_6 \cdot \text{SO}_4 \cdot \text{OH}$.

The *tantalum carbonate, nitrate, or phosphate* has not yet been prepared.
